Abstract. Lightning characteristics in all seasons are investigated across Europe because it is observed that lightning strikes to tall infrastructure have no or only a weak annual cycle whereas lightning in general has a pronounced annual cycle. Using cluster analysis on ERA5 reanalysis data and EUCLID lightning data, two major thunderstorm types are found: Wind-field thunderstorms characterized by increased wind speeds, strong updrafts, and high shear occurring mainly in winter. And mass-field thunderstorms characterized by increased mass-field variables such as large CAPE values, high dewpoint temperatures, and elevated isotherm heights, occurring mostly in summer. Several sub-types of these two main thunderstorm types exist. Using principal component analysis, four topographically distinct regions in Europe are identified that share similar thunderstorm characteristics: The mediterranean, alpine-central, continental, and coastal regions, respectively. Based on these results it is possible to differentiate lightning in different seasons without a static threshold or a seasonal criterion.

1 Introduction

Lightning may originate in various meteorological settings. Some conditions leading to lightning occur more frequently and are better understood than others. Plenty lightning climatologies are available but most of them focus on the dominant characteristics and seasons while infrequent thunderstorm types and rare lightning conditions are often neglected. This study describes thunderstorm types occurring in Europe using a balanced view on all four seasons to include also seasonally infrequent thunderstorm conditions. A comparison between different regions gives a comprehensive overview of lightning characteristics in Europe.

The general lightning pattern in Europe is well described in various climatologies (e.g., Taszarek et al., 2019; Enno et al., 2020; Poelman et al., 2016; Wapler, 2013; Taszarek et al., 2020a, b; Mäkelä et al., 2014; Vogel et al., 2016; Ukkonen and Mäkelä, 2019; Simon et al., 2017; Kotroni and Lagouvardos, 2016; Piper and Kunz, 2017; Anderson and Klugmann, 2014; Hayward et al., 2022; Holt et al., 2001; Enno et al., 2013; Poelman, 2014; Taszarek et al., 2015; Schulz et al., 2005; Coquillat et al., 2022; Manzato et al., 2022; Simon and Mayr, 2022). There is a north-south gradient of lightning frequency with a maximum in northern Italy and the Mediterranean. Lightning in central Europe follows a clear annual cycle with a maximum over land in summer (MJJA) and a secondary maximum in fall and early winter (SONDJ) in the Mediterranean (Taszarek et al., 2019; Poelman et al., 2016; Enno et al., 2020). In south-central Europe, the annual cycle is less pronounced and has sometimes two lightning maxima along with a local minimum in summer (Taszarek et al., 2019). There are differences in the annual...
lightning cycle: Offshore and coastal areas have a lower amplitude and a later maximum compared to inland or mountainous locations (Wapler, 2013; Enno et al., 2013). In the northern Atlantic region, occasional very intense thunderstorms are possible, even though the climatological thunderstorm activity is very low (Enno et al., 2020). There, lightning in the cold season (Oct.-Apr.) occurs predominantly over the seas (North Sea, Baltic Sea, Atlantic) and less so over the land (Mäkelä et al., 2014). The question remains if there are meteorologically different thunderstorm conditions at work leading to these spatial and temporal differences in lightning characteristics in Europe.

Many processes influencing lightning occurrence are known: The diurnal lightning cycle in Europe peaks in the afternoon over land and at night over the sea (Taszarek et al., 2020a; Enno et al., 2020; Manzato et al., 2022). Nighttime offshore lightning (Bay of Biscay, the North Sea, and the Baltic Sea) is explained by convection initiated at land and advected to the sea, where it endures longer as the water surface is unaffected by nighttime cooling (Enno et al., 2020). The most pronounced diurnal cycle is found over mountainous areas. Increased lightning in mountainous regions is commonly explained by the topography, which favors more unstable environments (less CIN when the surface is close to the level of free convection), mechanical forcing (forced lifting), and thermal forcing (elevated heating leads to positive buoyancy and up-mountain flow; Manzato et al., 2022). This is particularly relevant after the snow has melted at higher elevations (Simon and Mayr, 2022).

Most of continental Europe experiences 20 – 40 thunderstorm days annually, but the mountain ranges in southern Europe have thunderstorm frequencies of > 60 thunderstorm days per year. High structures, such as wind turbines or radio towers increase the occurrence of lightning (March et al., 2016), especially in the cold season (Vogel et al., 2016; Pineda et al., 2018) so that lightning damage to infrastructure is evenly distributed over the year even though lightning occurrence in the surroundings has a strong annual cycle (Stucke et al., 2022). Helicopter-triggered lightning in the North Sea occurs very often in the cold season (Wilkinson et al., 2013). The sea has an effect on lightning as the number of lightning strokes and the sea-surface temperature are positively correlated in fall (Kotroni and Lagouvardos, 2016). Mallick et al. (2022) even suggests to use the sea surface temperature as proxy for seasonal lightning forecasts. Warm oceanic currents are known to increase lightning densities in each season and particularly so in winter (Iwasaki, 2014; Holle, 2016). Wintertime lightning occurs usually in mid-latitudinal cyclones (Bentley et al., 2019) and lightning bands are found in wintertime storm tracks (Zhang et al., 2018; Virts et al., 2013).

