Abstract

Within the Northern Calcareous Alps fold-and-thrust belt of the Eastern Alps, multiple deformation phases have contributed to the structural grain that localised deformation at later stages. In particular, Jurassic rifting and opening of the Alpine Tethys led to the formation of extensional basins at the northern margin of the Apulian plate. Subsequent Cretaceous shortening within the Northern Calcareous Alps produced the enigmatic Achenal structure, which forms a sigmoidal transition zone between two E-W striking major synclines. One of the major complexities of the Achenal structure is that all structural elements are oblique to the Cretaceous direction of shortening. It was therefore proposed to be a result of forced folding at the boundaries of the Achenal basin. This study analyses the structural evolution of the Achenal structure through integrating field observations with crustal-scale physical analogue models, to elucidate the influence of pre-existing crustal heterogeneities on oblique basin inversion and the prerequisites for the formation of a sigmoidal hanging wall that outlines former basin margins. From brittle-ductile models, we infer that shortening oblique to pre-existing extensional faults can lead to the localisation of thrust faults at the existing structure within a single deformation phase. Prerequisites are 1) a weak basal décollement that is offset by an existing normal fault, 2) the presence of topography in the hinterland, 3) a thin-skinned deformation style. Consequently, the Achenal low-angle thrust and corresponding folds was able to localise exactly at the basin margin, with a vergence opposite to the Jurassic normal fault, creating the characteristic sigmoidal morphology during a single phase of NW-directed shortening.

1 Introduction

The deformational style and tectonic history of Earth's orogenic belts is strongly influenced by pre-existing structural elements. In particular, structures formed by shortening and inversion of pre-orogenic basins are often governed by the reactivation of former basin-bounding normal faults as summarised by Turner and Williams (2004) or Cooper and Warren (2020). Consequently, previous studies have focused on the mechanics of fault reactivation (e.g., Sibson 1995; Etheridge 1986; Tong and Yin 2011; Nielsen and Hansen 2000), or present regional case studies of basin inversion (e.g., Kley et al. 2005; Thorwart et al. 2021; Héja et al. 2022). Existing literature presenting analogue and numerical modelling of inversional settings is extensive and includes the re-activation of planar and listric extensional fault systems of various orientation as well as basin inversion orthogonal or oblique to the basin axes (e.g., Bonini 1998; Buiter and Pfiffner 2003; Amilibia et al. 2005; Buchanan and McClay 1992; Koopman et al. 1987; Konstantinovskaya et al. 2007; Sassi et al. 1993; Dubois et al. 2002; Zwaan et al. 2022; Brun and Nalpas 1996). In most models, newly formed reverse faults are synthetic to the pre-existing normal faults (see

40 also Bonini et al. 2012; their Figure 3), whereas the formation of thrust faults antithetic to the former basin-bounding faults is seldom described.

In this study, we use an example from the Northern Calcareous Alps (NCA) in Austria (Figure 1a), in which basin inversion during Alpine orogeny has created a low-angle thrust antithetic to a normal fault bounding a Jurassic extensional basin. In the hanging wall of this thrust, a fold train outlines the margins of this former basin, forming a characteristic sigmoidal shape that
45 has been the subject of geological investigations since the beginning of the 20th century (Ampferer 1902, 1941; Fuchs 1944; Nagel 1975; Nagel et al. 1976; Quenstedt 1933). We use the example of the Achenal structure as a starting point for analogue modelling, to simulate the oblique inversion of a former extensional basin and the deformation of a brittle-ductile sedimentary succession at its margins. In particular, this study examines whether a sigmoidal hanging wall shape outlining former basin margins can be explained by a single phase of oblique shortening and if so what are the critical rheological and kinematic
50 parameters to obtain such structures. Our modelling results are then compared to the Achenal structure, to better understand the formation of complex inversion structures in fold-and-thrust belts.

2 Geological setting

The Northern Calcareous Alps (NCA) of Austria (Figure 1a) have a polyphase tectonic and sedimentary history that started in the Permian. The following stages are distinguished:

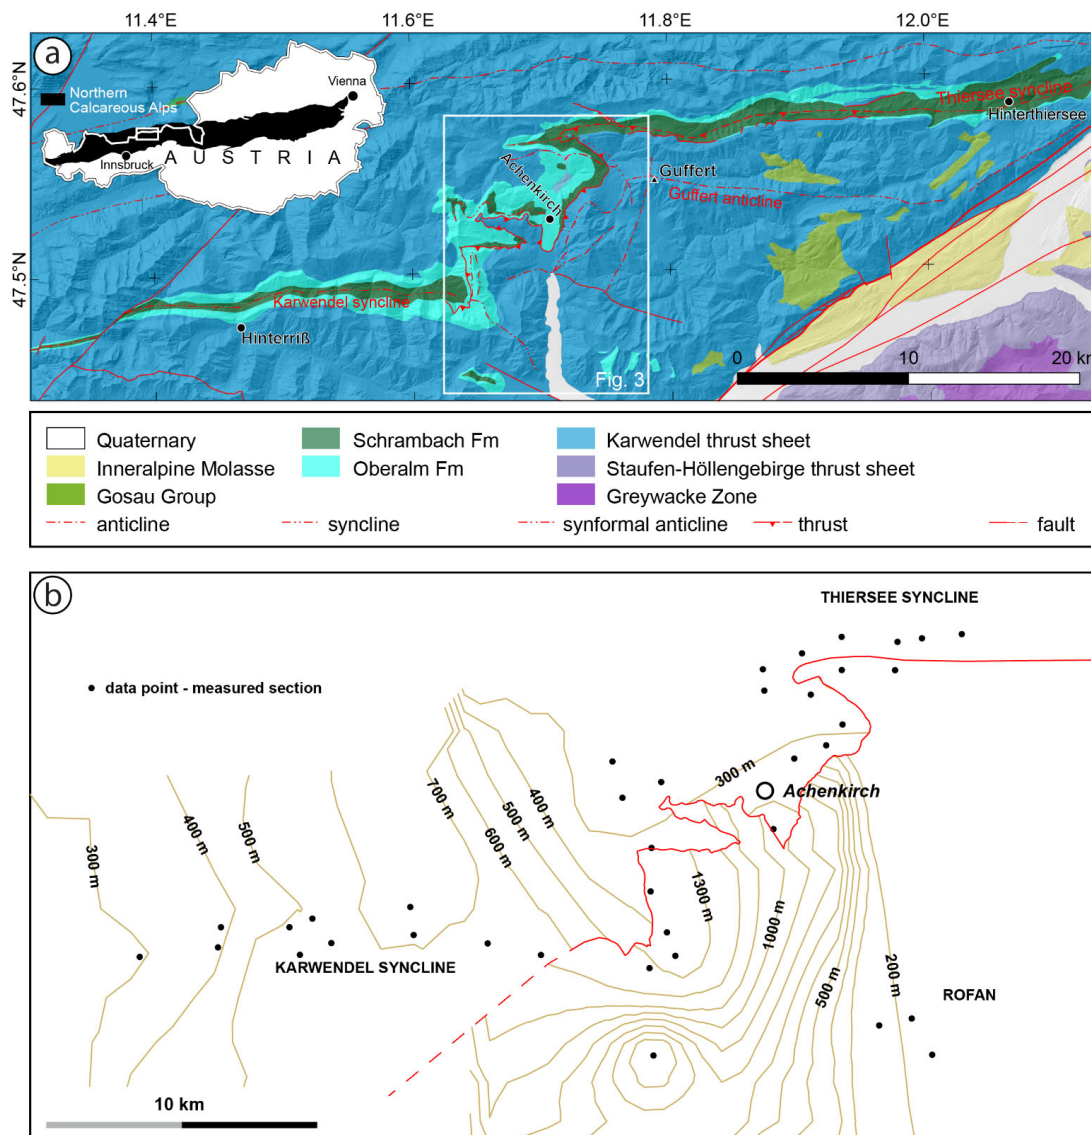

- 55 1) Deposition on the south(east)ern passive margin of Pangaea bordering the Neotethys from the Permian to the end of the Triassic (e.g., Haas et al. 1995; Lein 1987; Schmid et al. 2004; Stampfli et al. 1998; Schmid et al. 2008). The major part of the Permian-Triassic is carbonate platforms.
- 2) Early to Middle Jurassic rifting and subsequent opening of the Alpine Tethys that separated the Apulian/Adriatic microplate from the European continent (e.g., Faupl and Wagreich 1999; Schmid et al. 2004; Froitzheim and
60 Manatschal 1996). Rift-related subsidence caused the drowning of former Triassic carbonate platforms, rift-related faulting established the normal faults that were inverted during Cretaceous orogeny (Eberli et al. 1993; Ortner et al. 2008).
- 3) Shortening related to Late Jurassic obduction of Neotethys oceanic crust onto the southeastern Apulian margin heralded inversion of this margin that culminated in Cretaceous orogeny (Schmid et al. 2004; Stüwe and Schuster
65 2010). During Cretaceous orogeny the NCA were a typical thin-skinned fold-and-thrust belt at the external margin of the Austroalpine orogenic wedge in lower plate position (Eisbacher and Brandner 1996; Ortner and Kilian 2022).
- 4) During the Late Cretaceous this wedge was transported toward the northwestern passive margin of the Apulian plate. In the late Cretaceous, this margin became an active margin where the Alpine Tethys was subducted (Ortner and Sieberer 2022; Stüwe and Schuster 2010; Willingshofer et al. 1999).
- 70 5) Late Eocene closure of the Alpine Tethys caused collision between the lower, European and upper, Apulian plates and thus a second, Paleogene Alpine orogeny (Eisbacher and Brandner 1996; Schmid et al. 2004; Stüwe and Schuster 2010; Ortner 2003b). In the course of this process the Austroalpine units and the NCA fold-and-thrust belt were transported piggyback onto the European margin. Contrasting with Cretaceous orogeny, the Austroalpine wedge formed the upper plate during Paleogene orogeny.

75 The important stages in the frame of this study are Jurassic rifting that created basins, and Cretaceous and Paleogene shortening that led to basin inversion. Jurassic extensional basins formed along intersecting fault systems with N-S trending normal faults and E-W trending transform faults, as studied in the Eastern Alps of Switzerland (Eberli 1987, 1985; Weissert and Bernoulli 1985). Similar orientations of extensional normal faults have been found in the Western Alps (Lemoine et al. 1986). In the present-day Achensee region, Jurassic extension and the formation of an extensional basin is indicated by filled fissures that

80 occur in Oberrhätkalk (Gruber et al. 2022), strong lateral thickness variations of (Upper) Jurassic strata (Figure 1b) (Schütz
1979; Nagel et al. 1976) and characteristic breccias that are locally intercalated in basinal Jurassic sediments (Spieler and
Brandner 1989; Channell et al. 1992; Channell et al. 1990; Brandner et al. 2011).

