Abstract. The productivity of the world's natural resources is critically dependent on a variety of highly uncertain factors, which obscure individual investors and governments that seek to make long-term, sometimes irreversible investments in their exploration and utilization. These dynamic considerations are poorly represented in disaggregated resource models, as incorporating uncertainty into large-dimensional problems presents a challenging computational task. In this paper, we apply the SCEQ algorithm (Cai and Judd, 2023) to solve a large-scale dynamic stochastic global land resource use problem with stochastic crop yields due to adverse climate impacts and limits on further technological progress. For the same model parameters, the range of land conversion is considerably smaller for the dynamic stochastic model as compared to deterministic scenario analysis. This highlights the importance of incorporating uncertainty in the model's optimization stage to determine optimal paths of natural resource uses.

1 Introduction

Understanding the future allocation of the world's natural resources is an important research problem for environmental scientists and economists. This involves a thorough understanding of a complex interplay of different factors, including, among others, continuing population increases, shifting diets among the poorest populations in the world, increasing production of renewable energy, including biofuels, and growing demand for ecosystem services, including forest carbon sequestration (Foley et al., 2011). The problem is further confounded by faster than expected climate change, which is altering the biophysical environment of agriculture and forestry. Moreover, highly uncertain future productivities and valuations of ecosystem services, coupled with medium- to long-term irreversibilities in the extraction of nonrenewable or partially renewable resources, such as long-growth natural forests, give rise to a challenging problem of decision-making under uncertainty.

While there is a large body of research analyzing the problem of natural resource extraction and utilization under uncertainty theoretically or using stylized computational models (see, e.g., Miranda and Fackler (2004), Tsur and Zemel (2014) and references therein), quantifying the effects of uncertainty on natural resource use in a more realistic setting remains a challenging

problem. This is because natural resource allocation problems, like environmental policy problems in general, involve highly nonlinear structure and damage functions, important irreversibilities, and long time horizons (Pindyck, 2007). Computational integrated models of economy and environment are the standard workhorse mechanisms for modeling the long-term alloca-
25 tion of the world's natural resources, including particularly difficult land use problems (see, e.g., Füssel (2009), Schmitz et al. (2014), Nikas et al. (2019), and references therein). These models have the important advantage of detailed spatial and sectoral (particularly, energy and agricultural sector) coverage, which allows them to capture a broad range of responses to changes in demand and supply factors affecting the utilization of natural resources. However, given the high computational complexity of these models, they are typically either static or based on myopic expectations, whereby decisions about production, consump-
30 tion, and resource extraction and conversion are made only on the basis of information in the period of the decision (Babiker et al., 2009). These models, therefore, have limited ability to address important intertemporal questions such as, for example, a dynamic trade-off between conservation, carbon sequestration, and renewable offsets for fossil fuels. Among the few forward-looking, dynamic economy and environment models, none explicitly incorporates uncertainty into the determination of the optimal path of natural resource use.[1] This is because introducing uncertainty into these models is confined by an array of
35 computational obstacles that are very difficult (e.g., high dimensionality and kinks caused by occasionally binding constraints), if not impossible, to address using standard numerical methods such as projection methods and value function iteration (see, e.g., Judd 1998; Miranda and Fackler 2004; Cai and Judd 2014; Cai 2019). To the extent that uncertainty in these models is considered, this is only through parametric or probabilistic sensitivity analysis or the use of alternative scenarios. Therefore the high-dimensional resource use models have not effectively dealt with optimal extraction and conversion decisions along the
40 uncertain path of key drivers affecting resource allocation in the face of costly reversal of conversion decisions.

In this study, we seek to address this important limitation of the economy-environment modeling of natural resource use. In doing so, we build on recent advances in computational economics and operations research. Cai et al. (2017) introduced a nonlinear certainty equivalent approximation method (NLCEQ) for solving large-scale infinite horizon stationary dynamic stochastic problems and demonstrated how this method could be used to achieve an accurate solution to a stylized stationary
45 dynamic stochastic land use problem. The original NLCEQ method, however, is ill-suited for solving most environmental and resource economics problems. This is because stochastic problems of utilization of natural resources feature nonstationary stochastic trends, such as climate or technological trajectories, and some never converge to a stationary state. Building on the original NLCEQ work Cai and Judd (2023) introduced a simulated certainty equivalent approximation method (SCEQ), which efficiently solves nonstationary dynamic stochastic problems, including those with high dimensionality and occasionally
50 binding constraints. Cai and Judd (2023) showed that the SCEQ method is highly accurate and achieves stable numerical solutions for dynamic stochastic problems in economics.

We apply the SCEQ method to solve a large-scale dynamic stochastic model, focusing on the optimal global land use allocation problem. This highly complicated resource use problem features multiple cross-sectoral and dynamic trade-offs. Specifically, we apply the method to a global land use model nicknamed FABLE (Forest, Agriculture, and Biofuels in a Land

---

[1]Several recent studies, e.g., Cai and Lontzek (2019) have successfully integrated uncertainty about economic and climate outcomes in a stochastic integrated assessment climate-economy framework. For a review of this related literature, see Cai (2019, 2021).

use model with Environmental services) in the face of uncertainty. FABLE is a dynamic, forward-looking global multi-sectoral partial equilibrium model designed to analyze the evolution of global land use over the coming century. Prior applications of that model (Steinbuks and Hertel, 2013; Hertel et al., 2013, 2016; Steinbuks and Hertel, 2016) analyze the competition for scarce global land resources in light of the growing demand for food, energy, forestry, and environmental services and evaluate key drivers and policies affecting global land use allocation. All these applications, however, assume perfect foresight and treat uncertainty in a parametric fashion, thus ignoring the impact of future uncertainties on the optimal allocation of global land use.

By way of illustration, we focus on uncertainty emanating from crop productivity over the next century. Along with energy prices, regulatory policies, and technological change in food, timber, and biofuels industries, this is one of four core uncertainties affecting competition for global land use (Steinbuks and Hertel, 2013). To quantify the uncertainty in agricultural yields, we construct a stochastic crop productivity index that captures two key uncertainty sources: technological progress and global climate change (Lobell et al., 2009; Licker et al., 2010; Foley et al., 2011).[2] Following Rosenzweig et al. (2014), we use projections from climate and crop simulation models under Representative Concentration Pathways $6.0\mathrm{W/m}^2$ (RCP6) GHG forcing scenario (Moss et al., 2008), as well as the survey of recent agro-economic and biophysical studies to calibrate the index.

We simulate the results of the model where the global planner optimally allocates land uses under the perfect foresight of different realizations of the crop productivity index, focusing our attention on the current century. We then compare and contrast them with the results of the dynamic stochastic model, where the global planner has rational expectations about uncertain crop yields brought to the model's optimization stage. When the uncertainty in crop productivity is incorporated into the model, we see an additional redistribution of land resources to offset the impact of potentially lower yields. Due to intertemporal substitution, some of that redistribution occurs even in the absence of actual changes in the states of climate or technology affecting crop yields. Moreover, the range of these alternative optimal paths of cropland is considerably smaller than the magnitude of possible land conversion resulting from the scenario analysis based on the deterministic model. This result indicates that the scenario analysis may significantly overstate the expected agricultural land conversion magnitude under uncertain crop yields.

Our study contributes to the growing literature that analyzes the intertemporal allocation of land and other natural resources under uncertainty and irreversibility constraints. Most of the literature focuses on a particular type of resource or sector where intertemporal issues are significant and cannot be ignored. One example of this literature is forestry management in the context of uncertain fire risks and climate mitigation policies (Sohngen and Mendelsohn, 2003, 2007; Daigneault et al., 2010). Another example is natural land conservation decisions under irreversible biodiversity losses (Conrad, 1997, 2000; Bulte et al., 2002; Leroux et al., 2009). While these models are undoubtedly helpful for understanding the broad implications of uncertainty on the intertemporal allocation of land resources, they are less effective in quantifying the effect of uncertainty in the supply and

---

[2]Climate change will likely affect the productivity of other land resources, such as forestland. Several recent modeling studies (see, e.g., Tian et al. (2016) and references therein) have suggested that climate change is likely to result in higher forest growth and greater timber yields, as well as in more forest dieback, with the net effects varying over time and space. Incorporating these effects is beyond the scope of this study and is left for future research.

demand drivers in more complex settings, such as, e.g., optimal allocation of multiple competing land resources in the long run.

Our study is perhaps most closely related to the recent works of Lanz et al. (2017) and Zhao et al. (2021). Lanz et al. (2017) developed a two-sector stochastic Schumpeterian growth model with the endogenous allocation of global land use. As our paper does, they find that optimal allocation of global land use requires more cropland conversion when the uncertainty in agricultural productivity is present. Lanz et al. (2017), however, focused on endogenous population dynamics, labor allocation, and technological progress, whereas our paper is concerned with the endogenous allocation of multiple types of land use and corresponding land-based goods and services. Our paper also advances methodological grounds by applying a more advanced algorithm that overcomes computational difficulties in solving multidimensional stochastic land use models, which made Lanz et al. (2017) significantly simplify their model by assuming that their binary shocks occur only in three time periods. Zhao et al. (2021) compare models with adaptative expectations and perfect foresight assumptions for both price and yield for agricultural producers to make land allocation and production decisions. Zhao et al. (2021) find similar results that land use change variation becomes much smaller than in the perfect foresight model, which allows for faster land use adjustments while market price variations increase. Unlike our paper, Zhao et al. (2021) do not explicitly incorporate uncertainty in the model's optimization stage.