Even though the European lightning patterns are in general well described (e.g., Wapler and James, 2015; Enno et al., 2014), it is less known how winter lightning differs meteorologically from lightning in summer.

Morgenstern et al. (2022a) found that thunderstorms in the cold season differ physically from thunderstorms in the warm season when studying a small observational region in northern Germany. They describe wind-field thunderstorms dominant in winter in contrast to CAPE (mass-field) thunderstorms typical for summer. This study expands their findings to all of Europe answering two questions:

– How do meteorological thunderstorm characteristics vary regionally across Europe?

– What characterizes thunderstorms in different meteorological environments and how do these thunderstorm types vary seasonally across Europe?
To answer these questions, Europe is first divided into 12 domains (Sect. 2) for which a large set of meteorological parameters relevant for lightning is available. Applying similar methods as in Morgenstern et al. (2022a), principal component analysis finds the answer to the first question, and k-means clustering to the second one (Sect. 3). The general thunderstorm conditions in Europe are compared in Sect. 4.1 revealing that the 12 domains can be summarized into four regions with similar lightning characteristics. Cluster analysis on each domain in Sect. 4.2 leads to two main thunderstorm types and three variations thereof. The found thunderstorm types are then analyzed seasonally (Sect. 4.3) and compared to one another (Sect. 4.4). The results are discussed in Sect. 5, and Sect. 6 summarizes the main findings.

2 Data

Two data sets are incorporated in this study (cf. Morgenstern et al., 2022a): meteorological reanalysis data (ERA5, Sect. 2.1) and lightning observations (EUCLID, Sect. 2.2).

2.1 Meteorological data: ERA5

Directly available and derived meteorological data are extracted from single-level and model-level data of the ERA5 global reanalysis of ECMWF (Hersbach et al., 2020). The distance between vertical model levels varies from 10 m near the ground to 320 m in the lower stratosphere (lowest 74 levels). The horizontal resolution is 0.25° latitude–longitude and the temporal resolution is one hour. A binary land-sea mask sets ERA5 grid cells with at least 35% land to land to capture the influence of sub-grid islands. A set of 25 variables is chosen to portray physical atmospheric processes known to influence lightning, especially charge separation. It, therefore, contains derived variables such as the height of the −10 °C isotherm, cloud mass between −10 and −40 °C (ice and snow), and the product of maximum updraft and liquid particles between −8 and −12 °C (liquids updrafts). Further derived variables are cloud size, cloud shear, wind speed at cloud base, maximum upward vertical velocity, and the temperature difference between the air mass at 1000 m a.g.l. and the surface (sea surface temperature or skin temperature). The variable set focuses on the most important drivers to reduce correlation between the variables which is required for the statistical analysis. All 25 variables are listed in Table 1 and details on them and on how the derived variables are calculated are given in the online supplement (Morgenstern et al., 2022b). To ease interpretation, we often refer to physical-based categories to which each variable belongs: Mass-field variables refer to temperature, pressure, and humidity. Surface-exchange variables include atmospheric fluxes interacting with the surface. Wind-field variables cover everything related to wind. Cloud-physics variables refer to measures directly related to clouds. Topographic variables refer to surface geopotential height (orography) and a binary land-sea mask.

2.2 EUCLID lightning data and geographical domains

As lightning data EUCLID (European Cooperation for Lightning Detection, Schulz et al., 2016; Poelman et al., 2016) between 2010–2020 is used as this period is most stable regarding hardware and software changes for this data set. EUCLID is a cooperation of several local lightning location systems (LLS) in Europe. Only cloud-to-ground lightning flashes are considered
in this study. If at least one lightning flash occurred within an ERA5 cell in a given hour, the whole cell-hour is regarded as one lightning observation.