Cretaceous to Paleogene shortening within the NCA is characterized by two separate directions of transport. Whereas during
Cretaceous orogeny the thrust sheets of the NCA were transported and stacked in WNW- to NW-direction (Eisbacher and
85 Brandner 1996), during Paleogene orogeny the NCA fold-and-thrust belt was transported in N- to NNE-direction (Schmid et
al. 1996). The basement units of the Austroalpine wedge show a clear separation between the Cretaceous and Paleogene stages
(Froitzheim et al. 1994), but synorogenic growth strata show continuous shortening within the NCA (Ortner 2001, 2003a;
Ortner and Gaupp 2007; Ortner et al. 2016). The nappe structure of the NCA (Tollmann 1973; Hahn 1912, 1913b, 1913a;
Ampferer and Hammer 1911; Ampferer 1912; Heißel 1958; Eisbacher and Brandner 1996; Tollmann 1970, 1976) has recently
90 been revised (Ortner 2016; Ortner and Kilian 2022). Consequently, the former Inntal and Lechtal thrust sheets have been
combined in the Karwendel thrust sheet (Figure 1a), which overthrusts the Tannheim thrust sheet (combined from the Allgäu
thrust sheet, Puitentalzone and Karwendelschuppenzone) to the north (Ortner 2016; Ortner and Kilian 2022; Kilian and Ortner
2019).

95 **Figure 1:** (a) Geological overview of the Achenkirch structure within the Karwendel thrust sheet. Top inset shows the location of the NCA in Austria. Rectangle shows location of Figure 3. Modified after Ortner and Kilian (2016). (b) Isopach map of the Upper Jurassic Oberalm Fm. The Achenkirch thrust (red line) is given for reference of location. Data compiled from Nagel et al. (1976) and Schütz (1979). Hanging wall and footwall of the thrust were contoured separately, single outliers in the data were ignored. Major thickness changes occur from W to E, a maximum is observed in the southern hanging wall of the thrust.

100 2.1 Sedimentary succession

The sedimentary succession of the NCA encompasses a late Permian to Early Cretaceous stratigraphic column that reflects the growth of two major Middle and Upper Triassic carbonate platforms and their subsequent drowning (Figure 2). During the Permian-Middle Triassic, the marine ingressions of the Tethys led to the formation of a subtidal-supratidal marine environment, where evaporitic deposits (Haselgebirge) accumulated. The large amounts of halite, gypsum and anhydrite contained within these strata (Leitner and Neubauer 2011) are the cause of their highly incompetent behavior. The thickness of Haselgebirge is highly variable, due to salt diapirism and tectonics, although a primary thickness of 500-1000 m can be expected (Spötl 1989:

Fig. 2). Lower Triassic sandstones (Alpine Buntsandstein) overlie the Haselgebirge and are followed by the Anisian Reichenhall Formation (Fm) (Figure 2). The latter consists of alternating layered dolomite, cellular dolomite and bituminous limestone with a thickness of 80-200 m in the Achensee region (Nagel et al. 1976). The Haselgebirge-Reichenhall succession
110 composes a rheologically incompetent part of the stratigraphic column, forming the principal décollement of the NCA (Eisbacher and Brandner 1995). The Eben thrust (Figure 3) brings the Haselgebirge-Reichenhall succession to the surface in the Achensee region. Furthermore, its presence in the subsurface has been inferred from depth-extrapolated cross sections based on TRANSALP and industry reflection seismic lines (Auer and Eisbacher 2003; their Figure 15).

The evaporitic Haselgebirge-Reichenhall succession transitions into a succession of Anisian-Ladinian limestones (Alpine
115 Muschelkalk Group) (Bechstädt and Mostler 1974). These vary from shallow-water, strongly bioturbated mud- to wackestones (e.g., Virgloria Fm, Steinalm Fm) to basin marginal and basinal limestones (Reifling Fm) (Rüffer and Zühlke 1995). The uppermost Alpine Muschelkalk Group interfingers with the Wetterstein limestone (Anisian–Carnian), which forms the first of two major carbonate platforms of the NCA (Figure 2). Lithotypes consist of lagoonal, reefal and foreereefal lime- and dolostones with a fossiliferous content of e.g., stromatolithes, oolites, calcareous algae and sponges; (Sausgruber 1994a) and their
120 fragments. Although the Alpine Muschelkalk Group and Wetterstein limestone show a general thickness between 1000 to >2200 m in the Achensee region (Sausgruber 1994b; Nagel et al. 1976; Gruber et al. 2022), cross sections in Gruber et al. (2022) show a thickness up to 3500 m. These thickness variations are attributed to salt tectonics in the Triassic (see Ortner and Kilian 2022; Granado et al. 2019; Kilian et al. 2021). The Carnian Raibl event marks the abrupt termination of carbonate sedimentation on the Wetterstein platform (Hornung et al. 2007; Krainer et al. 2011). As a result, the Raibl beds (Carnian)
125 overlie the Wetterstein platform unconformably. They consist of sandstones, shales, dolomites, cellular dolomites, evaporites and limestones that were deposited on a marine shallow shelf with interval-bound terrigenous input (Gruber et al. 2022; Krainer et al. 2011; Sausgruber 1994a; Jerz 1966). Compared to the underlying Middle Triassic carbonate platform, the Raibl beds form a relatively incompetent succession. The increased eradication of ripple marks and intercalated shale horizons marks the transition between the Raibl beds and the overlying Hauptdolomit carbonate platform (Müller-Jungbluth 1968: Fig. 2), forming
130 the second major platform of the NCA. Lithologies consist of inter- to supratidal, laminated dolostone and subtidal dolomudstones (Fruth and Scherreiks 1982; Müller-Jungbluth 1968; Zorlu 2007), which contain scarce fossils. The early evolution of the Hauptdolomit platform is characterized by local anoxic basins, represented in the stratigraphic succession by bituminous intervals and coaly shales (Spieler and Brandner 1989; Donofrio et al. 2003). Sedimentary textures typical for a supra- to intertidal lagoonal depositional environment (Flügel 2010) occur in the middle level of Hauptdolomit (Müller-Jungbluth 1968).
135 The Hauptdolomit platform subsequently drowns towards its top; the alternation of limestone and dolomite in the upper Hauptdolomit succession gradually evolves into the well-bedded and fossiliferous Plattenkalk limestone (Norian) (Gümbel 1861). Together, Hauptdolomit and Plattenkalk show a thickness > 1000 m in the Achensee region (Gruber et al. 2022; Nagel et al. 1976; Bachmann and Müller 1981; Sausgruber 1994a, 1994b). Further drowning resulted in the deposition of the subtidal Kössen Fm (Norian-Rhaetian) (Müller-Jungbluth 1968; Czurda and Nicklas 1971), marked by increasing intercalated marls and shales (Lotter and Gruber 2011), which interfinger with Upper Rhaetian platform carbonates (Riedel 1988; Golebiowski 1991) (Figure 2).

While rifting of the Alpine Tethys (Eberli et al. 1993) in the Jurassic caused subsidence and drowning of the Triassic carbonate platforms (Ortner et al. 2008), rotational block faulting caused by the extensional movement (Lackschewitz et al. 1991) resulted in a differentiation of basin and swell facies (Nagel et al. 1976; Spieler and Brandner 1989). Early Jurassic red condensed
145 limestones (e.g., Adnet Fm, Sinemurian–Toarcian; Hierlatzkalk) containing manganese nodules (Sausgruber 1994a; Spieler 1994) were deposited on swells, and basinal strata (e.g., Scheibelberg Fm., Hettangian–Toarcian; Allgäu Fm. Hettangian–Oxfordian) in subsided areas (Brandner and Gruber 2011: Fig. 15). Gravitational scarp-fault breccias and debris flows are intercalated in the basinal slope specular limestones of the Scheibelberg Fm and the interfingering, more distal Allgäu Fm

(Spieler and Brandner 1989). The local basin-and-swell differentiation and sedimentation was preserved until the Middle-Late
150 Jurassic (Brandner and Gruber 2011; Ortner et al. 2008; Ortner and Kilian 2016; Spieler and Brandner 1989). The continental
margin reached its maximum subsidence in the Oxfordian (Ortner and Kilian 2016), when the Ruhpolding radiolarite
(Oxfordian) (Nagel et al. 1976; Sausgruber 1994a) as one of the deepest lithofacies of the Tethys (Bernoulli and Jenkyns 1974,
p. 141) was deposited. The overlying Late Jurassic-Early Cretaceous (Kimmeridgian-Berriasian) stratigraphic succession (e.g.,
Tauglboden Fm, Ammergau Fm, Oberalm Fm, Barmstein limestones) testifies to a shallowing depositional environment
155 (Gruber et al. 2022; Gawlick 2004; Kilian 2013; Sausgruber 1994a; Gümbel 1861; Lipold 1854). The Jurassic succession
(Scheibelberg Fm-Tauglboden Fm) has a mean thickness of 290 m (based on cross sections and compilations of Ortner and
Gruber 2011; Sausgruber 1994b; Spieler 1995; Auer 2001; Gruber 2011). The Ammergau Fm (Kimmeridgian-Tithonian) has
a mean thickness of 309 m and the Oberalm Fm (Tithonian-Berriasian) has a mean thickness of 1075 m.

An increase in siliciclastic detritus, beginning in the Early Cretaceous, marks the onset of synorogenic sedimentation,
160 commencing with the Schrambach Fm (Berriasian-Aptian), consisting of marls and intercalated calcareous and turbiditic
sandstones (Lipold 1854; Ortner 2003a). In the western Thiersee syncline, its thickness is ~ 300-400 m (Ortner and Gruber
2011; Schütz 1979), thinning to ~ 150 m east of Achenkirch (Ortner and Gruber 2011). The overlying synorogenic sediments
of the Gosau Group (Late Cretaceous to Paleogene) complete the stratigraphic succession of the Achenal structure and
Northern Calcareous Alps (Ortner 2003a).

165

Figure 2: Stratigraphic overview of the Permian–Cretaceous sedimentary succession of the Karwendel thrust sheet in the Achensee area. Compilation of data from Pilller et al. (2004), Nittel (2006) and Brandner and Gruber (2011).