2   Stochastic FABLE model

This section presents a modeling framework for analyzing nonlinear dynamic stochastic models of natural resource use with multiple sectors, in which preferences, production technology, resource endowments, and other exogenous state variables evolve stochastically over time according to a Markov process with time-varying transition probabilities. The constructed model belongs to the class of stochastic growth models with multiple sectors studied in Brock and Majumdar (1978), Majumdar and Radner (1983), and Stokey et al. (1989) among others.

Specifically, we develop a stochastic version of a global land use model nicknamed FABLE (Forest, Agriculture, and Biofuels in a Land use model with Environmental services), a dynamic multi-sectoral model for the world's land resources over the next century (Steinbuks and Hertel, 2012, 2016). This model combines recent strands of agronomic, economic, and biophysical literature into a single, intertemporally consistent analytical framework at the global scale. FABLE is a discrete dynamic partial equilibrium model where the population, labor, physical and human capital, and other variable inputs are assumed to be exogenous. Total factor productivity and technological progress in non-land-intensive sectors are also predetermined. The model focuses on the optimal allocation of scarce land across competing uses across time and solves the dynamic paths of alternative land uses, which together maximize global economic welfare.

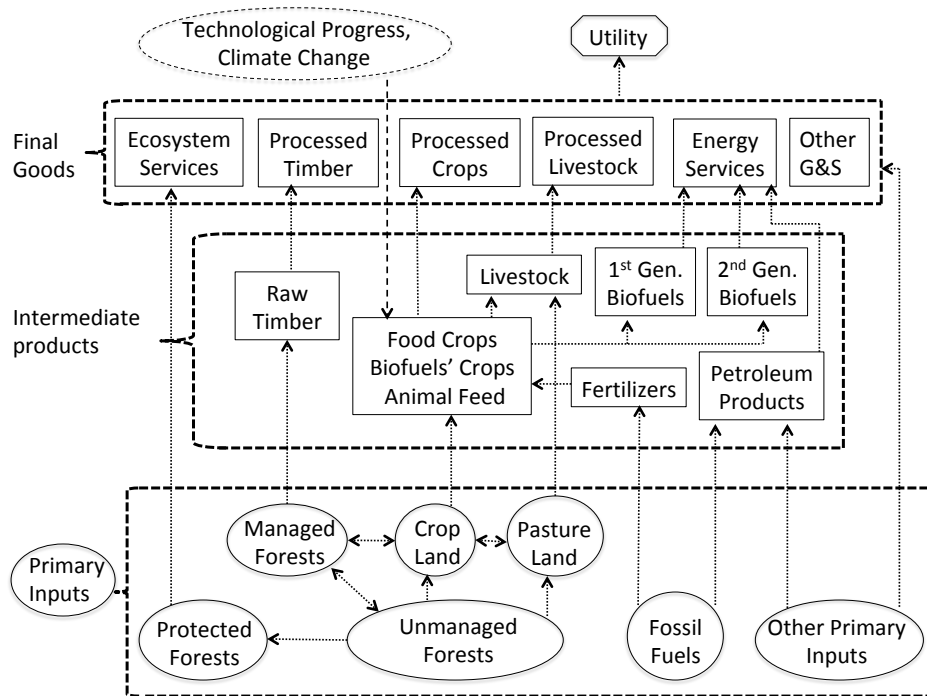
The FABLE model accommodates a complex dynamic interplay between different types of global land use, whereby the societal objective function places value on processed crops and livestock, energy services, timber products, ecosystem services, and other non-land goods and services (Figure 1). There are three accessible primary resources in this partial equilibrium model of the global economy: land, liquid fossil fuels, and other primary inputs, e.g., labor and capital (see the bottom part of Figure 1).


Figure 1. Structure of the FABLE Model

Note. State variables are shown as oval shapes. Decision variables are shown as rectangular shapes. The utility function is shown as an octagonal shape. Transition laws are shown as dotted arrows. Stochastic model terms incorporating random processes are shown as dashed shapes or arrows.

The supply of land is fixed and faces competing uses that are determined endogenously by the model. They include unmanaged forest lands - which are in an undisturbed state (e.g., parts of the Amazon tropical rainforest ecosystem), agricultural (or crop) land, pasture land, and commercially managed forest land. As trees of different ages have different timber yields and different propensities to sequester carbon, the model keeps track of various tree vintages in managed forests, which introduces additional numerical complexity for solving the model. We don't keep track of vintages for natural lands and assume they are primarily old-grown forests. We ignore other land use types, such as savannah, grasslands, and shrublands, which are largely unmanaged and often of limited productivity.[3] We also ignore residential, retail, and industrial uses of land in this partial equilibrium model of agriculture and forestry.

The flow of liquid fossil fuels evolves endogenously along an optimal extraction path, allowing for exogenously specified new discoveries of fossil fuel reserves. Other primary inputs include variable inputs, such as labor, capital (both physical and

---

[3]This makes them difficult to incorporate into an economic model of land use. Consequently, they have historically been neglected in economic models of global land use change. More recently, these natural lands have been incorporated via location-specific supply curves depicting the potential for bringing these lands into commercial production (e.g., in the REF MAGNET model: https://www.magnet-model.eu/model). However, the ecosystem services provided by these lands are not explicitly valued as they are in the FABLE model, where they are explicitly included in the utility function.

human), and intermediate materials. The endowment of other primary inputs is exogenous and evolves along a pre-specified global economic growth path.

There are six intermediate inputs used in the production of land-based goods and services in FABLE: petroleum products, fertilizers, crops, liquid biofuels,[4] live animals and raw timber (see the middle part of Figure 1). Fossil fuels are refined and converted to either petroleum products, that are further combusted, or to fertilizers, that are used to boost yields in the agricultural sector. Cropland and fertilizers are combined to grow crops, that can be further converted into processed food and biofuels, or used as animal feed. Specifically, we assume that agricultural land $L_t^{A,c}$ and fertilizers $x_t^{n,c}$ are imperfect substitutes in the production of food crops, x_t^c, with specific production technology given by the following constant elasticity of substitution (CES) function:

$$x_t^c = \theta_t^c \left(\alpha^n \left(L_t^{A,c} \right)^{\rho_n} + (1 - \alpha^n) (x_t^{n,c})^{\rho_n} \right)^{\frac{1}{\rho_n}}, \tag{1}$$

where θ_t^c is stochastic crop technology index, and α^n and ρ_n are, respectively, the input share and substitution parameters. Equation (1) captures three key responses within the model to changes in crop technology index: (i) demand response (change in consumption of food crops), (ii) adaptation on the extensive margin (substitution of agricultural land for other land resources), and (iii) adaptation on the intensive margin (substitution of agricultural land for fertilizers).

Biofuels substitute imperfectly for liquid fossil fuels in final energy demand. The food crops used as animal feed and pasture land are combined to produce raw livestock. Harvesting managed forests yield raw timber that is further used in timber processing.

The land-based consumption goods and services take the form of processed crops, livestock, and timber and are, respectively, outcomes of food crops, raw livestock, and timber processing. The production of energy services combines non-land energy inputs (i.e., liquid fossil fuels) with biofuels, and the resulting mix is further combusted. Finally, all land types can contribute to other ecosystem services, a public good to society, including recreation, biodiversity, and other environmental goods and services. To close the demand system, we also include other non-land goods services (e.g., manufacturing goods and retail, construction, financial, and information services), which involve the 'consumption' of other primary inputs not spent on the production of land-based goods and services. As the model focuses on the representative agent's behavior, the final consumption products are all expressed in per-capita terms.

A complete description of model equations, variables, and parameter values is presented in the appendix.

3   Modeling Crop Yield Uncertainty

This section characterizes uncertainty in future agricultural yields over the coming century, which is one of the core uncertainties shown to affect land use in the long run (Steinbuks and Hertel, 2013). Crop yields are subject to two types of uncertainties:

---

[4]In FABLE, bioenergy does not include the potential use of biomass in power generation. This limitation is acknowledged in Steinbuks and Hertel (2016, p. 566): "A more serious limitation to this study is our omission of the potential demand for biomass in power generation. Under some scenarios, authors have shown this to be an important source of feedstock demand by mid-century (Rose et al. 2012). However, absent a full representation of the electric power sector, our framework is ill-suited to addressing this issue."

those related to the development and dissemination of new technologies and those related to changes in the climatic conditions under which the crops are grown. The former type of uncertainty has until recently dominated the pattern of the evolution of global crop yields, whereas the latter is becoming an increasingly important factor (Lobell and Field, 2007; IPCC, 2014). While it is plausible to hypothesize that accelerating climate impacts may, in turn, induce further technological advances in an effort to facilitate adaptation to climate change, this hypothesis is not supported by limited empirical evidence (Burke and Emerick, 2016). Therefore, in this paper, these two sources of uncertainty are treated separately, although they are both characterized by the use of combined climate and crop simulation models run over a global grid.

We characterize future uncertainty in yields by constructing a stochastic crop productivity index, θ_t^c, which captures the evolution of future crop yields under different realizations of uncertainty in crop productivity based on the most recent projections in the agronomic and environmental science studies. An important characteristic of staple grain yields is that they tend to grow linearly, adding a constant amount of gain (e.g., ton/ha) each year (Grassini et al., 2013). This suggests that the proportional growth rate should fall gradually over time. However, crop physiology dictates certain biophysical limits to the rate at which sunlight and soil nutrients can be converted to the grain. And there is some recent agronomic evidence (Cassman et al., 2010; Grassini et al., 2013) showing that yields appear to be reaching a plateau in some of the world's most important cereal-producing countries. Cassman (1999) suggests that average national yields can be expected to plateau when they reach 70–80% of the genetic yield potential ceiling. Based on these observations from the agronomic literature, we specify the following logistic function determining the evolution of the crop productivity index over time:

$$\theta_t^c = \frac{\theta_T^c \theta_0^c e^{\kappa_c t}}{\theta_T^c + \theta_0^c (e^{\kappa_c t} - 1)}, \tag{2}$$

where θ_0^c is the value of the crop productivity index in period 0, which we calibrate to match observed weighted yields in key staple crops (corn, rice, soybeans, and wheat), θ_T^c is the crop yield potential at the end of the current century, that is, "the yield an adapted crop cultivar can achieve when crop management alleviates all abiotic and biotic stresses through optimal crop and soil management" (Evans and Fischer, 1999), and κ_c is the logistic convergence rate to achieving potential crop yields.