The EUCLID territory is separated into 12 domains with rather homogeneous topography and lightning detection efficiency (Fig. 1) aiming to represent typical European landscapes. Domain A covers large parts of the North Sea including the surrounding coastlines. It marks the furthest northern EUCLID domain with sufficient lightning detection efficiency and sufficient lightning observations in each season and year. Domain B covers large parts of Denmark and northern Germany as well as parts of the North Sea and the Baltic Sea. It also covers parts of the domain analyzed in Morgenstern et al. (2022a) to which the current study is an extension. Domain C is representative of the southern Baltic Sea and Poland, except for the Carpathian mountains in the South. Domain D covers the Gulf of Biscay, an Atlantic domain. Domain E covers the whole Iberian Peninsula including the Pyrenees and the surrounding coastal areas and is characterized by highlands. Domain F covers large parts of France and Belgium, being a less homogeneous but very representative domain. Domain G covers hills in Germany, Czech Republic, Southern Poland, and Slovakia. Domain H covers the east-west elongated part of the European Alps. Domain I covers Hungary, Croatia, and Bosnia and Herzegovina, a basin surrounded by several mountain ranges. Domain J covers the Balearic islands in the northwestern Mediterranean Sea and surrounding coastlines. Domain K covers the Tyrrhenian Sea and the Islands of Corsica and Sardinia and Italian coastal areas. Finally, domain L covers the northern part of the Adriatic Sea including the surrounding coastlines.

Figure 1. Overview of domains. Topographic data is based on ERA5 orography with a resolution of $0.25^\circ \times 0.25^\circ$ lon/lat. A land-sea mask is applied where each cell containing > 35% land is regarded as land.
3 Methods

To investigate spatio-temporal lightning characteristics, lightning data sets for the 12 domains are constructed that have the same number of observations from each season. The lightning data sets are then combined with 25 ERA5 variables representing the atmospheric conditions at the hour of the lightning observations. Using the domain means, a spatial lightning analysis for Europe is performed with the help of a principal component analysis. Then, thunderstorm types are found individually on each domain by a cluster analysis with $k = 3$ clusters. A seasonal lightning analysis follows by analyzing how many observations from each season have been classified into which thunderstorm type. Finally, the thunderstorm types are compared to one another using again a principal component analysis.

3.1 Composition of data

EUCLID lightning data is aggregated to the spatio-temporal resolution of ERA5 resulting in binary cell-hours indicative of lightning. For each lightning cell-hour, we use ERA5 data at the respective cell and from the last full hour to capture the build-up of the thunderstorms. Accumulated variables such as precipitation are taken from the next full hour to capture everything from the hour in which lightning was observed. Only cell-hours with lightning are considered. To investigate seasonal differences, the available data are reduced to contain the same number of lightning cell-hours from each season (winter = DJF, spring = MAM, summer = JJA, fall = SON). Therefore a random sample without replacement is drawn from the seasons with more lightning cell-hours. Depending on the domain size and general lightning frequency, the data set in each domain consist of 5320 – 40000 observations (Table 1). For robustness, the whole analysis is performed on 50 different samples in each domain. In the following, only one sample is discussed, as all repetitions led to qualitatively the same results.

$k$-means clustering requires scaled input variables that follow rather similar distributions. Therefore all ERA5 variables are square root transformed and scaled to a mean of zero and a standard deviation of one.

$$x_t = \text{sign}(x) \sqrt{\text{abs}(x)},$$

with $x$ being the original ERA5 value and $x_t$ its transformation.

$$x_s = \frac{(x_t - \mu)}{\sigma},$$

$\mu$ and $\sigma$ are the empirical mean and standard deviation and $x_s$ is the scaled value. The applied algorithm is supplied in the online supplement (Morgenstern et al., 2022b). For the cluster analysis in Sect. 4.2, transformation and scaling are performed individually on each domain. For the domain comparison in Sect. 4.1 (Sect. 4.4), scaling is performed on the domain means (cluster means) of all domains together.

3.2 Statistical methods

Principal component analysis (Mardia et al., 1995) is an approach for dimension reduction that computes several linear combinations of projected input data (principal components, PC) aiming to capture as much variability from the data as possible.
The first PC explains the most variance and each following PC is oriented perpendicular to the previous PC explaining less and less variance. Omitting the later PC results in the intended dimension reduction. We use the first two PC as axes for a so-called biplot to visualize the variance in our 25-dimensional data.

\( k \)-means cluster analysis (MacQueen, 1967) is a data-driven approach to find groups in data, aiming at maximum similarity within and minimum similarity between the groups. The similarity is measured with the squared euclidean distance between each observation and cluster means. Starting with \( k \) random cluster means, new cluster means are calculated iteratively to which the observations are assigned forming the clusters. The optimal number of clusters \( k \) for our data, derived from the sum of squared residuals, is between 2 and 4. We present the results from \( k = 3 \) in detail and also describe the results for \( k = 2 \) and \( \geq 4 \). Cluster analysis is used to identify different thunderstorm types. To account for possible regional differences, clustering is performed separately on each of the 12 topographically homogeneous domains.

The online supplement provides the R code to replicate the cluster analysis and the principal component analysis (Morgenstern et al., 2022b).