2.2 Achental structure

The Achental structure is located within the Karwendel thrust sheet of the NCA and geographically surrounds Lake Achen (German: Achensee) in Tyrol, Austria (Figure 1a, 3). The structure is characterized by the low-angle Achental thrust, which separates the Karwendel and Thiersee synclines in its footwall, from the Guffert-Unnutz-Montscheinspitze anticline fold train in its hanging wall. The Achental structure forms a NNE-SSW striking transfer zone between Karwendel and Thiersee synclines, with the Achental thrust reaching into the cores of these folds and gradually losing offset toward the NE and SW (Ortner and Gruber 2011). The thrust changes its orientation and stratigraphic offset throughout the Achental structure; in the north (Mahmooskopf-Natterwand section, Figure 3), the thrust strikes E-W and dips ~ 23-30° south (Ortner 2003a and Beer 2003, respectively) with a total displacement of ~ 5-7 km (Auer and Eisbacher 2003 and Ortner 2003a, respectively). In the

175

central section, the thrust strikes NNE-SSW and dips 15° SE (Spieler 1994). It reaches a maximum stratigraphic offset of ~ 8 km (Eisbacher and Brandner 1996) NE of Achenkirch, where Hauptdolomit (Norian) is thrust onto Schrambach Fm (Early Cretaceous) (Figure 3, 4a) (Gruber et al. 2022). In the south, the Achenal thrust runs into the core of the Karwendel syncline (Figure 3). Although here the thrust separates consecutive Late-Jurassic-Early Cretaceous strata, the SE dip of the thrust is strongly opposed to the steep E- to SE dip of the strata, ruling out a stratigraphic contact between these formations (Ortner and Gruber 2011). The Karwendel, Scharfreuter, Gröben and Großzemmalm synclines and the associated Hofjoch anticline and Klammbach syncline form the footwall of the Achenal thrust (Figure 3). These are km-scale, E-W striking north-vergent folds that are overturned to recumbent, and are overridden by the Achenal thrust and its associated faults (e.g., Leiten thrust; Ortner and Gruber 2011: their Figure 2). The recumbent Thiersee syncline forms the north vergent eastern continuation of the Klammbach syncline (Ortner and Gruber 2011; Sausgruber 1994b; Gruber et al. 2022).

The hanging wall of the Achenal thrust is referred to as the “Achentaler Schubmasse” after Quenstedt (1933). It is comprised of the connected Montscheinspitze, Unnutz and Guffert anticlines (Figure 3, 4), which change strike approximately parallel to the Achenal thrust. West of the Achenal structure, the Montscheinspitze anticline is connected to the Karwendel syncline (Ampferer and Heissel 1950: their section 3). In the SW corner of the Achenal structure, the northern anticline limb is folded with the Seebergspitze syncline into an overturned position (Fuchs 1944; Ortner and Gruber 2011) and thrust onto the Karwendel syncline along the Achenal thrust (Nagel et al. 1976). The Montscheinspitze anticline then continues toward the north as the Unnutz anticline, which is a recumbent fold with a SE-dipping axial surface and an increasingly SSW-plunging fold axis (From N-S 205/18, 200/27 and 187/23; Ortner and Gruber 2011). The Unnutz anticline (Figure 4a) resembles a dome, rather than a cylindrical fold (e.g., Mojsisovics 1871; Sausgruber 1994a, 1994b; Ortner and Gruber 2011) with an upright limb that changes strike from E-W to NE-SW. NE of Achenkirch, the Unnutz anticline is folded around the Steigwand anticline and Rotmöserkopf synform and continues as the E-W striking Guffert anticline (Gruber et al. 2022; Ortner and Gruber 2011) (Figure 3, 4b). The Guffert anticline has a S-dipping axial surface, sub-horizontal fold axis with ESE-WNW strike and shows an overturned northern limb.

The resulting Guffert-Unnutz-Montscheinspitze anticline fold train in the Achentaler Schubmasse forms a characteristic sigmoidal shape that has been noticed since the beginning of the 20th century (Ampferer 1902) and is one of the greatest complexities in geologic interpretation of the Achenal structure. Over the past century, four principal hypotheses have been developed to explain the formation of this sigmoidal fold train (see also Ortner and Gruber 2011; Gruber et al. 2022). These include 1) bending of an originally E-W striking anticline due to rotational movements, forming the N-S striking Unnutz anticline as a central segment (e.g., Ampferer 1921; Auer 2001; Spengler 1953, 1956; Ampferer 1941); 2) passive dragging of the central part of the structure, caused by a larger amount of shortening in the eastern part of the structure, compared to its western part (Nagel 1975); 3) polyphase deformation, in which a former W-directed thrust (Achenal thrust) was reactivated by N-directed thrusting (Fuchs 1944; Channell et al. 1992; Channell et al. 1990; Ortner 2003a; Spieler and Brandner 1989), and 4) forced folding of the Guffert-Unnutz-Montscheinspitze fold train at the border of a carbonate platform, or along an inverted Jurassic normal fault (Eisbacher and Brandner 1995, 1996; Ortner and Gruber 2011).

In accordance with the third hypothesis, the Achenal structure has been affected by polyphase shortening (Fuchs 1944; Spieler and Brandner 1989; Ortner 2003a; Ortner and Gruber 2011), beginning in the Early Cretaceous with the formation of the Guffert anticline (Ortner and Gruber 2011). Barremian sediments below the Achenal thrust indicate an Early Cretaceous maximum age of thrusting. Both the Achenal and Leiten thrust are folded with the E-W striking Roßstand anticline, but not with the parallel Scharfreuter anticline (Sausgruber 1994b; Ortner and Gruber 2011: their Fig. 2) (Figure 3). Folding of the Achentaler Schubmasse around these folds suggests that the Achenal thrust is older than the general N-directed shortening (Spieler and Brandner 1989). The oldest contractional deformation in the area is indicated by an angular unconformity in both limbs of the Guffert anticline at the base of the Gosau Group 15 km east of the Achenal structure (Ortner and Gruber 2011),

indicating Early Cretaceous growth of the anticline. Anticlines grow on top of décollements, and we speculate that the Achenal
220 thrust was already active. However, since the oldest sediments covering both the hanging wall and footwall of the northern
Achenal thrust belong to the Gosau Group, N-directed shortening must have occurred post-Gosau (Ortner 2003a), post-dating
the formation of the western Achenal thrust. Cretaceous shortening is evident from NNW- to NW-directed movement along
the Achenal thrust (Eisbacher and Brandner 1995, 1996), based on calcite fibre lineations (Sausgruber 1994a, 1994b). This
phase of shortening caused an initial uplift and tightening of the Unnutz-Achenal structure and is responsible for NW-striking
225 high-angle dextral transfer faults, which segment the Unnutz anticline (Eisbacher and Brandner 1995, 1996). In contrast, Late
Cretaceous to Paleogene (80-30 Ma) NE-directed shortening superimposed existing folds and fault movement, reactivating
pre-existing NW-striking transfer faults and forming NW-plunging folds and NE-striking high-angle transfer faults (Eisbacher
and Brandner 1995). As a result, three major fold orientations are recognized in the Achensee region (Sausgruber 1994a).
Folds with NE-SW striking fold axes formed during NW-directed, pre-Gosau contraction. E-W striking fold axes formed
230 during N-directed shortening and NW-SE striking fold axes formed during NE-directed shortening. Neogene folds
superimpose older folding and can be found e.g., within the Thiersee syncline (Sausgruber 1994b). In general, fold interference
creates intriguing dome-and-basin structures that complicate the geological interpretation of the Achenal structure. Although
polyphase deformation of the Achenal structure is visible from field evidence, showing refolded faults and fold axes (e.g.,
Gruber et al. 2022; Ortner and Gruber 2011; Sausgruber 1994b), it has not been proven that two phases of deformation were
235 necessary to create the Achenal structure (Gruber et al. 2022).

Following the fourth hypothesis, several studies propose a link between a Jurassic basin architecture and the present-day
sigmoidal form of the Achenal structure, suggesting that the latter is the result of forced folding (Eisbacher and Brandner
1995, 1996; Ortner and Gruber 2011) that depended on pre-existing extensional structures rather than the exact direction of
shortening (Töchterle 2005). The existence of a controlling inherited Jurassic basin-and-swell topography is supported by a
240 clear facies differentiation and an increasing thickness of basinal Jurassic strata, from 100 m near Mittenwald (30 km W of the
study area) to 1100 m in the Bächental (10 km NW of the study area; e.g., Ulrich 1960; Nagel et al. 1976; Schütz 1979; Ortner
and Kilian 2016; Gruber et al. 2022) (Figure 1b), showing an increased subsidence toward the SE end of the Karwendel
syncline. The Jurassic extensional basin-and-swell topography was proposed to form the foundation of the present-day
Achenal structure, in which a N-S to NE-SW striking pull-apart basin (Spieler and Brandner 1989; Ortner and Gruber 2011)
245 or negative flower structure (Sausgruber 1994b) was bordered by E-W striking sinistral strike-slip faults. This is supported by
Pliensbachian and Toarcian mass-flow sediments and scarp-breccias that are found near the basin slopes (Spieler and Brandner
1989).