Though the initial value of the crop productivity index is known with certainty, potential crop yields are highly uncertain. We assume that potential crop yields are affected by a two-dimensional stochastic process of climate and technological shocks, $J_{1,t}$, and $J_{2,t}$, respectively. For the technological shock, $J_{2,t}$, we assume that there are three states of technology: "bad" (indexed by $J_{2,t} = 1$), "medium" (indexed by $J_{2,t} = 2$), and "good" (indexed by $J_{2,t} = 3$). In the optimistic (i.e., "good") state of advances in crop technology, we assume that yields will continue to grow linearly throughout the coming century, eliminating the yield gap by 2100. In the "medium" state of technology, rather than closing the yield gap by 2100, average yields in 2100 are just three-quarters of the yield potential at that point in time. In the "bad" state of technology, there is no technological progress, and the crop yields stay the same as at the beginning of the coming century.

For the climate shock, $J_{1,t}$, we assume it is a Markov chain with five possible states at each time t. To construct these states, we use the results of ISIMIP fast-track crop simulation model comparison (Rosenzweig et al., 2014).[5] Since FABLE is a partial equilibrium model without an embedded climate module, we cannot directly capture all sources of GHG emissions and endogenize their effect on global crop yields. Instead, to ensure the simulation results' comparability with the structural parameters (e.g., demographic and economic growth, the rate of technological change) of the FABLE model, we select four crop simulation model runs under the RCP6 GHG forcing scenario.[6] We also consider alternative assumptions on CO_2 fertilization effects.

Based on these data, we construct five states corresponding to quintiles of the distribution of different outcomes of four global crop simulation models and five global climate models, with and without CO_2 fertilization effects for potential crop yields by 2100. Under two optimistic states of the world, we observe 2 and 15 percent increases in potential crop yields relative to the model baseline (calibrated based on historical trends over the reference period 1971 to 2004), respectively, whereby significant CO_2 fertilization effects offset the negative effects of climate change. For the next two states, we see 15 and 19 percent declines in potential crop yields relative to the model baseline whereby CO_2 fertilization effects are assumed to be either small or non-existent, and the negative effects of climate change tend to prevail. Finally, under the most pessimistic state of the world, drastic adverse effects of climate change combined with the absence of any CO_2 fertilization effects result in a 36 percent decline in potential crop yields relative to the model baseline.

Further details of constructing climate and technological states can be found in the appendix.

The path of technological change in crop yields evolves by reversible transitions across these states. The stochastic path of the crop productivity index is then given by

$$A_t = \frac{A_T(J_{1,t}, J_{2,t}) A_0 e^{\kappa_c t}}{A_T(J_{1,t}, J_{2,t}) + A_0 (e^{\kappa_c t} - 1)}, \tag{3}$$

where $A_T(i,j)$ represents the crop productivity index at the terminal time T at the state $J_{1,t} = i$ and $J_{2,t} = j$, for $i = 1, 2, ..., 5$ and $j = 1, 2, 3$. Thus, A_t is a Markov chain, which takes one of 15 possible time-varying values at each time period. This can be seen as a discretization of a mean-reverting process with continuous values and a time trend, but a finer Markov chain with more values can only marginally change our solution. As A_t is completely dependent on $J_{1,t}$ and $J_{2,t}$, it is not a state variable, whereas $J_{1,t}$ and $J_{2,t}$ are both state variables.

Having characterized the realizations of crop productivity under alternative states of agricultural technology and climate change impacts, we still need to calibrate the transition probabilities for the climate and technology shocks to construct the stochastic crop productivity index. As regards climate shock, the environmental and climate science literature acknowledges some degree of persistence but does not provide much guidance on the transition dynamics between alternative climate states

---

[5]More recent projections using ensembles of latest-generation crop and climate models find larger uncertainty of climate impacts on major crop yields (Jägermeyr et al., 2021). Unfortunately, these data were not available at the time of the research. Our results should therefore be taken as conservative estimates of the impacts of climate uncertainties on crop yields.

[6]FABLE model baseline assumes no climate regulations and other GHG mitigation measures required to achieve RCP4.5 or lower radiative forcing values, whereas realism of RCP8.5 as the 'business-as-usual' scenario has been questioned by the literature (Hausfather and Peters, 2020).
Figure 2. Crop Productivity Index

affecting crop yields. In the absence of reliable estimates for constructing the transition probability matrix of $J_{1,t}$, we assume simple transition dynamics, where each state has a 50 percent probability of retaining itself next period and a 25 percent probability of moving upwards and downwards to an adjacent state (note that realizations can only stay the same or move

220   upwards from the lowest state, e.g., $J_{1,t} = 1$, and only stay the same or move downwards from the highest state, e.g., $J_{1,t} = 5$). As regards the technology shock, since we do not have historical data on the evolution of agricultural technology, we assume that technological advances in agriculture follow a similar trend to advances in the rest of the economy and use the probability transition matrix of $J_{2,t}$ estimated by Tsionas and Kumbhakar (2004) for a comprehensive panel of 59 countries over the period of 1965–1990. These estimates correspond to a 20 percent probability of the "bad" technological state, 56 percent of

225   the "medium" state, and 24 percent of the "good" state. The transition probability matrices of $J_{1,t}$ and $J_{2,t}$ are shown in the appendix.

     Figure 2 shows the deterministic-baseline path (the solid line) used in the perfect foresight model and the range of the stochastic crop productivity index based on 1,000 simulation paths over the entire 21st century, with additional summary statistics presented in the appendix. The simulations start at the "medium" states of climate and technology in the initial year.

230   The deterministic-baseline path is calculated by taking expectations of the stochastic crop productivity index conditional on the initial "medium" states (equation 3). It also takes the same values as the median path (the "o" line) of simulations, whereby the climate and technological states are kept at "medium", while the average line (the "+" line) deviates a bit after the year

2070. At every time t, there are 1,000 realized values of A_t, among which there are only 15 different values. The 10% and 90% quantile lines (the dashed and dash-dotted lines) represent the 10% and 90% quantiles of these 1,000 simulated values of A_t at time t, so they are not the realized sample paths, but Figure 2 also displays one realized sample path of A_t which is the dotted line.

4   Method of Model Solution: the SCEQ Algorithm

In most resource use problems under uncertainty, including the FABLE model, the social planner's problem cannot be solved analytically, although certain inferences about the potential effects of uncertainty can be made from more stylized models. Numerical dynamic programming with value function iteration (see, e.g., Cai and Judd 2014; Cai 2019) is a typical method to solve these dynamic stochastic problems. However, numerical dynamic programming faces challenging problems such as high dimensionality of state space, shape-preservation of value functions (Cai and Judd, 2013), and kinks caused by occasionally binding constraints. These challenges are common in modeling natural resource use and are hard to address even with the most advanced methods, such as parallel dynamic programming (Cai et al., 2015).

For non-stationary problems, value function iteration involves computing decision rules at each period t. However, computing all these rules can be very time-consuming and unnecessary if our primary goal is to obtain simulation paths and their distributions until a time of interest, T^*, even a long one (in environmental and climate change economics, for example, we are often interested in solutions for the coming century and set the time of interest to 100 years and the problem horizon of more than 300 years to avoid a large impact of terminal conditions). Instead of solving for optimal decisions for all possible states at each time, we can approximately solve for optimal decisions for those simulated states along simulated paths. This logic is embedded in the novel SCEQ algorithm (Cai and Judd, 2023) used to solve for a simulated range of land use trajectories in the stochastic FABLE model.

Below we present the SCEQ algorithm version for solving the finite horizon nonstationary stochastic dynamic programming problems the FABLE model belongs to (for a detailed description of other cases, see Cai and Judd (2023) Following the standard notation in the literature, let $\mathbf{S_t}$ be a vector of state variables (here, land cover types and stocks of fossil fuels), and $\mathbf{a}_t$ be a vector of decision variables (here land conversion, resource extraction, transformation, and final consumption of land-based goods and services) at each time t. The transition law of the state vector $\mathbf{S}$ is

$$\mathbf{S}_{t+1} = \mathbf{G}_t(\mathbf{S}_t, \mathbf{a}_t, \epsilon_t)$$

where ϵ_t is a serially uncorrelated random vector process, and $\mathbf{G}_t$ is a vector of functions: its i-th element, $G_{t,i}$, returns the i-th state variable at $t+1$: $S_{t+1,i}$. For simplicity, we assume the mean of ϵ_t is 0.[7]

The FABLE model equations (see appendix) can be compactly represented by the following social planner's problem:

---

[7] For notational simplicity we keep the same mathematical representation of a transition function, even if some of its elements are redundant. For example, if $G_{t,i}$ is deterministic, we still denote it as $S_{t+1,i} = G_{t,i}(\mathbf{S}_t, \mathbf{a}_t, \epsilon_t)$ even though $S_{t+1,i} = \widetilde{G}_{t,i}(\mathbf{S}_t, \mathbf{a}_t) + 0 \cdot \epsilon_t$. Similarly, if there are some unused elements of ϵ_t or some redundant arguments in a function $G_{t,j}$, we can multiply them by zero in $G_{t,j}$ and thus still use $S_{t+1,j} = G_{t,j}(\mathbf{S}_t, \mathbf{a}_t, \epsilon_t)$.