4 Results

Thunderstorms in 12 domains in Europe are compared to one another using principal component analysis (PCA) investigating which domains have in general similar meteorological characteristics during lightning throughout the year (Sect. 4.1). Then we present the thunderstorm types found by \( k \)-means clustering and a decision tree to differentiate them (Sect. 4.2). Finally, the thunderstorm types are seasonally analyzed and compared in Sections 4.3 and 4.4.

4.1 Regional differences between thunderstorms in Europe

This section investigates how the meteorological conditions vary regionally in Europe and whether some of our 12 domains can be grouped together based on their meteorological similarities during lightning throughout the year.

Table 1 presents the meteorological mean values of 25 variables separately for each domain. These are typical values for thunderstorms throughout the year for the respective domains and are considered as ‘baselines’ there. A principal component analysis (Fig. 2) makes it easier to spot differences and commonalities between these domains. The first two principal components (x-axis and y-axis) explain together about 80% of the variance within the data. The further the domains (colored symbols) are from the origin, the larger their contribution to the variance in the respective direction. Meteorological similar domains gather close to one another. The loadings (labeled arrows) indicate the direction and strength of individual meteorological variables responsible for the variation in the respective direction.

The domains A, B, C, and D (blue triangles) are all located in the top-left of Fig. 2. The labeled arrows indicate that these domains are physically characterized by increased boundary layer heights (\( \sim 800 \) m) and increased wind speeds at 10 m (\( \sim 6 \) m s\(^{-1}\)) and at cloud base (\( \sim 12 \) m s\(^{-1}\)) relative to all other domains (Table 1). Long arrows pointing in opposite directions of domains A–D indicate decreased values. For example, decreased values in CAPE, CIN, pressure, and cloud size. The temperature difference between the ocean (or skin temperature over land) and the air at 1000 m altitude is on average 6.4 °C.
Table 1. Meteorological mean values during lightning for each domain. Domains with similar characteristics are grouped into four regions, for which a mean value is also given. ERA5 variables are grouped by their meteorological category.

* Derived variables.  
△ Accumulated variables considered at the next full hour after lightning observation. All other variables are considered at the last full hour.  
CAPE: convective available potential energy, CIN: convective inhibition, msl: mean sea level, a.g.l.: above ground level,  
Temp. diff. sfc (sot or skt) - 1000 m a.g.l.: Temperature difference between the surface and 1000 m a.g.l., where sfc is either sea surface temperature or skin temperature.
indicating a rather cool ground (Table 1). The regional characteristics of domains A–D are their large ocean areas including coastlines, hence they are grouped together as the ‘coastal’ region. The domains J, K, and L (turquoise squares) gather in the lower part of Fig. 2. Their common physical characteristics relative to the other domains are high 2 m dewpoint temperatures above 13 °C, elevated −10 °C isotherm heights of more than 4100 m, large CAPE values (> 400 J kg⁻¹), the presence of CIN, and high amounts of total column water vapor (~ 25 kg m⁻²). The temperature difference between the surface and at 1000 m altitude is more than 8 K, indicating a warm ground (Table 1). Regionally, all these domains are located in the Mediterranean, and are hence grouped together as the ‘mediterranean’ region. The domains H and I are located on the right or top-right of Fig. 2 (orange circles) and are physically characterized by increased cloud-physics variables and increased wind-field variables such as various increased cloud particle concentrations (ice, snow, and liquids), increased cloud shear, increased updrafts, and large amounts of large-scale precipitation. Regionally, both domains are located in Central Europe and are influenced by mountainous topography. Hence, they are grouped together as the ‘alpine-central’ region. The remaining domains E, F, and G (green diamonds) are all located in the center of Fig. 2 and share the physical characteristics of mostly average values but
increased surface exchange values. Spatially, their common characteristic is their location on the European mainland and hence they are grouped together as the ‘continental’ region.

Figure 3 shows how the meteorological conditions vary in detail between the four regions. It compares the mean meteorological values for each region (lines) relative to the others and shows how distinct thunderstorm conditions in Europe are. Scaled values (y-axis) close to zero indicate average values in the respective variable (x-axis) compared to the other regions. The figure shows that e.g. CAPE is in general much higher in the mediterranean region compared to the others, or that increased wind speed in the alpine-central region refers to much lower values than in all other regions. Appendix A1 dives deeper and presents the means of each domain separately.

With this the spatial different thunderstorm conditions in Europe are described and summarized into four regions, each with shared physical characteristics during lightning throughout the year: the mediterranean region, the alpine-central region, the coastal region, and the continental region.
4.2 Thunderstorm types

After finding four regions where thunderstorms have similar characteristics throughout the year, the next goal is to investigate whether individual thunderstorms occur under similar larger-scale meteorological conditions, i.e. whether different thunderstorm types exist.