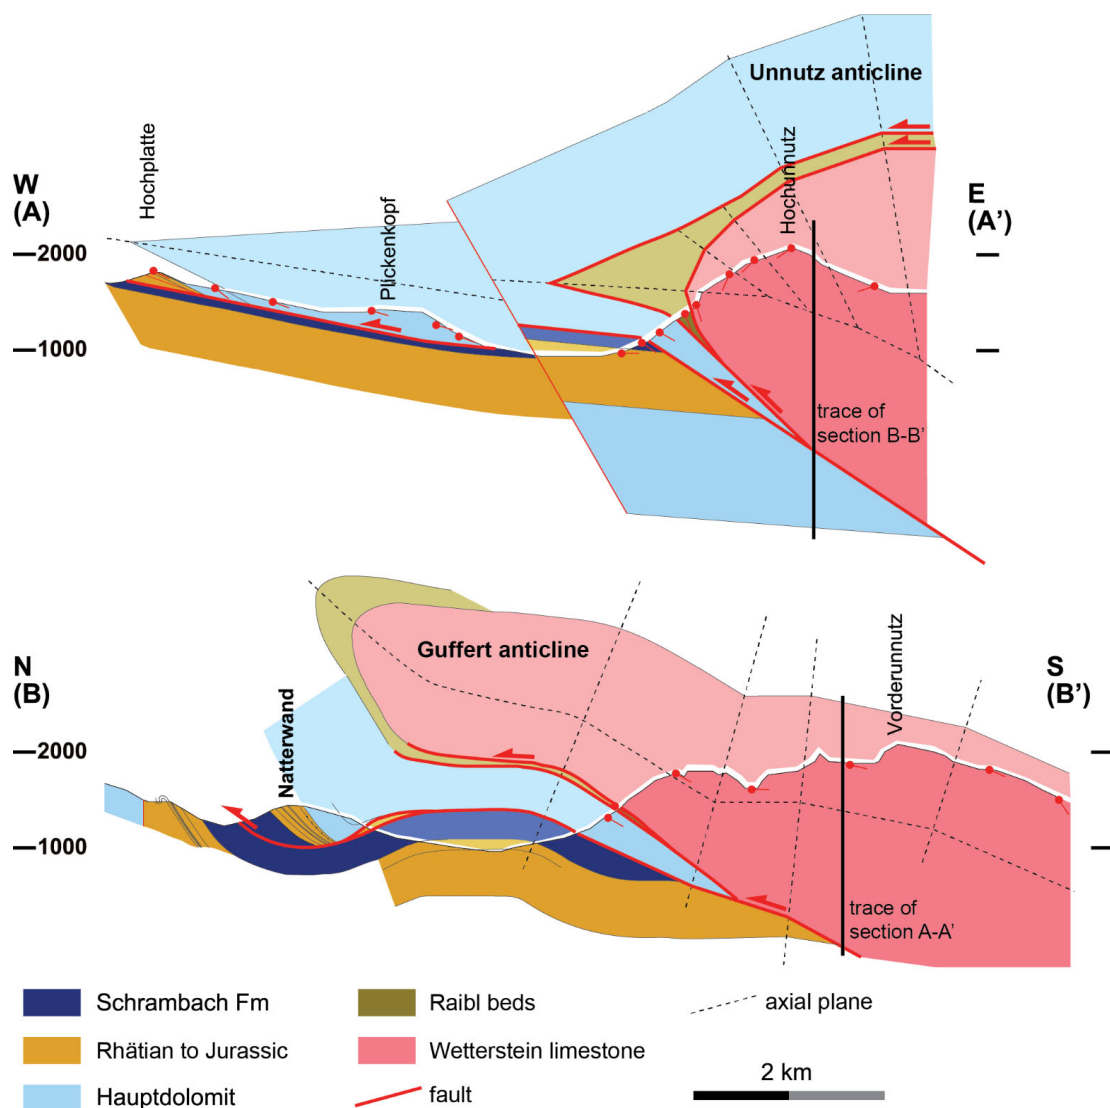

Figure 4: Cross sections (a) of the Unnutz anticline (Section A-A') and (b) of the Guffert anticline (Section B-B'). Section traces are marked in Figure 3. Modified after Ortner (2003a).

3 Analogue modelling

255 3.1 Modelling strategy

Regional-scale physical analogue modelling was conducted to investigate the influence of pre-existing basin-bounding extensional faults on oblique basin inversion, within the geological framework of the Achenal structure. The goals of the experiments included testing 1) the importance of a weak basal décollement, 2) the influence of thick-skinned versus thin-skinned tectonics, and 3) the role of pre-existing structures in deformation localisation. Analogue models were set up to show an increasing lithological and structural likeness to the eastern margin of the Jurassic Achenal basin, resulting in an increasing model complexity.

Figure 5: Schematic diagram showing the geological set-up of the eastern margin of the Achenal basin, prior to inversion. Grey bold line represents inversional trace of the Achenal thrust. Lithologies are marked brittle or ductile, depending on their mechanical properties.

265 3.2 Geometric and kinematic setup

270 Brittle and ductile modelling materials represent different parts of the NCA and Tethyan stratigraphy. A ductile layer of ~ 400 m thick, incompetent evaporites and shales, forming the basal décollement of the NCA was represented by silicone putty in models, with a thickness of 0.4 cm (Figure 5 and 6a). The silicone putty is a mixture of RBG-0910 Dow Corning silicon polymer and fine iron powder (~ 32 wt.%) with a density of ~ 1360 kg m⁻³. We determined a viscosity (η) of 20456 Pa s for the modified silicone putty, using a conical-cylindrical viscometer under room temperature (21 ± 1 °C) (Mooney and Ewart 1934; Lee and Warren 1940, see also Willingshofer et al. 2005). The viscosity of natural evaporites, albeit highly variable, is estimated to be 10^{19} Pa s (Allen and Beaumont 2016; Weijermars 1986a; Weijermars 1986b, 1986c; Weijermars et al. 1993; Weijermars and Schmeling 1986), resulting in a viscosity ratio of $2.046 \cdot 10^{-15}$. The modified silicone putty exhibits near-Newtonian behaviour and has an n-value of 1.27 in laboratory tests. The predominantly carbonatic, brittle sedimentary cover of the NCA was represented by dry quartz sand (Figure 5), a Mohr-Coulomb material, with a density of 1510 kg m⁻³ (e.g., Willingshofer et al. 2018). The quartz sand was sieved on top of the silicone putty, to create a total model thickness of 5 cm (Figure 6a). The density of the natural prototype was approximated by the density of Triassic Muschelkalk and amounts to ~ 2680 kg m⁻³ (Manger 1963: p. E31), so that a density ratio (ρ^*) of 0.56 between model and nature exists. An intermediate layer of Upper Triassic carbonatic-evaporitic strata was modelled as either brittle or ductile, depending on the model-specific set-up (Figure 6a, 6b). Assuming that inertial forces can be neglected in the analogue models (see discussion in Wickham 2007; Del Ventisette et al. 2007), the scaling of time and length is allowed to deviate from the principle of dynamic similarity and their “ratios can be considered as independent variables” (Dombrádi et al. 2010, p. 109). The principles of dynamic, geometric and rheological scaling are discussed in Hubbert (1937), Ramberg (1981), Weijermars and Schmeling (1986), Merle and Abidi (1995), Brun (1999), Sokoutis et al. (2000; 2005) while their relationships between model and nature are summarized in Table 285 1.

Table 1: Summary of model parameters. Experimental material parameters from Willingshofer et al. (2005; 2018). For strength envelopes, see Figure 6b.

Materials/parameters		Model	Nature	Ratio (m/n)
<i>Brittle layer</i> (<i>Quartz sand</i>)	Thickness	Max. 0.05 m	Max. 5000 m	10^{-5}
	Density	1510 kg m ⁻³	2680 kg m ⁻³	0.56
	Strength	Max. 1471.5 Pa	Max. $2.63 \cdot 10^{-8}$ Pa	$5.597 \cdot 10^{-6}$
<i>Ductile layer</i> (<i>Silicone mixture</i>)	Thickness	0.004 cm	400 m	10^{-5}
	Density	1360 kg m ⁻³	2450 kg m ⁻³	0.56
	Viscosity	20456 Pa s	10^{19} Pa s	$2.046 \cdot 10^{-15}$
	Strength	28.41 Pa	2550933 Pa	$1.11 \cdot 10^{-5}$
	n-value	1.27		
Length				10^{-5}
Strain rate		0.01 m/h	0.00323 m/yr	27137
Time		8–11 h	2.478–3.408 Ma	$3.685 \cdot 10^{-10}$
Bulk shortening		0.08–0.11 cm	8000–11000 m	10^{-5}

Model materials were placed in a rectangular fault box with metal bars as sidewalls and a wooden piston of 40 or 83 cm width as a moving wall (Figure 6c). We chose a length ratio (L^*) of 10^{-5} , so that 1 cm in the model represents 1 km in nature (Table 1). In all experiments, a pre-existing normal fault, similar to the boundary fault of the Achenal basin was represented by a rigid basal plate (footwall block) with a 60° dipping ramp (fault plane). In model-specific set-ups, the direction of shortening (at 90° or 45° to the ramp), the movement of the basal plate (fixed or mobile) and the layering sequence of the model (Figure 6a) were varied. The modelling strategy evolved from a basic model set-up, which was applied to one brittle (A1) and three brittle-ductile (B1-3) models. The set-up featured a basal plate with dimensions of 40 x 22.5 cm, a thickness of 1 cm and a 60° dipping front ramp (Figure 6). A wooden piston of 40 cm width was placed behind (A1, B1) or on top of (B2, B3) the basal plate, so that the plate was either mobile or fixed, exemplifying the effect of thick- versus thin-skinned tectonics. Shortening was applied at 90° to the front ramp with a convergence rate of 8 cm/h for the brittle model (A1) and 1 cm/h for the brittle-ductile models (B1-B3), and a total shortening of 8 cm (Table 1). For the brittle model, only quartz sand was used as a modelling material. In the brittle-ductile models, a basal layer of silicone putty was placed on top of the basal plate (B1, B3) or over the basal plate, ramp and tabletop (B2). A small amount of dishwashing soap was spread between the plate and the silicone putty, to increase the décollement function of the ductile layer. Model B2 featured an additional, upper ductile layer (Figure 6a). For model C1 we added two plates to the north and south of the fixed main basal plate, to simulate E-W striking strike-slip faults bounding the Achenal basin. This required the use of a piston with a width of 83 cm. Shortening remained orthogonal to the ramp at 1 cm/h, but total shortening was increased to 11 cm. The basal ductile layer of silicone putty was placed on top of the basal plates and on the tabletop, but was disconnected at the ramp (Figure 6). For models D1 and D2 the fixed main basal plate and two auxiliary plates were rotated 45°, to simulate oblique shortening at 45° to the ramp. We applied a total shortening of 11 cm. For both models, the basal ductile layer was placed on the basal plate and tabletop, while being disconnected at the ramp to create a clear velocity discontinuity (see e.g., Allemand and Brun 1991; Tron and Brun 1991), but model D2 featured an extra, upper ductile layer. After reaching the desired shortening, models were covered with black sand for protection, drenched with water until saturation and left to rest for at least 2 hours. Sections were then cut orthogonal to the strike of major structures.

(b) Strength envelopes showing strength (in Pa) of different modelling materials. (c) Basal plate set-ups showing the basal plate size (in cm).

3.3 Monitoring and model analysis

Particle image velocimetry (PIV) was used to analyse incremental displacements in the analogue models (see e.g., Leever et al. 2011; van Gelder et al. 2017), using powdered coffee grains on the model surface as markers. For all models, photographs of the top surface of the experiment were taken in a fixed time interval of 30 minutes. Photos were then rectified to correct for lens distortion and processed using the MATLAB® vR2022a application PIVlab v2.57 (Thielicke and Sonntag 2021; Thielicke and Stamhuis 2014; Thielicke 2014). In the image pre-processing settings, we enabled Contrast-Limited Adaptive Histogram Equalization (CLAHE) to locally enhance the contrast. FFT window deformation was used as the PIV algorithm. As post-processing steps we applied a vector validation using a standard deviation filter and interpolated missing data points.

The “strainmap” package (Broerse 2021) for MATLAB® (vR2022a) was used for calculating cumulative strain type maps for models C and D1 based on incremental displacements from the PIV analyses. For a review of the underlying algorithms and practical applications of this software, see Broerse et al. (2021) and Krstekanić et al. (2021; 2022). Resulting colour-coded maps show the cumulative strain type (extension, strike-slip movement or shortening) at four points during the model runs (see figures in Sect. 4).