$$\max_{\mathbf{a}_t} \quad \mathbb{E}\left\{\sum_{t=0}^{T-1} \delta^t \mathcal{U}_t\left(\mathbf{S}_t, \mathbf{a}_t\right) + \delta^T V_T(\mathbf{S}_T)\right\} \tag{4}$$

$$\text{s.t.} \quad \mathbf{S}_{t+1} = \mathbf{G}_t(\mathbf{S}_t, \mathbf{a}_t, \epsilon_t), \ t = 0, 1, 2, ..., T-1,$$

$$\mathbf{F}_t(\mathbf{S}_t, \mathbf{a}_t) \geq 0, \ t = 0, 1, 2, ..., T-1,$$

where $\mathcal{U}_t$ is a utility function, $\delta \in (0,1)$ is the discount factor, $\mathbb{E}$ is the expectation operator, T is the horizon ($T = \infty$ if it is an infinite-horizon problem), $V_T(\mathbf{S}_T)$ is a given terminal value function depending on the terminal state $\mathbf{S}_T$ (it is zero everywhere for an infinite-horizon problem), and $\mathbf{F}_t(\mathbf{S}_t, \mathbf{a}_t) \geq 0$ is a vector of feasibility constraints of actions $\mathbf{a}_t$ at time t. And we assume that the initial state $\mathbf{S}_0$ is given, as it can usually be observed or estimated.

Algorithm 1 SCEQ for Finite-horizon Stochastic Dynamic Programming Problems with Time-Variant Exogenous Paths

Step 1. Initialization step. *Given the initial state $\mathbf{S}_0$ and a time of interest T^*, as well as a terminal value function $V_T(\mathbf{S}_T)$. Simulate a sequence of ϵ_t to get m paths, denoted ϵ_t^i for path i, from $t = 0$ to $T^* - 1$. Let $\mathbf{S}_0^i = \mathbf{S}_0$ and iterate forward through steps 2 and 3 for $s = 0, 1, 2, ..., T^* - 1$.*

Step 2. Optimization step. *Solve the following deterministic model starting from time s and simulated node $\mathbf{S}_s^i$:*

$$\max_{\mathbf{a}_t} \quad \sum_{t=s}^{T-1} \delta^{t-s} \mathcal{U}_t\left(\mathbf{S}_t, \mathbf{a}_t\right) + \delta^{T-s} V_T(\mathbf{S}_T) \tag{5}$$

$$\text{s.t.} \quad \mathbf{S}_{t+1} = \mathbf{G}_t(\mathbf{S}_t, \mathbf{a}_t, 0), \ t = s, s+1, ..., T-1,$$

$$\mathbf{F}_t(\mathbf{S}_t, \mathbf{a}_t) \geq 0, \ t = s, s+1, ..., T-1,$$

where $\mathbf{S}_s$ is given by $\mathbf{S}_s^i$, for each $i = 1, ..., m$.

Step 3. Simulation step. *Set $\mathbf{S}_{s+1}^i = \mathbf{G}_t(\mathbf{S}_s^i, \mathbf{a}_s^i, \epsilon_s^i)$, where $\mathbf{a}_s^i$ is the optimal decision at time s of the problem (5), for each $i = 1, ..., m$.*

Algorithm 1 obtains simulated pathways of optimal decisions and states. Note that the inside loop across i can be switched with the outside loop across time, that is, for each i, we can obtain one simulation path by iteratively solving (5) and simulating $\mathbf{S}_{s+1}^i = \mathbf{G}_t(\mathbf{S}_s^i, \mathbf{a}_s^i, \epsilon_s^i)$ for $s = 0, 1, 2, ..., T^* - 1$.

The optimization step of Algorithm 1 applies the certainty equivalent approximation idea of the NLCEQ method (Cai et al., 2017): for a given state at time s, $\mathbf{S}_s^i$, we replace all future stochastic variables by their corresponding expectations conditional on the current state $\mathbf{S}_s^i$,[8] and convert the dynamic stochastic problem (4) into a deterministic finite-horizon dynamic problem (5).

---

[8]As ϵ_t is a serially uncorrelated stochastic process, we can replace ϵ_t by its zero mean in the functions of $\mathbf{G}_t$ in (5) if all transition laws are continuous. For problems with a discrete Markov chain in transition laws, we can use the same technique as described in Cai et al. (2017) for NLCEQ with a discrete

We implement the optimal control method (Cai, 2019) to solve (5) numerically, that is, we view (5) as a large-scale nonlinear constrained optimization problem with $\{\mathbf{a}_t^i : t \geq s\}$ and $\{\mathbf{S}_t^i : t \geq s\}$ as its variables, and the transition equations and feasibility restrictions as its constraints. The problem can be directly solved with an appropriate nonlinear optimization solver such as CONOPT (Drud, 1994).

Observe that we just need to save the solution of (5) at time s, $\mathbf{a}_s^i$, for use in the next step. In step 3 of Algorithm 1 we use the saved optimal decision $\mathbf{a}_s^i$ to generate the next-period state, $\mathbf{S}_{s+1}^i = \mathbf{G}_t(\mathbf{S}_s^i, \mathbf{a}_s^i, \epsilon_s^i)$, given realization of shocks, ϵ_s^i. Once we reach the state $\mathbf{S}_{s+1}^i$ at time $s+1$, we come back to implement step 2 and then step 3. In other words, Algorithm 1 uses an adaptive management way: decisions are made for the current period in the face of future uncertain shocks; once the next-period shock is observed, decisions for the next period are made with re-optimization given the observed shock and new state variables at the next period. Observe that the serial correlation of random variables has been captured in their associated transition laws. Repeating this process iteratively through T^* times, we compute a representative simulated pathway of optimal decisions, $\{\mathbf{a}_s^i\}_{s=0}^{T^*-1}$, and states, $\{\mathbf{S}_s^i\}_{s=0}^{T^*}$, which corresponds to the realized path of shocks, $\{\epsilon_s^i\}_{s=0}^{T^*-1}$. Repeating over i, we compute m simulated paths of optimal states and decisions and then obtain their distributions. This simulation process can be naturally parallelized.

After we obtain the simulated solutions for our dynamic stochastic land use problem, we also check the normalized Euler errors and find that the $\mathcal{L}^1$ error of the solutions for the first 100 years (the periods of interest) among 1,000 simulated paths is only 8.6×10^{-4}, and the corresponding $\mathcal{L}^\infty$ error is only 0.02.This is within range of acceptable accuracy for the most dynamic stochastic problems (Cai and Judd, 2023).

5 Model Results

Below, we describe the results of the impact of crop yield uncertainty on the optimal path of global land use based on the dynamic stochastic model simulations. We solve the model over 400 years with 5-year time steps and present the results for the first 100 years to minimize the effect of terminal period conditions on our analysis.[9] We first present the results of the perfect foresight model, wherein the optimal land allocation decisions are made based on the values of the crop productivity index in the absence of climate and technology shocks. This deterministic analysis is a useful reference point for further discussion when the uncertainty in food crop yields is introduced. We then present the results of the dynamic stochastic model, where the impact of the intrinsic climate and technology uncertainty is brought into the model optimization stage. Specifically, we

---

stochastic state to obtain the corresponding deterministic model (1). That is, given the realization of the Markov chain at time s, we can compute expectations of the Markov chain at all times after s conditional on the value at the time s and then replace the stochastic process by the path of the conditional expectations in step 2 of Algorithm 1.

[9]The model converges to its stationary state around 2150. The differences in land use allocations between 2100 and 2150 are small and, therefore, not reported.

generate 1,000 sample paths of optimal global land use under different realizations of the stochastic crop productivity index.[10] The results are presented as the difference between the stochastic path and deterministic reference solution.

5.1 Optimal Path of Global Land Use under Crop Yield Uncertainty

305 Figure 3 depicts the optimal allocation of global land use over the next century. The left-hand side of Figure 3 shows the deterministic paths of different types of land considered in this study, i.e., when the food crop yields are perfectly anticipated. Specifically, it shows three scenarios where the value of the crop technology index corresponds to (i) expected values of the stochastic crop productivity index (*deterministic-baseline* scenario), (ii) the most pessimistic climate and bad technology states (*deterministic-pessimistic* scenario), and (iii) the most optimistic climate and good technology states (*deterministic-optimistic*

310 scenario). The right-hand side of Figure 3 shows the difference range between the 1,000 simulation paths based on different ex-ante realizations of the stochastic crop productivity index and the deterministic-baseline path. The 10%, 50% and 90% quantile lines represent 10%, 50% and 90% quantiles of 1,000 simulated values respectively at each time, and the average line (the "+" line) represents the average of 1,000 simulated values respectively at each time.

The right-hand side of Figure 3 also shows two extreme cases of optimal land-use paths conditional on period t realizations

315 of crop productivity index states $A_t(J_{1,t}, J_{2,t})$. The realized crop productivity index always takes the highest possible value in a *stochastic-optimistic* case (the line of squares) and the lowest possible value in a *stochastic-pessimistic* case (the line of marks). As future realizations of the stochastic crop productivity index are uncertain, these extreme stochastic solutions are not the same as the corresponding deterministic solutions, where the values of the future crop productivity index are known with certainty. In the stochastic-optimistic case, for example, potentially lower realizations of future crop productivity index

320 result in larger current-period agricultural land allocation as compared to the deterministic-optimistic solution. For other model variables, due to resource limits (e.g., the total land area is unchanged over time) and other constraints, the impact of uncertainty is theoretically difficult to assess. Finally, to ensure consistent interpretation of deterministic and stochastic solutions, the right-hand side of Figure 3 also shows the difference range between the deterministic-optimistic and deterministic-pessimistic cases relative to their deterministic baselines (using the same markers as on the left-hand side of Figure 3).