Cluster analysis with $k = 3$ is performed separately on every domain to find thunderstorm types (clusters) relative to the overall lightning characteristics in that domain. Each found cluster from each domain is then described by its driving meteorological characteristics using the average values of the 25 input variables (cluster means). Then the average values within the physically-based categories (mass field, wind field, cloud physics, surface exchange, and topography) are computed for each cluster to yield an overall characterization. Two major thunderstorm types emerge as the wind-field category and the mass-field category always deviate substantially. The decision tree in Fig. 4 distinguishes between these two types and helps to identify further sub-types. Wind-field thunderstorms are characterized by increased wind-field variables and sometimes decreased mass-field variables and are indicated by bluish colors. There are two wind-field sub-types: Wind-field$_{CP}$ thunderstorms (dark blue) have additionally enhanced cloud-physics variables (CP) and wind-field$_{noMF}$ thunderstorms (light blue) that have decreased mass-field variables (no MF) while wind-field variables and cloud-physics variables are at their average values. The other major thunderstorm type is a mass-field thunderstorm characterized by average or increased mass-field variables plus often decreased surface-exchange variables and is indicated by reddish colors. There is one sub-type, mass-field$_{SX}$ thunderstorms (dark red), that has increased surface-exchange variables (SX) and sometimes average mass-field values.

Now we dive deeper into the characteristics of the found thunderstorm types by investigating the cluster means of three representative domains in Fig. 5. The cluster means (lines) are displayed as scaled values (y-axis) of the meteorological variables (x-axis). A value close to zero indicates a typical value for thunderstorms in that domain while large deviations indicate

---

**Figure 4.** Decision tree to label the clusters with the corresponding two major thunderstorm types and three sub-types (colored boxes). The abbreviations in the sub-types stand for: CP = additionally increased cloud-physics variables, noMF = decreased mass-field variables, and SX = increased surface-exchange variables.
**Figure 5.** Parallel coordinate plot of thunderstorm types (clusters) found in three representative domains (B, I, K; panels) and expressed by the cluster means (lines) for each meteorological variable (x-axis) using scaled values (y-axis). The ERA5 variables are grouped by their meteorological category (secondary x-axis). Colors indicate the thunderstorm types (legend; blues = wind-field thunderstorms, reds = mass-field thunderstorms). The abbreviations in the sub-types stand for: CP = additionally increased cloud-physics variables, noMF = decreased mass-field variables, and SX = increased surface-exchange variables. Category means between the dashed lines (+/- 0.3) are considered as average.
large differences in this variable for different thunderstorm types in that domain (as standard deviations). The average values or ‘baselines’ (y = 0) for each domain in Fig. 5 are provided in Table 1. Baselines are required to decide whether a value refers to a general high value. The unscaled cluster means are given in Table 2. The dashed lines indicate the +/- 0.3 threshold used for the decision tree. Results for all domains are supplied in Appendix B1–B4, Table 2, and in the online supplement (Morgenstern et al., 2022b). For robustness, each cluster analysis is repeated 50 times but only one representative result is shown.

Figure 5 shows, how the wind-field thunderstorms (middle-blue triangles) in domain B are driven by enhanced wind speeds, enhanced boundary layer dissipation, lower −10 °C isotherm heights, little water vapor, small CAPE, and large boundary layer heights of more than 1200 m (Table 2). Different from this, the wind-field CP thunderstorms (dark-blue circles) in domains I and K show thick clouds (8731 m and 9756 m) with concentrations of cloud ice, cloud snow, and supercooled liquids that are 2 – 6 times higher compared to the other two thunderstorm types in these domains as well as large precipitation amounts and strong updrafts. Wind-field noMF (light blue pluses) have in general very low mass-field values as seen in the lowest panel (domain K). All three bluish wind-field thunderstorm types have low CAPE values across all domains with means of 194 J kg⁻¹ in wind-field CP thunderstorms, 91 J kg⁻¹ in wind-field noMF thunderstorms, and 56 J kg⁻¹ in the remaining wind-field thunderstorms (without sub-type). This suggests to associate at least the latter two as no-CAPE thunderstorms. The reddish mass-field thunderstorms have in all domains high mass-field variables with large CAPE, high water vapor concentrations, and elevated −10 °C isotherm heights. Differences between the two reddish lines occur almost only in the surface-exchange variables. High surface-exchange values are characteristic of mass-field SX thunderstorms which are characterized by high downward solar radiation (> 320 W m⁻²), large latent heat fluxes (> 140 W m⁻²), and upward oriented sensible heat fluxes. The thunderstorm sub-types wind-field noMF and mass-field SX both occur in conditions where the (sea) surface is hot relative to the air at 1000 m altitude with an average temperature difference of 10.5 K, while in mass-field thunderstorms the air mass at 1000 m is only about 3.9 K colder than the surface. Regarding the topographical influences, mass-field thunderstorms occur more often over land (higher land-sea mask values), and wind-field thunderstorms more often over the sea. In each domain, at least one wind-field related thunderstorm type and one mass-field related thunderstorm type are found. The two major thunderstorm types clearly separate from one another. Varying the number of clusters k robustly finds similar results. With k = 2 only the two major types are found. With k > 3 more and more clusters are found referring to the same thunderstorm type revealing no additional meteorological insights.