3.4 Limitations and simplifications

One of the major limitations of the experiments in this study is the necessary simplification of the initial fault configuration. The Jurassic basin-bounding faults are presently not exposed at the surface and thus their geometry and exact position are not known. It is assumed that the major present-day structural elements are aligned to the margins of the Jurassic Achental basin (Sausgruber 1994b; Töchterle 2005; Ortner and Gruber 2011). Therefore, a simple initial fault arrangement with one N-S and two E-W striking elements was chosen as the basis for the analogue models. Splay faults and additional basin-bounding faults are thus not considered here. The models were shortened in one single phase, simulating Cretaceous NW-directed shortening. However, the Achental structure was affected also by N-directed Paleogene and NE-directed Neogene shortening (Eisbacher and Brandner 1995; Ortner and Gruber 2011). These posterior phases of deformation were not taken into consideration for the analogue modelling, because they cannot explain the large offset along the Achental thrust in W–E sections (Ortner and Gruber 2011; Ortner 2003a) and are thus not expected to have created the main structural elements. The model set-up emphasizes the rheological contrast between a weak ductile basal décollement and a stronger upper brittle layer, whereas the characteristic, more complex heterogeneity of the NCA sedimentary cover was not included. Finally, the models ignore natural recovery processes such as erosion and sedimentation, which may influence the time–space evolution of structures. Despite these simplifications, our analogue models were able to tackle the problem and trace the large-scale deformation pattern as a response to compression.

4 Results

Model A is a purely brittle experiment with a maximum thickness of the sand layer of 5 cm. The piston pushed both the sand and the basal plate. In the initial stages of the experiment, an asymmetrical pop-up structure with a master back-thrust (1) and an antithetic fore-thrust (1) formed (Figure 7). The master thrust is accompanied by a blind thrust that did not fully reach the surface. Further shortening was accommodated by transient fore-thrusts (2, 6-8), which developed at the base of the ramp and migrated upward through the wedge, along the master thrust, with increasing shortening. At 50% of total shortening, the frontal part of the wedge experienced gravitational collapse along a normal fault (4).

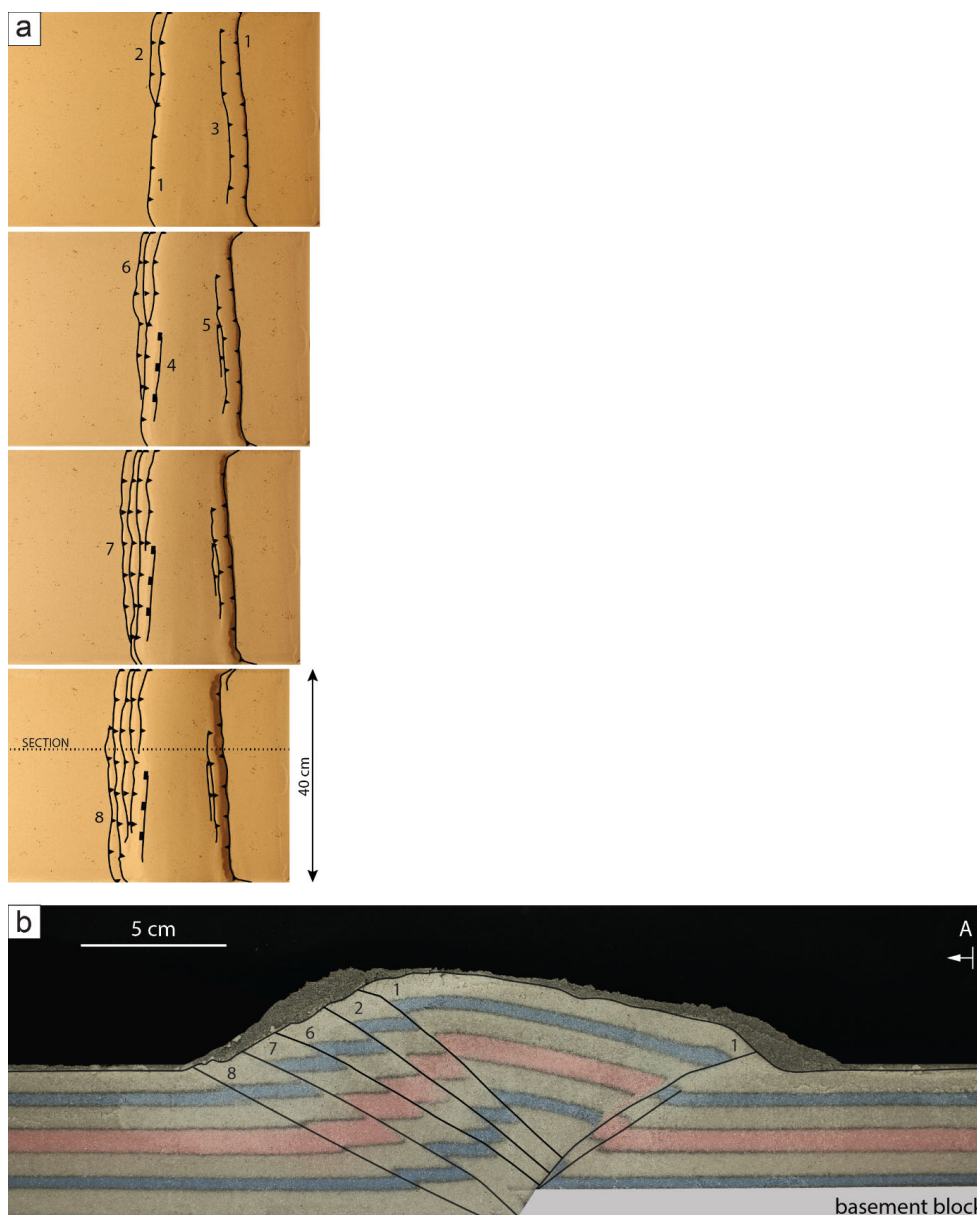

Figure 7: Modelling results of model A, showing (a) top views at 25, 50, 75 and 100 % of total shortening, and (b) side view at 100 % of total shortening. Location of section is marked in (a). Numbers show sequence of initial fault activity.

Model B1-B3 (Figures 8 and 9) were set up similar to model A, but were designed as brittle-ductile models with a basal detachment of silicone putty, to study coupling and decoupling processes at the basal plate and ramp. Model B1 initially developed an asymmetrical pop-up structure with an antithetic fore-thrust (1) and a master back-thrust (2) similar to model A (Figure 8a, 9a). Shortening was initially accommodated equally along the back-thrust and the fore-thrust, but final sections show that the bulk shortening occurred along the master back-thrust. With further shortening, additional fore-thrusts (7, 9) form and previously active thrusts migrate upward along the master back-thrust. All major thrusts originate from the velocity discontinuity at the ramp. Several secondary pop-up structures formed along splay faults (e.g., 3, 4, 6). The final resulting wedge is both wider and lower than in the brittle model A, and the internal wedge structure more complicated. In model B2,

we tested a different layering sequence with an additional, upper ductile layer. Furthermore, the basal ductile layer was draped
365 over the entire model base and connected at the mobile ramp, as opposed to model B1, where the silicone putty was placed
only on the basal plate (Figure 6a). During the first 25% of total shortening, a central wedge developed over the ramp, formed
by two main back-thrusts separated at the upper layer of silicone putty. Deformation shifted to the hinterland at ~50% of total
shortening, where an asymmetrical pop-up structure with a main back-thrust was formed in the lower sand layers, and a
symmetrical pop-up structure was formed in the upper sand layer above the upper ductile horizon. Pockets, filled with air that
370 was trapped underneath the silicone during model construction and migrated during shortening, form modelling artefacts.
Overall, the height of the resulting wedge was far less than in model B1 and structures were mainly hinterland-oriented and
dominantly backwards thrusting (Figure 8b, 9b). Thrusts might have initially originated at the velocity discontinuity, but were
laterally transported onto the mobile basal plate as shortening progressed. The upper and lower sand layer were completely
decoupled at the upper silicone layer. For model B3 we used an identical layering as for model B1, but the basal plate was
375 fixed and the piston was placed on top of the basal plate (Figure 6). In the first half of the experiment (0-50% total shortening),
a flip-type pop-up structure (see Smit et al. 2003, their Figure 4) with two back-thrusts and conjugate fore-thrust (1) developed
directly in front of the piston (Figure 8c, 9c). Movement occurred along the main back-thrust, switched to the fore-thrust and
back to the secondary back-thrust, as visible from lobes of silicone putty along the thrusts. At ~ 75% of total shortening,
thrusting propagated into the foreland to form a strongly asymmetric pop-up structure with a master fore-thrust (5) and a minor
380 back-thrust (6). The master thrust originated directly at the velocity discontinuity above the ramp. Although in the fixed plate
scenario, as opposed to the mobile plate scenario, deformation did not localise directly above the ramp but rather required a
wedge in the hinterland, the wedge geometry is much more asymmetric with most of the shortening occurring along a low-
angle master fore-thrust that is antithetic to the original normal fault geometry.

385 **Figure 8:** Top views of models (a) B1, (b) B2, and (c) B3 at 25, 50, 75 and 100 % of total shortening. Locations of sections are indicated (dotted lines). Numbers show sequence of initial fault activity.