325 We start a discussion of the left-hand side of panels (a)-(e) of Figure 3, which shows the optimal land use paths under perfect foresight. Given the methodological scope of the paper, we will cover these results briefly. Interested readers should refer to Steinbuks and Hertel (2016) for a more detailed analysis of the perfect foresight model.

Beginning with the description of the baseline scenario, we see that, in the first half of the coming century, the area dedicated to food crops increases, peaking around mid-century and declining significantly thereafter (panel a), as population

330 growth declines while crop production and food processing technologies improve. Consistent with the literature on 2G biofuels' deployment potential (National Research Council, 2011), absent aggressive GHG regulations and biofuels' policies, land allocation for second-generation biofuels remains close to zero until the second half of the coming century (panel b). It then

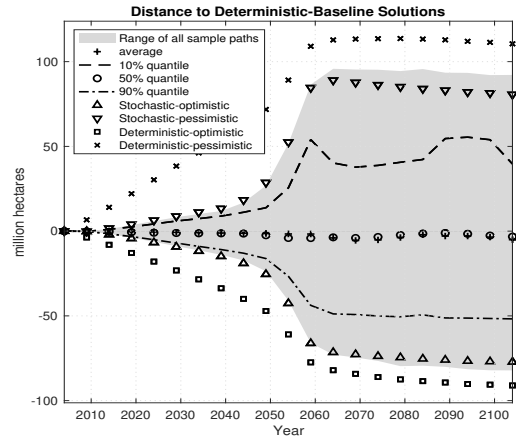
---

[10]Since the SCEQ algorithm is based on simulation, additional simulations could lead to a wider range, and our current solution could underestimate the range in comparison with the range from all possible simulation paths. The difference will, however, be small and won't affect the economic significance of the main findings.

a)

b)

c)

d)


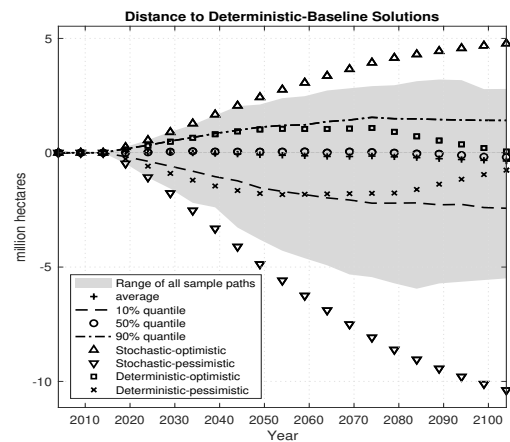


Figure 3. Optimal Global Land Use Paths

becomes viable as fossil fuels become scarce and the costs of producing second-generation biofuels decline. This results in greater land requirements for second-generation biofuels crops. As substitution of pasture land for animal feed in livestock production increases (Taheripour et al., 2013), global pasture area declines while managed forest area increases throughout the entire century (panels c and d). Finally, unmanaged forest areas decline in response to greater requirements for agricultural land (panel e), while protected forest areas will more than double by the end of the coming century in light of strong growth in the demand for ecosystem services (panel f). The other two scenarios exhibit broadly similar dynamics.

We now turn to our main findings about the impacts of uncertainty in the crop productivity index on the distribution of global land resources depicted on the right-hand side of panels (a)-(e) of Figure 3. Compared to deterministic scenarios, this uncertainty results in additional redistribution of land resources to offset the impact of potentially lower yields. The key reason behind this finding is that social preferences exhibit relative risk aversion (Arrow, 1965; Pratt, 1964) in this stochastic application of the FABLE model. Owing to risk aversion and high adjustment costs of future land conversion, some redistribution takes place as a precautionary policy, even in the absence of actual changes in the states of climate or technology. This is a well-known theoretical result in environmental economics literature (Tsur and Zemel, 2014). Compared to the deterministic baseline scenario, the median (i.e., the 50 percent quantile) path of global land use that corresponds to the "medium" state of climate ($J_{1,t} = 3$) and the "medium" technological state ($J_{2,t} = 2$) foresees a smaller use of land for food crops (panel a), and greater use of land for 2G biofuels' crops (panel b), managed forests (panel d), and protected land resources (panel f). The differences between stochastic and deterministic paths are small and economically insignificant for all other land resources. This is because land conversion costs of agricultural land for other types of land become larger in the presence of uncertainty. These other types of land have higher adjustment costs of conversion associated with additional time costs of regrowing lumber and livestock and irreversibilities in accessing protected land areas. Land rotation between food crops and 2G biofuels crops is less costly in the FABLE model. This result is consistent with earlier studies that find that closer integration with the energy sector offers greater potential for food-energy substitution and thus also a greater resilience against adverse climate conditions affecting food crop yields (Diffenbaugh et al., 2012; Verma et al., 2014).

While the direction of the effect of the uncertainty in the crop productivity on land conversion can be inferred from the economic theory of environmental and natural resource management under uncertainty (see, e.g., Tsur and Zemel (2014) and references therein), the extent to which this uncertainty propagates into land conversion depends critically on chosen model structure and parameters. For example, Alexander et al. (2017, p.1) find that even in the absence of intrinsic uncertainty, "systematic differences in land cover areas are associated with the characteristics modeling approach are at least as great as the differences attributed to scenario variations". Depending on the assumptions on the substitution of land for other resources, the size of technological progress, and the responsiveness of demand for land-based goods and services to changes in crop productivity, this magnitude can be substantially different from other land use models. However, as we see in Figure 3, for the same model parameters, the range of land conversion is considerably smaller for the dynamic stochastic model compared to the deterministic scenario analysis. Unlike deterministic analysis, where the solutions paths always stay on a known 'good' or 'bad' trajectory, stochastic analysis allows for future states not to stay in their 'best' or 'worst' stage. Consequently, optimal land conversion decisions in the stochastic application of the FABLE model are less extreme.

Turning to a specific example, we see from Figure 3, panel (a) the difference between the most extreme paths of the stochastic crop productivity index is about 160 million hectares by 2100 or about 11 percent of the total agricultural area dedicated to food crops. Much of that variation can be attributed to the most extreme (i.e., falling beyond 10th and above 90th percent quantiles) realizations of crop productivity. In line with the argument above, this is because the climate and technological states affecting crop yields are reversible in the stochastic model (that is, if the current state is "bad" (or "good"), it could be "good" (or "bad") in the future).

Compared with the deterministic model under the pessimistic (or optimistic) scenario, the social optimum in the stochastic model requires a smaller (or greater) conversion of other types of land to cropland. This is because when the current state of the crop technology index is the worst (best), its future states cannot be worse (better) and have a nonzero probability of being better (worse). The expected future yields will then be better (worse) than the deterministic-pessimistic (optimistic) scenario. As the size of expected crop yields affects the magnitude of the land conversion decisions, the range of stochastic model solutions for agricultural land will be smaller than the range between the most extreme deterministic model solutions. Note this result may not hold if the model solution space is unbounded. This concern doesn't apply to the stochastic FABLE model because (i) the model's time horizon is finite; (ii) the crop technology shocks are discrete and finite (hence bounded) based on scientific projections used for the model's calibration; (iii) all of the model's state variables (land and fossil fuel resources) are bounded because the total land and the total fossil fuel resources are finite; and (iv) we impose bounds on model decision variables based on the theory of economic dynamics (Barro and Sala-i Martin, 2004), such as strictly positive and finite consumption and output of land-based goods and services; land conversion cannot exceed the total supply of land). The solution space, therefore, must also be bounded because the extent of movement of optimal land uses in any direction is limited by the constraints mentioned above.

Thus, the agricultural land area in the deterministic pessimistic (or optimistic) scenario is larger (or smaller) than the largest (or the smallest) path in the stochastic simulations. For example, in 2100, under the deterministic-pessimistic scenario, the cropland deviation from the deterministic-baseline scenario is about 110 million hectares, which is 30 percent larger than the largest deviation under the stochastic simulations and more than half of the deviation above the 90% quantile of the stochastic crop technology index. This result (along with similar results for other land types) demonstrates that scenario analysis can significantly overstate the magnitude of expected agricultural land conversion under uncertain crop yields.