In summary, there are two major thunderstorm types in Europe (wind-field thunderstorms and mass-field thunderstorms) and three sub-types thereof. Thunderstorm types are found by applying cluster analysis on 12 domains. A decision tree is developed to differentiate the found thunderstorm types using their driving meteorological categories.
Table 2. Cluster means for each thunderstorm type and domain.

CAPE: convective available potential energy, CIN: convective inhibition, msl: mean sea level, a.g.l.: above ground level, Temp. diff. sfc (sst or skin) - 1000 m a.g.l.: Temperature difference between the surface and 1000 m a.g.l., where sfc is either sea surface temperature or skin temperature.
Now that the thunderstorm types are found, named, and described, their seasonality is investigated.

The stacked barplots in Fig. 6 show how many lightning observations from each season belong to a given thunderstorm type. As the data set is built to have the same number of observations from each season, the bars are equally high. The absolute numbers of observations per domain are given in Table 1. In all domains, winter (DJF) is dominated by wind-field thunderstorm types (blues) and summer (JJA) by mass-field thunderstorm types (reds). Spring and fall are transitional seasons with varying proportions. If a domain has two wind-field thunderstorm types (e.g., domain K), there is often a bigger one with a more pronounced annual cycle (wind-field$_{noMF}$) while the other one (wind-field$_{CP}$) is smaller and shows less seasonality.

**Figure 6.** Seasonal variation of the thunderstorm types within three representative domains (B, I, K; panels). Bars are equally high because the same number of observations from each season is used. Results for each domain are based on cluster analysis estimated on each domain separately using local scaling values.

### 4.3 Seasonal differences between thunderstorm types in Europe

The stacked barplots in Fig. 6 show how many lightning observations from each season belong to a given thunderstorm type. As the data set is built to have the same number of observations from each season, the bars are equally high. The absolute numbers of observations per domain are given in Table 1. In all domains, winter (DJF) is dominated by wind-field thunderstorm types (blues) and summer (JJA) by mass-field thunderstorm types (reds). Spring and fall are transitional seasons with varying proportions. If a domain has two wind-field thunderstorm types (e.g., domain K), there is often a bigger one with a more pronounced annual cycle (wind-field$_{noMF}$) while the other one (wind-field$_{CP}$) is smaller and shows less seasonality.
The map in Fig. 7 spatially compares barplots that are estimated individually on each domain using local mean and standard deviations for scaling. The polygon colors indicate which domains are similar to one another (Sect. 4.1) and hence more comparable as they are scaled with similar values (baselines, Table 1). In every domain, wind-field thunderstorms (blues) dominate in winter (first bar) and contribute to a varying fraction of thunderstorms in spring and fall, which is higher the more maritime a domain gets (domains A, D, J, K, L). Mass-field thunderstorms (reds) always dominate in summer (third bar) and over the mainland also in spring and fall. The presented cluster analysis with $k = 3$ has in all maritime domains (A, D, J, K, L) two wind-field thunderstorm types present, and in all domains at the mainland (B, C, E, F, G, H, I) two mass-field thunderstorms. This reveals the importance of wind-field thunderstorms over the seas. Higher $k$ results in further splitting of the displayed thunderstorm types to have at least two wind-field thunderstorm types and two mass-field thunderstorm types present in every domain. In Fig. 7 wind-field thunderstorms in the southern domains (E, H, I) are accompanied by enhanced cloud-physics variables (wind-field CP) which is remarkable in the alpine-central region (H, I) as all thunderstorms have in general very high cloud-physics variables there. As the presented thunderstorm characteristics are relative to other thunderstorms in each domain they are not directly comparable because some of them refer to very different baselines (Sect. 4.1). The mediterranean region (J, K, L) for example refers to much higher overall mass-field variables (Fig. 3) than the coastal domains (e.g., domain A).

In summary, we conclude that wind-field thunderstorms dominate the cold season and are more important over the sea while mass-field thunderstorms dominate the warm season and are more important over the mainland.

### 4.4 Comparability of the found thunderstorm types

The thunderstorm types are identified relative to the general meteorological conditions during lightning in each domain and the question remains how similar are thunderstorm types with the same name from different domains.