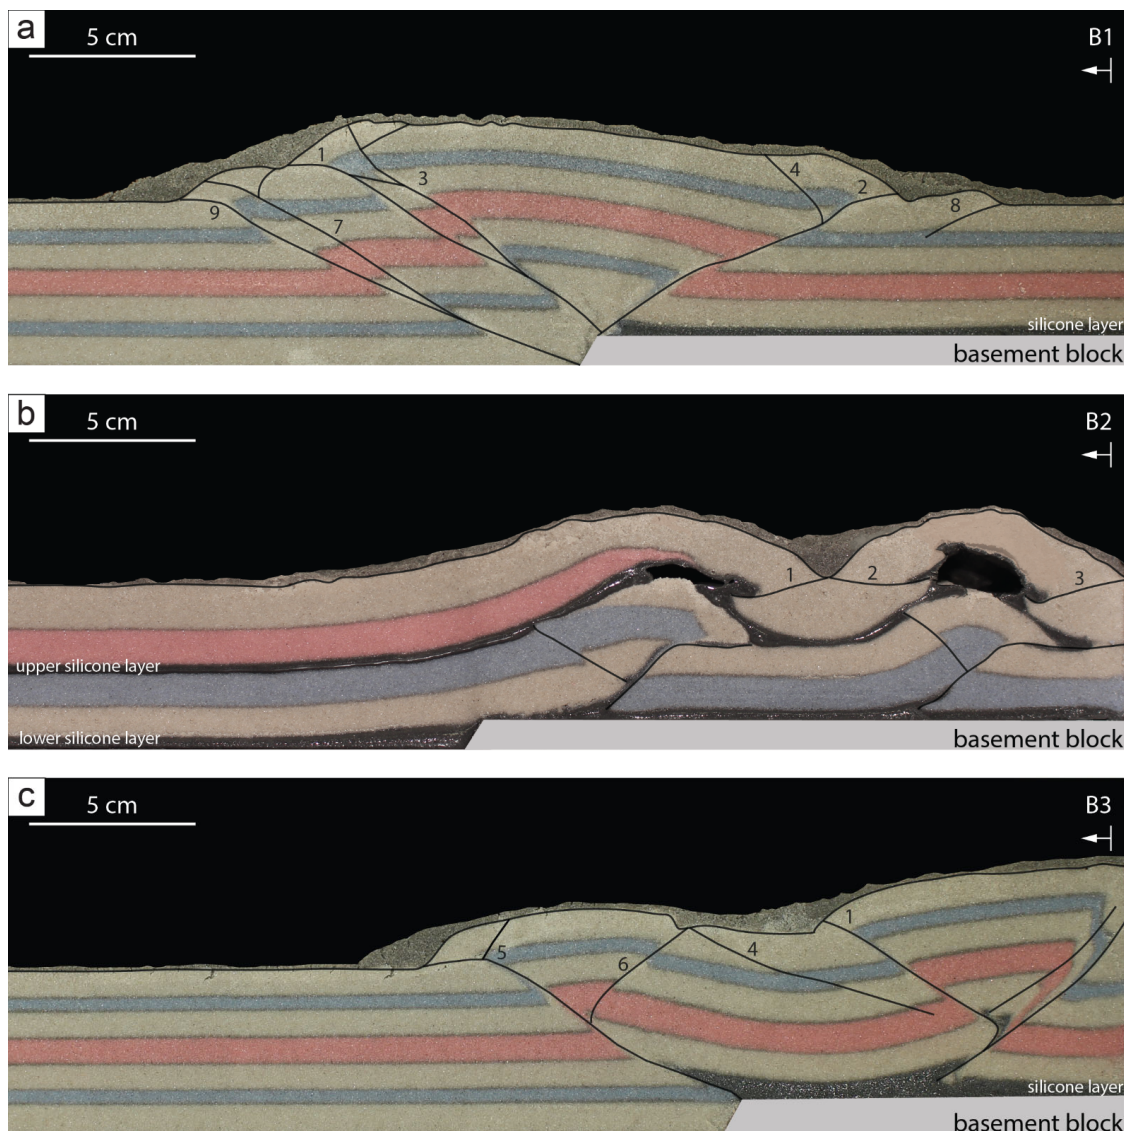

Figure 9: Side views of models (a) B1, (b) B2, and (c) B3 at 100 % of total shortening. Locations of sections are marked in Figure 8. Numbers show sequence of initial fault activity.

390 For model C, we increased the number of basal plates to three, aligning them so that the margins of the plates formed one N-S and two E-W striking elements (Figure 6c). We placed silicone putty on both the basal plates and the table top, disconnecting it at the ramp to form a similar mechanical scenario as in model B3. Because of the larger size of the model, we increased the total shortening to 11 cm. Initially, a slightly asymmetrical pop-up structure formed close to the piston, with a back-thrust that migrated slightly upward along the main fore-thrust (2) (Figure 10a, b). Additional fore-thrusts (1, 3) developed especially in the northern area of the model, where the basal plate was missing. After approximately 55% of total shortening, deformation propagated into the foreland, where a second asymmetrical pop-up structure formed above and parallel to the ramp in the subsurface. The master fore-thrust (5) accommodated most of the shortening, whereas several minor back-thrusts migrated upward along the master thrust. The sand layer forms a ramp anticline over the master thrust, which approaches lower angles toward the surface. Close to reaching the total shortening, deformation propagated in the southern area of the model, where

395

400 the basal plate reaches into the foreland, and third pop-up structure was formed there (9), but was not able to develop further with this amount of shortening. Overall, the wedge was relatively low compared to the brittle model A and the brittle-ductile model B1. The deformation front at total shortening approximately shows the contours of the basal plate in the centre and southern parts of the model (Figure 10a).

Calculation of mean shortening vectors via PIV analysis shows that surface deformation occurs in the tectonically active region west of the deformation front, with a localisation of strain at the foremost thrust (2, 5, 9/10). Vectors rotate outward on both the northern and southern side of the wedge. The dominant type of strain at the active fore-thrusts is shortening (red colours in Figure 10c). Extensional strain on top of the wedge (blue colours in Figure 10c) is mainly caused by gravitational collapse of parts of the wedge. More importantly, along the entire deformation front, strike-slip strain (turquoise colours in Figure 10c) is subordinate to shortening, even in areas of the model where the trace of the deformation front is oblique to the direction of shortening.

410 shortening.

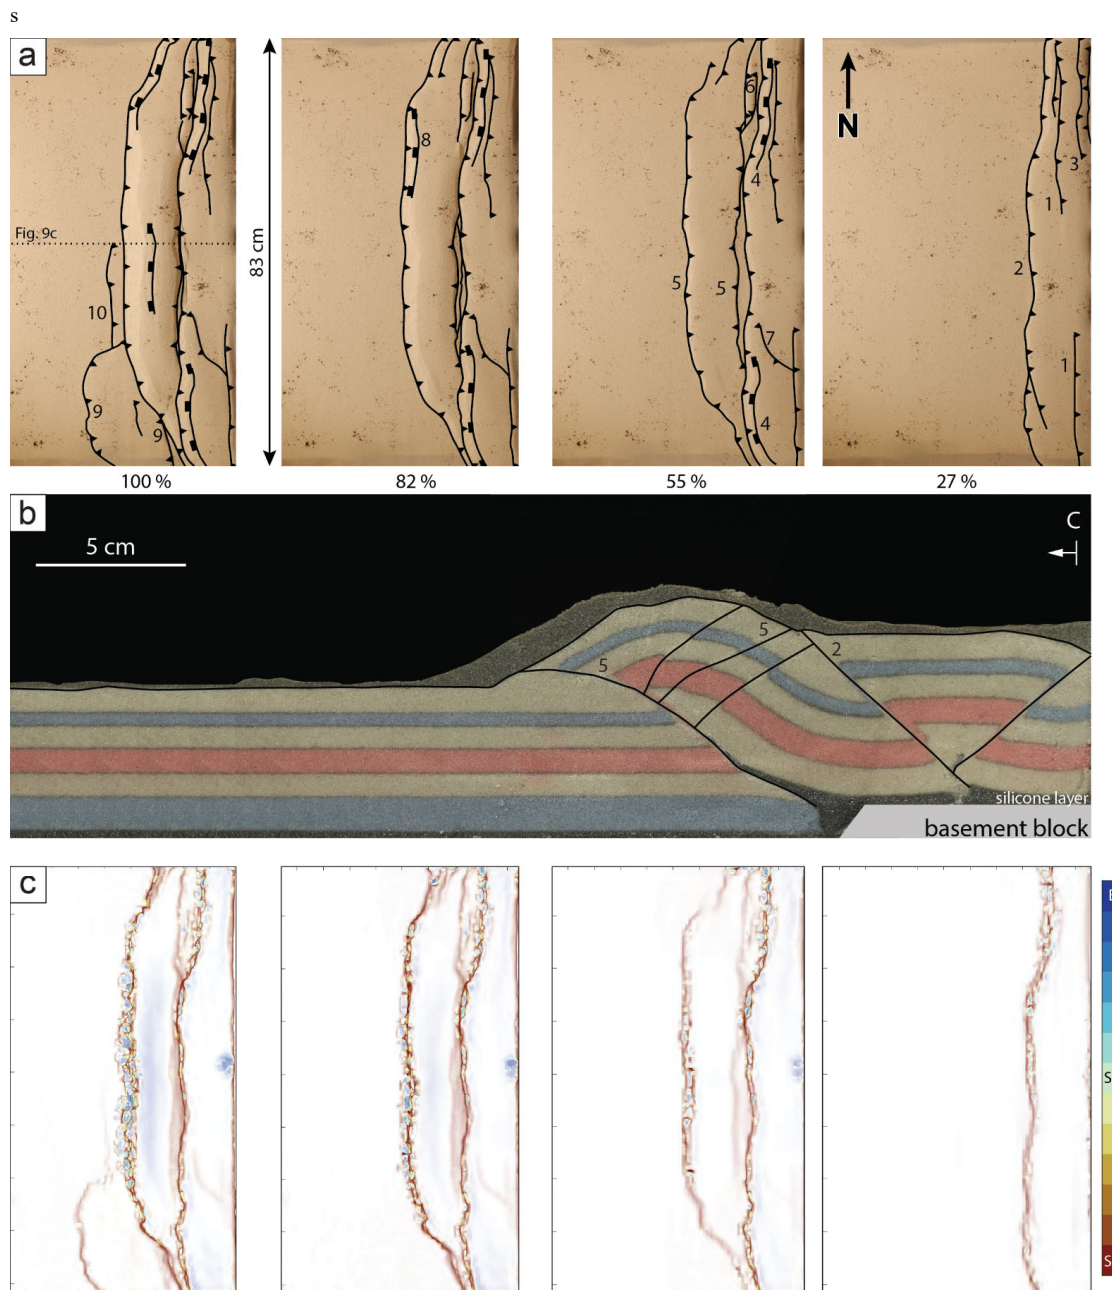

Figure 10: Modelling results of model C, showing (a) top views at 27, 55, 82 and 100 % of total shortening, and (b) side view at 100 % of total shortening. Numbers show sequence of initial fault activity. (c) Strain type analysis of model C, showing areas of extension (E), strike-slip movement (Ss) and shortening (Sh).

For model D1 and D2 the plate set-up was rotated, so that shortening was directed at an angle of 45° to the basal plate and ramp (Figure 6c). Model D1 used a layering sequence identical to model C. In the initial stages of the experiment, up to 55% of total shortening, a pop-up structure developed over the entire length of the piston (Figure 11a). In the south of the model, the initial pop-up structure is asymmetric with a main fore-thrust, whereas in the centre area of the model, where the basal plate set-up creates a 90° angle, the structure is of a flip-type (see Smit et al. 2003, their Figure 4), where shortening was

initially accommodated along a fore-thrust, before switching to a back-thrust. The structures did not form entirely parallel to the piston, but from approximately 27% of total shortening on, the wedge widened along the main fore-thrust (1) in the south, where the basal plate extends into the foreland, whereas in the centre and north of the model, shortening was accommodated
425 by a series of minor fore-thrusts (3-5) that migrated along their associated back-thrust. The thrusts are more closely spaced within the corner between the plates. With further shortening, the wedge propagated, first on the southern basal plate (7) from approximately 82% of total shortening, and in a later stage on top of the northern plate (8). The surface expression of the propagating fore-thrusts runs parallel to the plate structure in the subsurface; whereas sections show that they originate directly at the velocity discontinuity at the ramp (Figure 12a, b). The fore-thrusts form hinterland-dipping ($\sim 30^\circ$) master thrusts in
430 strongly asymmetric pop-up structures, similar to model B3. In contrast, in the corner between basal plates shortening is completely accommodated within the initial pop-up structure with a steepening of the back thrust, caused by the confinement of the piston, and irregularly spaced fore-thrusts that migrate, but do not propagate significantly. In all cases, deformation does not propagate further than the velocity discontinuity and thus stays within the upper décollement level.