5.2 Optimal Path of Land-Based Goods and Services under Crop Yield Uncertainty

We now turn to the discussion of optimal paths of land-based goods and services (4), keeping the same presentation structure as in the previous section. Deterministic model scenarios (shown on the left-hand side panels of Figure 4) for land-based goods and services largely mimic trajectories of associated land resources. Specifically, we see steady increases in the production of food crops (panel a), including livestock and biofuels feedstock, peaking around mid-century and moderating thereafter as consumers satiate their food requirements and the technology of food marketing and processing improves. By 2100, crop production for the livestock feed levels off and even begins to decline. Production of both first- and second-generation biofuels grows as oil becomes more scarce along the baseline path and agricultural yields increase (panels b and c). Along that optimal

a)

b)

c)

d)

e)

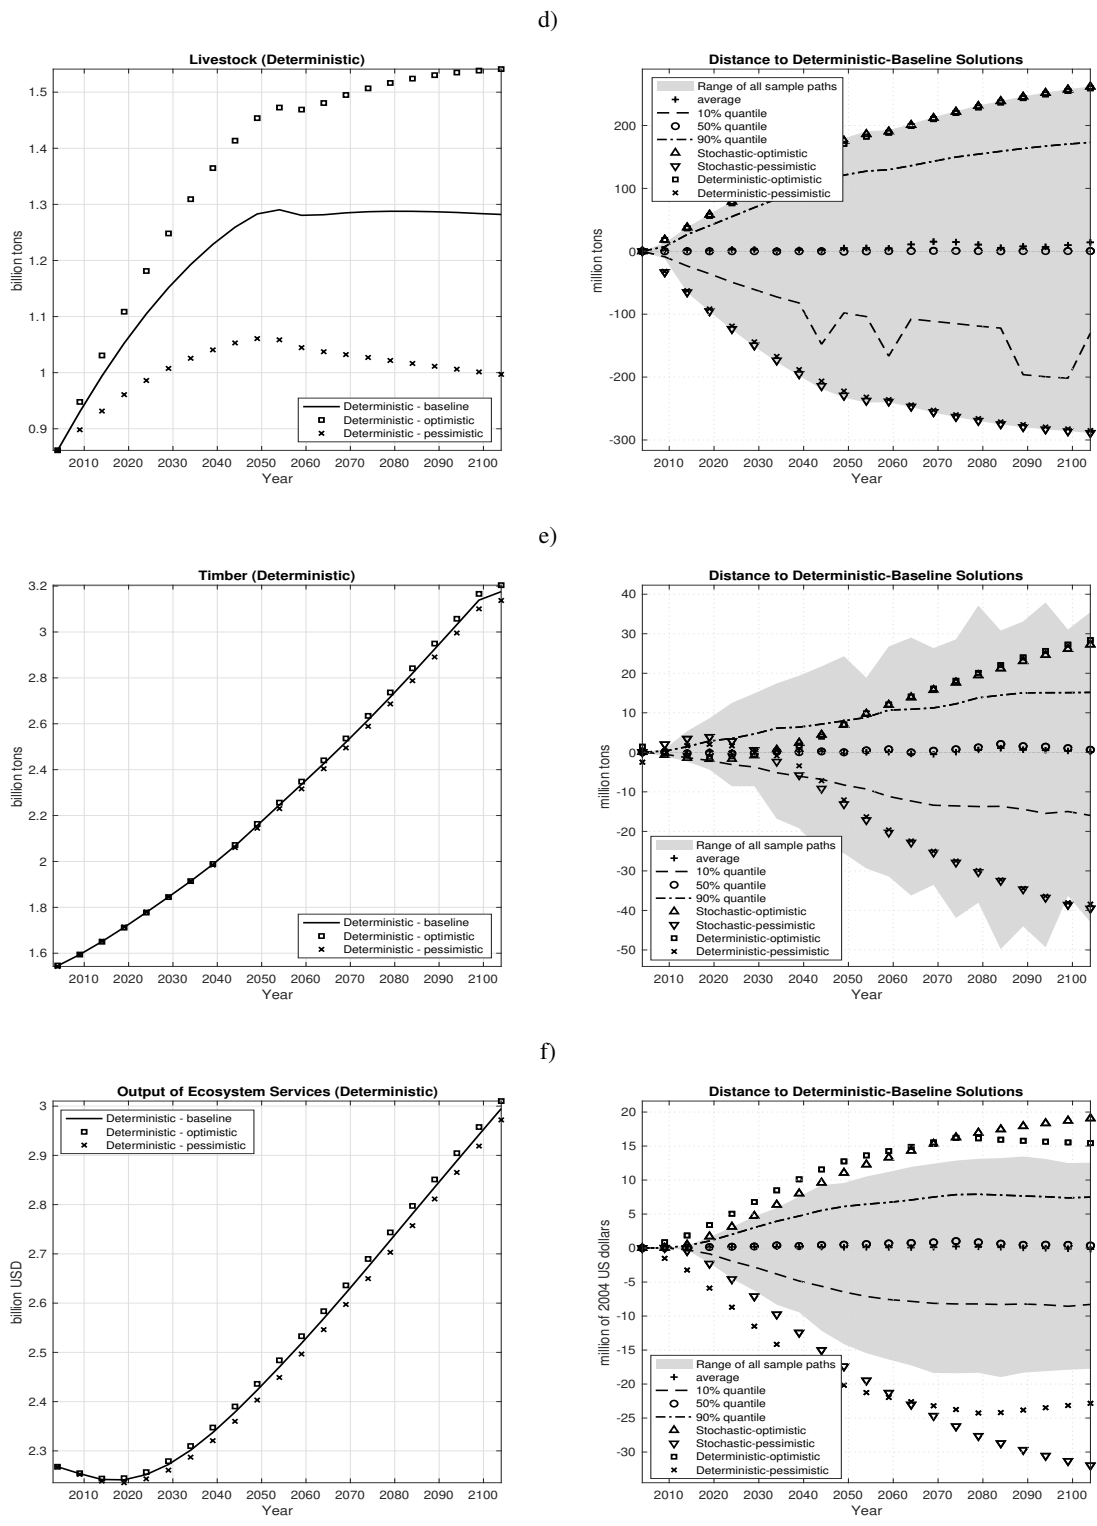
f)


Figure 4. Optimal Paths of Land-Based Goods and Services

path, first-generation biofuels never become a large source of energy consumption, while the production of second-generation biofuels takes off sharply and expands rapidly after 2040 as they become cost-competitive relative to increasingly costly fossil fuels. Production of livestock increases throughout the coming century (panel d), reflecting shifting diets and the growing demand for processed meat as population income increases (Foley et al., 2011). Production of timber also expands with the growing demand for timber products and further improvements in forest yields (panel e). Finally, the consumption of ecosystem services increases throughout most of the coming century as the demand for ecosystem services increases and more natural forest lands become institutionally protected (panel f).

The results of the dynamic stochastic model simulations (shown on the right-hand side panels of Figure 4) show that un-certainty in the crop productivity index has a profound effect on the optimal consumption paths of food crops, biofuels, and livestock, and much smaller effect on consumption paths of merchantable timber and ecosystem services. This result is not very surprising as crop productivity does not directly affect the production of timber and ecosystem services, whereas indirect land use change effects are relatively small in this stochastic application of the FABLE model. Observe that, unlike land use paths, consumption of land-based goods and services is a decision rather than a state variable, and therefore, there are no significant differences between deterministic and stochastic consumption paths.

Focusing on the larger impacts, we see that between the most extreme paths of the stochastic crop productivity index, the production of food crops varies by about 5.3 billion tons along both deterministic and stochastic policy paths. This is a sizable change, which suggests a significant variation in levels of consumption in 2100 along different paths of the stochastic crop productivity index. In the FABLE model, much of the variation in the optimal path of food crops comes on the demand side, with the crop productivity decline resulting primarily in the reduced consumption of processed crops and livestock.[11] As shown above, the uncertainty-induced supply response is relatively small along the extensive margin in the dynamic stochastic model (i.e., land conversion). In the appendix (Figure A.2, panel a), we show that the supply response on the intensive margin is smaller, with the ratio of fertilizers to cropland increasing by less than 6 kg/Ha (or eight percent) under extreme realizations of climate and technology uncertainties. About half of that variation corresponds to the most extreme (i.e., falling beyond 10th and above 90th percent quantiles) realizations of crop productivity. This result indicates that extreme uncertainty in crop productivity could have a significant impact on food consumption over the coming century.

Uncertainty in food crop yields has important implications for the production of the first-generation biofuels that are directly affected by both climate and technology states of food crop yields. The difference between the best and worst states of the crop productivity index is about 31 million tons of oil equivalent, which exceeds their expected baseline production in 2100. Although climate and technology states of food crop yields do not directly affect yields of the second-generation biofuels crops, production of second-generation biofuels is nonetheless affected through indirect substitution effects of food for energy in the

---

[11]Demand for land-based goods and services in the FABLE model is governed by the AIDADS demand system designed to encompass consumption behavior across a wide range of incomes (Rimmer and Powell, 1996). This is essential for a dynamic model of the global economy. We have estimated three key parameters for each commodity category – the subsistence level of consumption, the marginal budget share at very low (subsistence) income, and the marginal budget share at very high levels of income. The former two are large for food products. In the FABLE model, baseline households become wealthier, and the marginal budget share for food items and the subsistence share become very small, approaching zero for very high incomes. Consequently, households' demand response becomes larger.

FABLE demand system. There is a sizable variation in the production of second-generation biofuels between extreme paths of the stochastic crop productivity index, which accounts for 450 Mtoe, or about 30 percent of their total production in 2100.

Given the important contribution of livestock feed in the production of livestock, we can see its production is smaller in the pessimistic scenario and larger in the optimistic scenario. The difference in livestock production between the optimistic and pessimistic scenarios accounts for about 550 million tons. As the significance of animal feed in livestock production grows over time, the effect of uncertain crop yields becomes more pronounced. Similar to the result for food crops, the most extreme paths of crop productivity account for about a third of all variation in livestock production.

6 Conclusions

This paper shows the effects of uncertainties associated with nonstationary biophysical processes and technological change on the optimal allocation of natural resources in the long run. In doing so, it applies SCEQ, a cutting-edge computational method for solving nonstationary dynamic high-dimensional stochastic problems, to FABLE, a multi-sectoral dynamic model of global land use.

The study focuses on uncertainty in future crop yields, one of the core uncertainties affecting the evolution of global land use in the long run. Combining scenarios from global climate models and high-resolution output from spatial crop simulation models for four major crops, it comes up with a plausible range of realizations of climate shocks and their effect on future crop yields. These estimates are supplemented with an extensive survey of recent agro-economic and biophysical studies assessing the potential for closing yield gaps as well as attaining further advances in potential yields through plant breeding.