To make the thunderstorm types more comparable, a principal component analysis is estimated on all cluster means from every domain using the same scaling (Fig. 8). Again, the first two principal components are displayed on the axis explaining together about 70% of the variance (PC 3 explains additionally 13.4%) and the labeled arrows (loadings) indicate the contribution of each variable to the variance in the respective direction. Each domain (letters) is represented by three colored circles, the thunderstorm types found there. First of all, the figure shows that the two major thunderstorm types, wind-field thunderstorms and mass-field thunderstorms, are clearly separable from one another as the bluish and reddish circles are located in different parts of the figure. The difference between the mass-field thunderstorms is small as the reddish circles gather close to one another. Their major difference is in the surface-exchange variables that separate the light red mass-field thunderstorms from the dark red mass-field SX thunderstorm sub-type, which becomes more relevant in PC 3. Wind-field thunderstorms are more diverse as the bluish circles spread widely. They dominate the cold season, where climatologically little thunderstorms occur. Hence, the scarce cold-season thunderstorms in Europe originate in very diverse thunderstorm conditions while frequent summertime mass-field thunderstorms originate in similar weather patterns.
Figure 7. Spatio-temporal thunderstorm analysis in Europe. Barplots are based on cluster analyses that are individually estimated on each domain using local scaling values (as in Fig. 6). The colors of the domain borders indicate the similarity of some domains.
Figure 8. Comparison between all found clusters from all domains using the same scaling. The figure shows a biplot based on a PCA estimated on Table 2 and taking the first two principal components (PC) as axes. Each point represents a cluster and is colored and labeled according to its thunderstorm type and domain. The labeled arrows (loadings) indicate the contribution of each variable to the variance in the respective direction.
Regional lightning differences are described by four distinct regions: coastal, continental, mediterranean, and alpine-central. And thunderstorm characteristics in different meteorological environments are provided by the thunderstorm types (wind-field thunderstorms and mass-field thunderstorms plus sub-types).

Other authors have also investigated thunderstorm conditions. The variables important for our wind-field thunderstorms are similar to Mäkelä et al. (2013)’s investigations of winter lightning in Finland revealing the importance of vertical temperature difference between the surface and mid-troposphere (700/500 hPa) and shear, but not CAPE. Another classification was performed by Fujii et al. (2013) in Japan, who found that the number of winter lightning strokes and the probability of high-current lightning strokes, group into the storm type and inactive type dependent on the $-10 \degree C$ isotherm height. Sherburn and Parker (2014) coined the term HSLC-thunderstorms, which are meteorological environments of high-shear ($\geq 18 \text{ m s}^{-1}$ at $0-6 \text{ km}$) and low-CAPE ($\leq 500 \text{ J kg}^{-1}$) producing lightning in all seasons and at all times of day in the United States. Considering the overall lower CAPE values in Europe, this HSLC concept relates to our wind-field thunderstorm type, especially the sub-type with reduced mass-field values (wind-field$_{noMF}$). Market et al. (2002) show in their thundersnow climatology over the contiguous United States that lightning associated with snowfall origins in seven different meteorological environments. This supports our finding of the very diverse wind-field thunderstorm conditions. Stucke et al. (2022) relate our two thunderstorm types as described in Morgenstern et al. (2022a) to upward lightning at two alpine towers and find that most upward lightning occurs in wind-field thunderstorm conditions. In general, thunderstorm frequencies under different synoptic conditions are often described (e.g., Wapler and James, 2015; Enno et al., 2014; Bielec, 2001; Kolendowicz, 2006) and regional thunderstorm differences are often subject of classical climatologies as mentioned in the introduction. For the baltic countries, Enno et al. (2013) found three distinct thunderstorm regions (continental, transitional, maritime) similar to some of our thunderstorm regions (continental, coastal). And for the UK and Ireland, Hayward et al. (2022) conduct a regional cluster analysis aiming to identify areas where the seasonal distributions of lightning densities differ. This climatology nicely complements our approach with the PCA (Sect. 4.1) as it has a better resolution and covers adjacent regions, where EUCLID data does not fulfill our quality requirements.

This study is limited by the resolution of the data used. A higher resolution of atmospheric data in space and time and longer time series in the EUCLID data would improve the analysis. Applying a cluster analysis with more clusters or including also non-lightning information would lead to the same major results but could uncover more thunderstorm sub-types.