PIV analysis of the incremental displacements shows that shortening localises at the foremost thrust in model D1 (1, 7). When
435 analysing the strain type, the results are similar to model C, in the sense that shortening is the dominant type of strain, independent of the orientation of the thrust trace, whereas the dominant strain direction is mostly perpendicular to the thrust trace. As such, the orientation of the basal plates evidently controls the orientation of the thrusts, with a rotating local strain field, depending on the plate in the subsurface.

In model D2, the same basal plate set-up was used as in model D1, but we tested the effect of two ductile layers, similar to
440 model B2 (Figure 6). Similar to model D1, an initial pop-up structure formed at the wedge, featuring a main back-thrust within the lower part of the model, which is decoupled from the upper part at the upper ductile layer. Propagation into the foreland occurred swiftly, beginning around 55% of total shortening, resulting in pop-up structures with a master fore-thrust in the lower sand layer, which localised at the ramp (Figure 11c, 12c). The pop-up structures form a sigmoidal shape that straddles the basal plate structure in the subsurface. However, due to the strong decoupling at the upper ductile layer, the surface
445 structures do not reflect the situation in the lower part of the model and the wedge reached far less height than in experiments with a single ductile layer.

450 **Figure 11:** Top views of models (a) D1, and (c) D2 at 27, 55, 82 and 100 % of total shortening. Numbers show sequence of initial fault activity. PIV strain type analysis of model (b) D1, showing areas of extension (E), strike-slip movement (Ss) and shortening (Sh).

5 Discussion

5.1 Analogue modelling

455 Inversion of basins, either orthogonal or oblique to the former basin margins, has been subject of many analogue modelling studies (e.g., Deng et al. 2020; Yagupsky et al. 2008; Del Ventisette et al. 2006; Bonini et al. 2012; Brun and Nalpas 1996; Zwaan et al. 2022). The high variance of geological structures leads to a myriad of deformation styles characterizing inverted and reactivated fault systems (Bonini et al. 2012; their Figure 3), especially for inversional set-ups involving a viscous décollement (Brun and Nalpas 1996). The modelling strategy (see Sect. 3.1) followed in this study aimed to test three factors that may affect the structural grain of obliquely inverted extensional basins. These factors included the influence of 1) a weak basal décollement, 2) pre-existing structures attributed to an extensional basin, and 3) thick-skinned or thin-skinned tectonics.

460

The increasing complexity of the models is a result of consecutively implementing parameters that were found to be of relevance to the natural example, the Achenal structure. Apart from its sigmoidal hanging wall shape, one of the complexities of the Achenal structure is that its dominant fore-thrust is antithetic to the existing Jurassic normal fault in the subsurface (Figure 5). Most of the deformational styles associated with basin inversion are synthetic to existing normal faults (e.g., Héja et al. 2022: their Figure 4 and 11; Bonini et al. 2012: their Figure 3), although the formation of an antithetic low-angle thrust has been predicted (Laubscher 1986; Tavarnelli 1996) and successfully simulated (Caër 2016).

5.1.1 Influence of mechanical stratigraphy

In our study, the influence of a weak basal décollement has been tested using two models (A1 and B1). These have an identical mechanical set-up, using a rigid ramp, which represents a pre-existing normal-fault controlled mechanical heterogeneity in the model and is pushed into a brittle (A1) or brittle-ductile (B1) cover. The brittle model shows strong similarities to existing analogue experiments (e.g., Bonini et al. 2000; Persson and Sokoutis 2002) and the brittle-ductile model (B1), but the latter shows a markedly lower angle of thrusting, wider thrust spacing and faster propagation. Decoupled thrust wedges are known to show these effects in analogue models, attributed to a lower basal friction compared to frictional Coulomb wedges (Smit 2005; Smit et al. 2003; Mulugeta 1988; Cotton and Koyi 2000). Comparing models A1 and B1, which were shortened orthogonally, our brittle-ductile model B1 is able to better represent the low-angle character of the natural example.

Models of oblique basin inversion show that the use of a ductile layer results in decoupling of the sedimentary cover and a strong localisation of deformation at existing extensional structures (e.g., Del Ventisette et al. 2006; Brun and Nalpas 1996). Similarly, the use of an upper (second) ductile layer (models B2, D2) leads to a decoupling between the upper and lower sediment cover (e.g., Fan et al. 2020; Del Ventisette et al. 2006). As a result, structures within the lower brittle layer are terminated at the upper ductile layer, and do not reach the surface. Consequently, low-angle hinterland-dipping thrusts emerging from the velocity discontinuity are not visible in top view (see e.g., model D2, Figure 11b). Decoupling thus prevents the formation of large-scale structures across the entire sedimentary cover.

5.1.2 Favourable kinematic conditions for basin inversion

The movement of the basal plate (i.e., fixed or mobile) greatly influences the structure and location of the resulting wedge in brittle-ductile models (compare e.g., model B1 and B3). By using a mobile plate (model B1), this rigid block acts as a buttress, localizing deformation at the ramp already in the initial stages of the experiment, but also restraining further movement of thrust sheets (Bailey et al. 2002; Héja et al. 2022; Gomes et al. 2010). As a result, further shortening was accommodated along a main back-thrust with multiple fore-thrusts, reflecting the relative movement of the sand layer opposite to the piston. The use of a fixed plate (model B3) represents a thin-skinned deformation style, where the sediment cover and basement are decoupled at a basal décollement. Deformation first localises at the backstop (see also Deng et al. 2020; Yagupsky et al. 2008; Caër 2016), but then propagates to the ramp. The mechanical contrast between the rigid ramp, quartz sand and silicone putty forms a velocity discontinuity (Allemand and Brun 1991; Tron and Brun 1991), which is crucial for localisation during deformation. The step at the ramp, where silicone putty and quartz sand meet, works as a “fault generator” or a “nucleation site for thrust faulting” (Yagupsky et al. 2008, p. 852), not dissimilar to the “thrust mill” of Laubscher (1986), which is also demonstrated in models that use silicone putty or glass microbeads as a weak layer (Caër 2016; Yagupsky et al. 2008). At the same time, structures localizing at the ramp accommodate a large amount of shortening, preventing deformation from propagating further (Caër 2016; Laubscher 1986; Tavarnelli 1996). Therefore, using a thin-skinned deformation style leads to the formation of a low-angle fore-thrust that nucleates at the velocity discontinuity and accommodates a great amount of shortening.

As a prerequisite for fault propagation, the initial wedge at the backstop needs to reach a certain height, analogue to the critical taper theory of Davis et al. (1983). This theory is a popular approach to thrust system mechanics of (foreland) fold-and-thrust belts (Graveleau et al. 2012, and references therein). In all experiments, a wedge of 5.7–7.6 cm high was formed in front of the piston and at least 6 cm of shortening was needed for the thrusts to propagate into the foreland. An alternative approach was provided by Caër (2016), who used a sand prism at the back-stop as pre-existing hinterland topography for brittle-ductile models of basin inversion, resulting in an early propagation of deformation within 0.6 cm of shortening. The early evolution of our analogue models highlights the role of a fold-and-thrust belt in the hinterland for propagation of deformation.

5.1.3 Influence of structural inheritance

Although in all brittle-ductile models with a fixed plate an initial wedge formed parallel to the piston, propagation of deformation led to a series of structures that were oriented parallel to the basal plate boundaries in the subsurface. Models of oblique shortening of pre-existing grabens or steps show similar results, where newly formed reverse and thrust faults more or less outline the structure in the subsurface (e.g., Deng et al. 2020; Yagupsky et al. 2008; Caër 2016). Thrusts in models of Caër (2016) appear to consistently dip towards the backstop. However, PIV analyses of our models show that the dominant strain direction is approximately perpendicular to the thrust trace. The localisation of structures at steps and the geometry of the resulting low-angle fore-thrust with a hanging wall anticline (e.g., model D1, Figure 12a, b) is similar to the models of Caër (2016; their Figure 4.11 b–e) and it is evident that in models with oblique shortening (model D1, D2) thrust faults outline the basal plate structure.

The obliquity angle between the basin axis and subsequent shortening has proven to greatly influence structures formed by basin inversion (Brun and Nalpas 1996; Yagupsky et al. 2008; Del Ventisette et al. 2006; Deng et al. 2020). In purely brittle experiments, low obliquity angles are associated with an increasing angle of the reverse faults (Brun and Nalpas 1996) and dominant fore-thrusts, whereas a higher obliquity angle preferably creates symmetrical pop-up structures (Deng et al. 2020). Our brittle-ductile models were able to create a dominant fore-thrust that localizes at the ramp regardless of the obliquity angle (90° for models B–C, 45° for models D). Fault localisation at subsurface steps was most distinctive in models with a lower obliquity angle (45°, models D). Furthermore, our large-scale models (C and D) agree with those of Yagupsky et al. (2008), where the graben segment closest to the deformation front is reactivated first.

The analogue models prove that low-angle hinterland-dipping thrusts can originate from a pre-existing high-angle normal fault with an opposite dip (see also Figure 5), as predicted (Tavarnelli 1996; Laubscher 1986). A pre-existing network of extensional faults in the subsurface is able to control the geometry of structures related to its inversion. Furthermore, the models exemplify that through localisation of the thrusts at the ramps in the subsurface, the sigmoidal geometry of the Achenal thrust hanging wall can be created within a single deformation phase and with a single direction of oblique shortening.

5.2 Comparison with the natural example

In analogue models we aim to create a scaled and simplified version of the natural example, the Achenal structure. In the models we show that it is possible to form a sigmoidal structure, characterized by a low-angle main fore-thrust, hanging wall anticlines and a localisation at a pre-existing step, within a single phase of shortening. Model parameters that were found to be applicable to the Achenal structure are 1) the presence of a weak basal décollement, 2) thin-skinned deformation, and 3) a clear velocity discontinuity at the frontal ramp acting as a “fault generator”. However, laboratory experiments cannot fully encompass the complexities of natural geological structures. In this section, we compare features of the analogue models and the Achenal structure.

5.2.1 Mechanical stratigraphy

540 Rheological properties of the sedimentary succession are important parameters for both analogue models and natural processes. A brittle-ductile succession is able to re-create large-scale structures in analogue models. However, small-scale faulting and folding within the sedimentary cover of the NCA is “lost in translation”. Comparison between brittle and brittle-ductile models shows that a very weak décollement is imperative for the low-angle Achenal thrust to form at a pre-existing basement step. Whether or not this décollement is present in the hanging wall, does not influence localisation of deformation in the models, 545 although it might impact propagation with further shortening (Caër 2016). An offset of the décollement, as opposed to a monocline across the ramp, increases the effect of the velocity discontinuity, but is not strictly necessary for localisation to occur. The Haselgebirge-Reichenhall succession at the base of the Karwendel thrust sheet consisting mostly of rock salt forms the main décollement of the NCA (Eisbacher and Brandner 1995), providing the required weak basal layer. The Kössen Fm may also be represented by a ductile layer, decoupling the lower and upper carbonate platform. However, analogue models 550 show that structures in the lower section do not connect to the upper section. Although in the Achenal structure, small-scale folding dies out near the Hauptdolomit-Plattenkalk transition, the overall geometry of the Unnutz anticline is preserved through the entire outcropping sedimentary succession. Therefore, we dismiss the hypothesis that the Kössen Fm behaves as a ductile material.