The paper's key insight is to illustrate the magnitude of optimal land conversion decisions in the context of different realizations of stochastic crop productivity. Consistent with the economic theory of natural resource management under uncertainty, the agricultural productivity shocks due either to adverse climate impacts or unexpected limits on further technological progress, resulting in additional conversion of scarce land resources to offset the impact of potentially lower yields. Owing to intertemporal substitution, some of that conversion takes place even in the absence of actual realization of the climate shocks or technology outcomes. This expansion is accompanied by changes in the consumption of processed food, livestock, and biofuels- the land-based products most affected by changes in crop productivity.

The chosen model (FABLE) seeks to balance computational complexity and economic tractability. It thus ignores many features that are standard in more advanced computational land and other resource use models. Future research should focus on integrating economic decisions under uncertainty into large dynamic natural resource models that feature spatial disaggregation at the regional or zonal level, a more extensive representation of the energy sector, and different types of resources and their production derivatives. Another promising research direction would be to incorporate a more detailed representation of uncertain states backed by an econometric analysis that recovers underlying distributions of uncertain natural resource drivers over time.

Code and data availability. Numerical implementation of the FABLE model and the SCEQ method in the GAMS modeling language is available at the following URLs: https://github.com/jsteinbuks/stfable and https://zenodo.org/records/10014997. The FABLE model is calibrated based on the GTAP land use database and publicly available data sources. Calibration details are available in the appendix. The uncertainty of climate impacts on agricultural yields is estimated based on the results of Rosenzweig et al. (2014). Calibration details are available in the appendix.

Author contributions. Steinbuks and Cai were the lead contributors to the manuscript. Steinbuks and Hertel developed and calibrated the FABLE model. Cai developed the SCEQ algorithm and numerically implemented it to assess uncertainty in climate and technology impacts quantitatively. Jaegermeyr and Steinbuks estimated the uncertainty of climate impacts on global crop yields.

Appendix A: FABLE Model Description

This section describes key elements of the FABLE model, as well as its equations, variables, and model parameters. For a full description of the model, including details on model baseline calibration and extensive sensitivity analysis, please refer to Hertel et al. (2016) and Steinbuks and Hertel (2016) and technical appendices therein.

A1 Primary Resources

Primary resources comprise land, liquid fossil fuels, and other primary inputs, e.g., labor and capital. The supply of land is fixed and faces competing uses that are determined endogenously by the model. The flow of liquid fossil fuels evolves endogenously along their optimal path, accounting for exogenous discoveries in new fossil fuel reserves. The endowment of other primary inputs is exogenous and evolves along the prespecified global economy growth path.

A1.1 Land

The total land endowment in the model, L^{total}, is fixed. It belongs to a global planner, which fully redistributes land rents back to consumers of land-use goods and services. For each period of time t there are four profiles of land in the economy.

They include unmanaged forest land, L^N, agricultural land, L^A, pasture land, L^P, and commercially managed forest land, L^C. The agricultural land area can be allocated for the cultivation of food crops (denoted $L^{A,c}$), and second-generation biofuels feedstocks (denoted $L^{A,b2}$). We assume that the natural forest land consists of two types. Institutionally protected land, L^R, includes natural parks, biodiversity reserves, and other types of protected forests. This land is used to produce ecosystem services for society, and cannot be converted to commercial land. Unmanaged natural land, L^N, can be accessed and either converted to managed land or to protected natural land. Once the natural land is converted to managed land, its potential to yield ecosystem services is diminished. This potential can be partially restored for managed forests with significant land rehabilitation costs incurred. The use of managed land can be shifted between cropland, forestland, and pasture land (see Figure 1 in the main manuscript for a graphical representation of these transitions). We denote land transition flows from land type i to land type j as $\Delta^{i,j}$ (a negative value means a transition from land type j to land type i). Equations describing the allocation of land across time and different uses are as follows:

$$L^{total} = \sum_{i=A,P,C,N,R} L^i_t \tag{A1}$$

$$L^A = L^{A,c} + L^{A,b2} \tag{A2}$$

$$L^N_{t+1} = L^N_t - \Delta^{N,A}_t - \Delta^{N,R}_t + \Delta^{C,N}_t \tag{A3}$$

$$L^A_{t+1} = L^A_t + \Delta^{N,A}_t - \Delta^{A,P}_t + \Delta^{C,A}_t \tag{A4}$$

$$L^P_{t+1} = L^P_t + \Delta^{A,P}_t \tag{A5}$$

$$L^R_{t+1} = L^R_t + \Delta^{N,R}_t \tag{A6}$$

Equations (A1) and (A2) define, respectively, the composition of total land and agricultural land in the economy. Equations (A3)-(A5) describe the transitions for unmanaged land, agricultural land, and pasture land.[12] Equation (A6) shows the growth path of protected natural land.

---

[12]Equations (A2) and (A4) do not account for the transition from forestry to pasture land. Throughout the past century, tropical forests, particularly in the Latin America region, have been extensively converted to pasture land (Barbier et al., 1994). However, in the FABLE model, the conversion of forest land to pasture is never optimal as cropland has higher productivity for cattle breeding at the same conversion (stumpage) cost.

Accessing the natural lands comes at a cost associated with building roads and other infrastructure (Golub et al., 2009). In addition, converting natural land to reserved land entails additional costs associated with passing legislation to create new natural parks. We denote the natural land access, rehabilitation, and protection costs as $C^{N,A,R}$, $C^{C,N}$, and $C^{N,R}$, respectively. There are also costs of switching between the cropland and the pasture land, denoted as $C^{A,P}$. We assume that all these costs are continuous, monotonically increasing, and strictly convex functions of converted land. Since we are not aware of empirical studies estimating the magnitudes of long-term adjustment costs in land conversion problems we choose to calibrate these parameters to match historical land conversion patterns. There are no additional costs of natural land conversion to commercial land, as the revenues from deforestation offset these costs.

Managed forests are characterized by $v_{\max}$ vintages of tree species with vintage ages $v = 1, ..., v_{\max}$. At the end of period t each hectare of managed forest land, $L_{v,t}^C$, has an average density of tree vintage age v, with the initial allocation given and denoted by $L_{v,0}^C$. The forest rotation ages and management are endogenously determined. Each period the managed forest land can be either planted, harvested, or left to mature. The newly planted trees occupy $\Delta^{C,C}$ hectares of land, and reach the average age of the first tree vintage next period. The harvested area of tree vintage age v occupies $\Delta_v^{C,H}$ hectares of forest land. The difference between the harvested area of all tree vintage ages and the newly planted area is used for cropland, i.e.,

$$\Delta_t^{C,A} = \sum_v \Delta_{v,t}^{C,H} - \Delta_t^{C,C}$$

The following equations describe land use of managed forests:

$$L_t^C = \sum_{v=1}^{v_{\max}} L_{v,t}^C, \tag{A7}$$

$$
\begin{aligned}
L_{v+1,t+1}^C &= L_{v,t}^C - \Delta_{v,t}^{C,H}, \quad v < v_{\max} - 1 &\text{(A8)}\\
L_{v_{\max},t+1}^C &= L_{v_{\max},t}^C - \Delta_{v_{\max},t}^{C,H} - \Delta_t^{C,N} + L_{v_{\max}-1,t}^C - \Delta_{v_{\max}-1,t}^{C,H} &\text{(A9)}\\
L_{1,t+1}^C &= \Delta_t^{C,C}. &\text{(A10)}
\end{aligned}
$$

Equation (A7) describes the composition of managed forest area across vintages. Equation (A8) illustrates the harvesting dynamics of forest areas with the ages $v_{\max} - 1$ and $v_{\max}$. Equation (A10) shows the transition from the planted area to new forest vintage area.

The average harvesting and planting costs per hectare of new forest planted, $c^{o,H}$, and $c^{o,C}$, are invariant to scale and are the same across all vintages. Harvesting managed forests and conversion of harvested forest land to agricultural land is subject to additional near term adjustment costs, c^H. The specific functional forms of land conversion costs are shown in section C, equations (C33)-(C38).

Thus, we have defined the vector of land state variables:

$$\mathbf{L} = \left(L^N, L^A, L^P, L^R, L_1^C, ..., L_{v_{\max}}^C \right)$$

and its associated transition laws.

A1.2 Fossil Fuels

The initial stock of liquid fossil fuels, X^F, is exogenous, and each period of time t adds a new amount of fossil fuels, $\Delta^{F,D}$, which reflects exogenous technological progress in fossil fuel exploration. This technological progress comprises of both discoveries on new exploitable oil and gas fields, as well as development of new technologies for extraction of non-conventional fossil fuels. The economy extracts fossil fuels, which have two competing uses in our partial equilibrium model of land-use. A part of extracted fossil fuels, $\Delta_t^{F,n}$, is converted to fertilizers that are further used in the agricultural sector. The remaining amount of fossil fuels, $\Delta_t^{F,E}$, is combusted to satisfy the demand for energy services. The following equation describes supply of fossil fuels:

$$X_{t+1}^F = X_t^F - \Delta_t^{F,E} - \Delta_t^{F,n} + \Delta_t^{F,D}. \tag{A11}$$

The cost of fossil fuels, c^F, reflects the expenditures on fossil fuels' extraction, refining, transportation and distribution, as well the costs associated with emissions control (e.g., Pigovian taxes) in the non-land-based economy. We assume that the cost of fossil fuels is a nonlinear quadratic function with accelerating costs as the stock of fossil fuels depletes (Nordhaus and Boyer, 2000):

$$c_t^F = \xi_1^F \left(\Delta_t^{F,E} + \Delta_t^{F,n} \right)^2 \left(\frac{X_0^F + \Delta_t^{F,D}}{X_t^F + \Delta_t^{F,D}} \right), \tag{A12}$$

where the parameter ξ_1^F captures the curvature of the liquid fossil fuel cost function.