Now that the thunderstorm types are found, several new research questions arise that are beyond the scope of this paper. How often are wind turbines or other high structures struck by which thunderstorm type? What is the relation of the thunderstorm types to lightning properties such as the lightning duration, transferred charge, polarity, or channel length? It would also be interesting to model lightning probability maps for each thunderstorm type in each season.
6 Conclusions

This study investigates regional and seasonal thunderstorm characteristics in Europe. Very destructive lightning damages often occur in seasons and regions where lightning is climatological unlikely. Our analysis includes infrequent lightning conditions by considering the same amount of lightning observations from each season. EUCLID lightning data is combined with meteorological ERA5 data to answer two research questions: “How do meteorological thunderstorm characteristics vary regionally across Europe?” and “What characterizes thunderstorms in different meteorological environments and how do these thunderstorm types vary seasonally across Europe?”. Using principal component analysis, the European territory can be separated into four regions in which the atmospheric conditions for thunderstorms are similar throughout the year: The alpine-central region with thick clouds, large cloud particle masses, and strong updrafts relative to the other regions; the mediterranean region with increased mass-field variables; the coastal region with increased wind speeds; and the continental region with in general average conditions and increased solar radiation relative to the other regions. Cluster analysis is performed individually on 12 domains in Europe to find different thunderstorm types and a decision tree is developed to easily differentiate them (Fig. 4). There are two major thunderstorm types, wind-field thunderstorms and mass-field thunderstorms, and three sub-types thereof. Mass-field thunderstorms are characterized by increased CAPE values, the presence of CIN, large \( m \) dewpoint temperatures, high \(-10^\circ C\) isotherm heights, and high mean sea level pressure relative to other thunderstorms in that domain. They occur mostly in the warmer seasons and always in similar weather conditions and are more important over the European mainland. The mass-field\(_{\text{SX}}\) sub-type is associated with enhanced surface-exchange (SX) variables such as solar radiation and sensible heat flux and accounts for about half of the mass-field thunderstorms on the European mainland. The other major thunderstorm type is wind-field thunderstorms, which are more diverse but share the characteristics of average or reduced values in mass-field variables and elevated or average values in wind-field variables (high wind speeds at different heights, strong updrafts, large cloud shear, increased boundary layer dissipation) relative to other thunderstorms in that domain. They dominate the cold season, especially winter, and are more important over the sea. Sometimes the cloud-physics (CP) variables are additionally increased leading to the wind-field\(_{\text{CP}}\) thunderstorm sub-type with large cloud sizes, increased concentrations of cloud particles (snow, ice, supercooled liquids), and large precipitation amounts. Another sub-type, wind-field\(_{\text{noMF}}\) is characterized by decreased mass-field variables (no MF) and occurs often over the sea. In summary, this study shows that lightning in Europe origins in different meteorological environments, that winter lightning is not just a rarer sibling of summer lightning, and provides a decision tree to easily differentiate thunderstorm types in Europe independent of a seasonal criterion or static thresholds.

Code and data availability. The supplementary material (Morgenstern et al., 2022b) contains a R script to reproduce the core findings and main figures along with the required data for the presented sample, the domain definitions, a precise variable description, and the two tables. ERA5 data are freely available from the Copernicus Climate Change Service (C3S) Climate Data Store (Hersbach et al., 2020; https://cds.climate.copernicus.eu, last access: 30 September 2022). We use ERA5 hourly data 1959 to present on single level and model level (https://doi.org/10.24381/cds.adbb2d47, Hersbach et al., 2018; https://confluence.ecmwf.int/display/CKB/How+to+download+ERA5, last access: 25 November 2022). The results contain modified Copernicus Climate Change Service information for 2010–2020. Neither the European Commission nor ECMWF is responsible for any use that may be made of the Copernicus information or data it contains. EUCLID (Poelman et al., 2016; Schulz et al., 2016) data are available on request from ALDIS (Austrian Lightning Detection & Information System, aldis@ove.at) or Siemens BLIDS (Blitzinformationsdienst, fees may apply).

Author contributions. DM performed the investigation, wrote the software, visualized the results, and wrote the paper. IS, TS, and DM performed the data curation, built the data set, and derived variables based on ERA5 data. TS contributed coding concepts. GJM provided support for the meteorological analysis, data organization, and funding acquisition. AZ supervised the formal analysis and interpretation of the statistical methods. AZ, GJM, and TS are the project administrators and supervisors. All authors contributed to the conceptualization of this paper, discussed the methodology, evaluated the results, and commented on the paper.

Competing interests. The authors declare no competing interests.

Acknowledgements. We are grateful to Gerhard Diendorfer, Wolfgang Schulz, and Hannes Pichler from ALDIS for data support and discussions about lightning physics and to EUCLID for providing the LLS data. This research has been supported by the Österreichische Forschungsförderungsgesellschaft (FFG) with grant no. 872656 and the Austrian Science Fund (Fonds zur Förderung der wissenschaftlichen Forschung, FWF) with the grants no. P 31836 and no. P 35780-NBL and with financial support from the State Tirol, Austria.

The computational results presented have been achieved in part using the Vienna Scientific Cluster (VSC).