Because carbonate units of the Achenal structure are represented by quartz sand in analogue models, simulating brittle 555 behaviour, the models are not able to simulate folding of the Guffert-Unnutz-Montscheinspitze anticline. Ortner (2003a) proposes a progressive rollover-fault-propagation model (Storti and Salvini 1996) for the Unnutz anticline. This type of folding leads to strongly overturned or recumbent anticlines in fold-and-thrust belts (Storti and Salvini 1996) and involves a fault-propagation fold with strong, layer-parallel shear (flexural slip). Although for fault-propagation folds “important field evidence (...) is the observation that some faults, particularly thrust faults, die out in the cores of folds.” (Suppe 1985, p. 350), this is 560 not necessarily the case for progressive rollover-fault-propagation folds, because the overturned limb of the hanging wall anticline has been completely detached from the footwall (Storti and Salvini 1996: Fig. 2). Flexural slip accommodating deformation within the Guffert-Unnutz-Montscheinspitze anticline is seen from layer-parallel and very low-angle fault planes within Hauptdolomit, and support the progressive rollover-fault-propagation model. Fault-propagation folding as a mechanism is seen in the La Roche d’Or anticline, Swiss Alps (Caër 2016). This anticline formed along a thrust fault that, in depth, 565 localises at a basement step attributed to extensional faulting, thus showing strong similarities to the Achenal structure. Similar to the Reichenhall-Haselgebirge succession in the NCA, evaporitic sediments form a décollement between the basement and the sediment cover. Martin and Mercier (1996) provide a natural example of the western Jura, showing the development of a low-angle ramp above pre-existing structures of the Bresse graben.

5.2.2 Kinematic parameters and structural inheritance

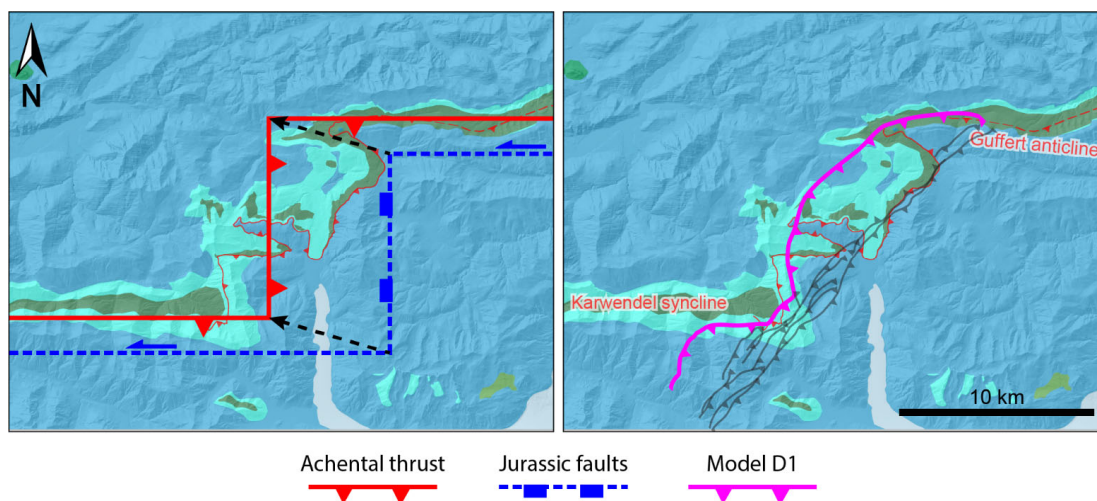

570 In analogue models, the use of a fixed basal plate translates to a thin-skinned tectonic style, in which the sedimentary cover is decoupled from the basement by a décollement (Rodgers 1949). Such thin-skinned structural style is well known from the NCA (e.g., Eisbacher et al. 1990; Auer and Eisbacher 2003). However, for a correct localisation and propagation of deformation, the presence of a step in the subsurface and topography in the hinterland is important as well. Keeping in mind model scaling, Early Cretaceous topography must have existed at no more than ~ 14 km SE of the Jurassic normal fault. The 575 advancing front of the NCA fold-and-thrust belt and the uplift resulting from movement along the NW-verging Eben thrust (Eisbacher and Brandner 1996) may have provided this topography. Within the subsurface, the Jurassic basin architecture is thought to have provided steps where deformation could localise. Thickness and facies differentiations of Jurassic sediments (Figure 1b) (Schütz 1979; Nagel et al. 1976) underline the presence of such a basin. Following the geometry of the Achenal structure, at least one west-dipping normal fault must have been oriented approximately N-S. Strike-slip faults trending E-W

580 (Eisbacher and Brandner 1995, 1996) may form additional steps (Figure 13). Such a basin geometry is similar to Jurassic fault systems in more western parts of the Alpine orogen (Eberli 1987, 1985; Weissert and Bernoulli 1985).

The models were subjected to a single phase of oblique shortening, simulating NW-directed Cretaceous convergence related to Alpine orogeny. Field data from the Achensee area (Sausgruber 1994b; Beer 2003) support the influence of NW-directed shortening. On the other hand, Ortner and Gruber (2011) argue that the offset in the central Achental thrust is larger than in its
 585 northern and southern thrust segments, and that the direction of shortening must have been $< 270^\circ$. Because the orientation of the folds (e.g., the Thiersee syncline; Töchterle 2005) and faults within the Achental structure is oblique to Cretaceous shortening (e.g., Eisbacher and Brandner 1996), many studies have offered alternative hypotheses involving multiple deformation phases and directions (e.g., Spengler 1953; Auer 2001; Ampferer 1921; Fuchs 1944; Channell et al. 1992; Channell et al. 1990; Ortner 2003a). The formation of the Guffert-Unnutz-Montscheinspitze anticline and the Achental thrust
 590 is ascribed to pre-Gosau, deformation (Ortner and Gruber 2011; Töchterle 2005), which does not prove that the entire sigmoidal hanging wall formed during a NW direction of shortening. However, in our models we re-create the geometry of the Achental structure by applying shortening at 45° to the N-S trending Jurassic fault, demonstrating that a single uniform phase of oblique shortening is sufficient to create a sigmoidal shape of the hanging wall that outlines the subsurface basin geometry of the Achental structure. Our results thus agree with the hypothesis that the characteristic shape of the Achental structure formed
 595 due to forced folding at the borders of a Jurassic basin (Eisbacher and Brandner 1995, 1996; Ortner and Gruber 2011).

One limitation of the analogue models compared to the natural example is that we did not consider Paleogene reactivation of Cretaceous structures. Paleogene folding however, is common throughout the Achental structure and Achensee area. E.g., the Hofjoch, Blaubergalm and Seekar folds (Figure 3) (Eisbacher and Brandner 1995; Brandner and Gruber 2011; Sausgruber 1994b) show an orientation corresponding to post-Cretaceous shortening. The Seekar folds are offset by the N-S striking
 600 Seekar fault, which shows dextral strike-slip movement and a P-axis that corresponds to NNE- to NE-directed Paleogene shortening. Paleogene reactivation of fault planes also occurs at the west side of the Achensee (Sausgruber 1994b). Although this post-Cretaceous reactivation may have imprinted on existing structures, we propose that the rough outlines of the Achental structure were established after Cretaceous orogeny (Figure 13).

605 **Figure 13:** Summary figure showing possible arrangement of Jurassic basin-bounding faults in relation to the Achental thrust (left) and overlay of inversion structures formed in analogue model D1, outlining the subsurface architecture (right). Modified after Ortner and Gruber (2011) and Ortner and Kilian (2016). For legend of background figure, see Figure 1.

6 Conclusions

Analogue models were used to infer favourable kinematic and mechanic conditions for the oblique inversion of a pre-existing extensional basin margin. Yet relevant for understanding deformation geometries arising from oblique basin inversion in general, the modelling results have been discussed in the frame of the Achental structure in the European Alps, which evolved from the inversion of the Jurassic Achental basin during Alpine orogeny. Based on the modelling results we conclude:

- 1) A thin-skinned style of deformation that characterises Cretaceous orogeny in the NCA and leads to the formation of a fold-and-thrust belt in the hinterland, provides the structural framework for propagation of deformation to the basin margins,
- 2) The Jurassic basin geometry consists of at least (1) an approximately N-S trending, W-dipping normal fault, and (2) two E-W trending additional strike-slip faults. When applying shortening at 45° to the Jurassic structures, newly formed thrusts then form along these steps.
- 3) The sedimentary cover is represented by a brittle succession that is separated from the basement by a ductile décollement, the (Haselgebirge-Reichenhall succession). This basal décollement is crucial for the decoupling of the sedimentary cover and is together with the mechanical contrast across the basin bounding normal fault controlling the localisation of a low-angle thrust dipping opposite to the inherited normal fault, the Achental thrust.

When these parameters are applied, a low-angle thrust, antithetic to the Jurassic normal fault, is formed due to thrust localisation at the eastern margin of the Achental basin. The hanging wall of this thrust, the Achentaler Schubmasse, outlines the Jurassic basin architecture in the subsurface, proving that pre-existing extensional faults are a controlling factor for structures that form during subsequent shortening. Thus, a single phase of oblique shortening at 45° to the Jurassic basin axis is sufficient to form a sigmoidal geometry of the hanging wall.

Author contributions

The conceptualization of the study was done by HO and EW; Field investigations were performed by WvK, HO, AG and TS; Analogue modelling was planned and performed by WvK, EW and DS; Data preparation, analysis and visualisation were performed by WvK; WvK prepared the original draft of the manuscript with input from all co-authors; All co-authors reviewed and edited the manuscript and approved the final version.

Competing interests

At least one of the (co-)authors is a guest member of the editorial board of Solid Earth and has collaborated as a (co-)author on publications involving one of the guest editors of Solid Earth. The peer-review process was guided by an independent editor, and the authors have also no other competing interests to declare.

Acknowledgements

This work was completed as part of a Master Thesis at the University of Innsbruck. The University of Innsbruck through a needs-based scholarship provided financial support covering fieldwork and travel expenses. Laboratory experiments were conducted at the TecLab of Utrecht University. We sincerely thank Antoine Auzemery for assistance with the conceptualization and realization of analogue experiments, as well as fruitful discussions. We also thank Lukas Schifferle for assistance during fieldwork and digitalization. The authors thank Midland Valley for providing their Move Software in the frame of their academic software initiative.