A1.3 Other Primary Resources

The initial endowment of all other primary resources in the non-land-based economy, such as labor, physical and human capital, and materials inputs, X^O, is exogenous in this model. We assume that the growth rate of all other primary resources is a weighted average of the population growth, which reflects demographic changes, and the physical capital growth, $\kappa^{o,X}$. The following equation describes the supply of other primary inputs:

$$X_t^O = X_0^O \left[\alpha^{o,l} \frac{\Pi_t}{\Pi_0} + \left(1 - \alpha^{o,l} \right) \left(1 + \kappa^{o,X} \right)^t \right], \tag{A13}$$

where Π_t is the economy's population, and $\alpha^{o,l}$ is the share of population growth to the growth rate of all other primary resources. Other primary inputs can be used for the production of land-based goods and services or converted to final goods and services in the non-land economy. The production costs incurred by using these inputs are exogenous and have an 'iceberg' representation, i.e., they are subtracted from the gross output of land-based goods and services. Thus, state variables for resources other than land are defined as:

$$\mathbf{X} = (X^F, X^O).$$

As X^O is exogenous and deterministic, it is a degenerated state variable and not counted as a state variable for model solution purposes.

A2 Intermediate Inputs

We analyze six intermediate inputs used in the production of land-based goods and services: petroleum products, fertilizers, crops, biofuels, and raw timber. Fossil fuels are refined and converted to either petroleum products, x^p, that are further combusted, or to fertilizers, x^n, that are used to boost yields in the agricultural sector. Agricultural land and fertilizers are combined to grow food crops, x^c or 2G biofuels crops, $x^{c,b2}$. Food crops can be further converted into processed food and 1G biofuels, x^{b1}, or used as an animal feed, $x^{c,l}$. 2G biofuels crops can only be converted into 2G biofuels, x^{b2}. 1G biofuels substitute imperfectly for liquid fossil fuels in final energy demand, whereas 2G biofuels and liquid fossil fuels are the perfect substitutes The food crops used as animal feed and pasture land are combined to produce raw livestock, x^l. Harvesting managed forests yield raw timber, x^w, that is further used in timber processing. The production functions for intermediate inputs can be illustrated by the following equations

$$x_t^j = g^j \left(\Delta_t^{F,\{E,n\}}, L_t^{\{A,P\}}, \sum_v \Delta_{v,t}^{C,H}, x^{c,\{l,b\}} \right), j = p,n,c,b,l,w. \tag{A14}$$

where $\Delta_t^{F,\{E,n\}}$ represents that either $\Delta_t^{F,E}$ or $\Delta_t^{F,n}$ is an argument of g^j, similarly for $L_t^{\{A,P\}}$ and $x^{c,\{l,b\}}$. The specific functional forms of $g^j(\cdot)$ are shown in section C, equations (C13)-(C21).

A3 Final Goods and Services

We consider five per capita land-based services that are consumed in the final demand: services from processed crops, y^f, livestock, y^l, energy, y^e, timber, y^w, and ecosystem services, y^r. Processed crops, livestock, and timber are respectively products of food crops, raw livestock, and timber processing. The production of energy services combines liquid fossil fuels with the biofuels, and the resulting mix is further combusted. The ecosystem services are the public good to society, which captures recreation, biodiversity, and other environmental goods and services. To close the demand system, we also include other goods and services, y^o, which comprise of consumption of other primary inputs not spent on the production of land-based goods and services. We have defined all state variables for the deterministic model:

$$\mathbf{S} := (\mathbf{L}, \mathbf{X}),$$

and the vector of decision variables

$$\mathbf{a}_t := (\Delta_t^{N,A}, \Delta_t^{N,R}, \Delta_t^{C,N}, \Delta_t^{A,P}, \Delta_t^{C,A}, \Delta_{1,t}^{C,H}, ..., \Delta_{v_{\max},t}^{C,H}, \Delta_t^{C,C}, \Delta_t^{F,E}, \Delta_t^{F,n}, L_t^{A,F}, L_t^{A,B}, \mathbf{x}_t, \mathbf{y}_t),$$

where $\mathbf{x}_t \equiv [x_t^p, x_t^n, x_t^c, x_t^b, x_t^l, x_t^w, x_t^{c,l}, x_t^{c,b}]$ and $\mathbf{y}_t = \left(y_t^f, y_t^l, y_t^e, y_t^w, y_t^r, y_t^o \right)$. The production functions for final per capita land-based goods and services can be illustrated by the following equation:

$$y_t^i = \mathcal{Y}_t^i(\mathbf{S}_t, \mathbf{a}_t), i = f,l,e,w,r. \tag{A15}$$

where some arguments in $\mathcal{Y}_t^i(\cdot)$ could be redundant. It follows from equation (A15) that production of final goods and services involves the combination of land resources and intermediate inputs. The specific functional forms of $\mathcal{Y}_t^i(\cdot)$ are shown in section C, equations (C22)-(C28), which are functions of $\mathbf{L}$ and $\{x^j\}$. All these equations constitute a part of the feasibility constraint $\mathbf{a}_t \in \mathcal{D}_t(\mathbf{S}_t)$.

605 The production of intermediate inputs or final land-based goods and services i incurs costs, $c^{o,i}$, that are subtracted from available other primary resources. The remaining amount of other primary resources is converted into other goods and services, which are subsequently consumed in final demand. As the focus of this model is on the utilization of land-based resources, we introduce the other goods and services, y^o, in a very simplified manner. We introduce no additional cost of producing other goods and services, assuming that it is reflected in the size of the endowment of other primary inputs. The specific functional

610 form for y^o is shown in section C, equation (C27).

A4 Preferences

The economy's per-capita utility, u, is derived from the per capita consumption of processed crops, livestock, timber, energy and ecosystem services, and other goods and services. Following the macro economic literature, we assume constant relative risk aversion utility,

$$615 \quad u(\mathbf{y}) = \frac{\mathcal{C}(\mathbf{y})^{1-\gamma}}{1-\gamma}, \tag{A16}$$

where is the per capita consumption bundle of goods and services, $\mathcal{C}(\mathbf{y})$ is a nonlinear aggregator over $\mathbf{y}$, and γ is the coefficient of relative risk aversion, which captures the economy's attitude to uncertain events. We choose a non-homothetic AIDADS preference (Rimmer and Powell, 1996) to compute $\mathcal{C}(\mathbf{y})$ implicitly:

$$\log\left(\mathcal{C}(\mathbf{y})\right) = \sum_{q=f,l,e,w,r,o} \left(\frac{\alpha_q + \beta_q \mathcal{C}(\mathbf{y})}{1 + \mathcal{C}(\mathbf{y})} \right) \log\left(y^q - \underline{y}^q\right) \tag{A17}$$

620 where α, β, and $\underline{y}^q$ are positive parameters with $\sum_q \alpha_q = \sum_q \beta_q = 1$. These preferences place greater value on eco-system services, and smaller value on additional consumption of food, energy, and timber products as society becomes wealthier. When $\gamma = 1$, our utility function is equivalent to the AIDADS utility.

A5 Welfare

We denote the transition laws of land, (A3)-(A6) and (A8)-(A10), as

$$625 \quad \mathbf{L}_{t+1} = \mathbf{G}_t^L(\mathbf{S}_t, \mathbf{a}_t), \tag{A18}$$

and the transition laws for other resources, (A11)-(A13), as

$$\mathbf{X}_{t+1} = \mathbf{G}_t^X(\mathbf{S}_t, \mathbf{a}_t). \tag{A19}$$

Combining (A18) and (A19), we have

$$\mathbf{S}_{t+1} = \mathbf{G}_t(\mathbf{S}_t, \mathbf{a}_t) \tag{A20}$$

630   for the deterministic model in the notations of Section 2.

The objective of the planner is to maximize the total expected welfare, which is the cumulative expected utility (i.e., a sum of utilities in each state weighted by the probability of each state in a given period) of the population's consumption of final goods and services, $\mathbf{y}$, discounted at the constant rate $\delta > 0$. The planner allocates managed agricultural, pasture, and forest lands for crop, livestock, and timber production, the scarce fossil fuels, and protected natural forests to solve the following
635   problem:

$$\max_{\mathbf{a}} \sum_{t=0}^{\infty} \delta^t \mathcal{U}(\mathbf{S}_t, \mathbf{a}_t) \tag{A21}$$

subject to the transition laws (A20) and the feasibility constraints

$$\mathbf{F}_t(\mathbf{S}_t, \mathbf{a}_t) \geq 0$$

which include (A15), (C22)-(C28), (C27), (A17) and nonnegativity constraints for the variables. Here

640   $\mathcal{U}(\mathbf{S}_t, \mathbf{a}_t) = u(\mathbf{y}_t)\Pi_t$

is the utility function in the notations of Section 4.

Appendix B: Quantifying the Uncertainty in Crop Yields

B1   Uncertainty in Agricultural Technology

Advances in crop technology are very difficult to predict due to four interconnected factors (Fischer et al., 2011). First, there
645   is significant uncertainty about the potential for exploiting large and economically significant yield gaps (i.e., the differences between observed and potential crop yields) in developing countries, especially those in Sub-Saharan Africa. A second and closely related point is that it is unclear how fast available yield-enhancing technologies can be adopted at a global scale. Third, there is a significant variation in developing countries' institutions and policies that make markets work better and provide a conducive environment for agricultural technology adoption. Finally, while plant breeders continue to make steady gains in
650   further advancing crop yields, progress depends on the level of funding provided for agricultural research. This has proven to be somewhat volatile, with per capita funding falling in the decades leading up to the recent food crisis (Alston and Pardey, 2014). The food price rises since 2007 have stimulated new investments. However, whether this interest will be sustained remains to be seen. Overall, progress from conventional breeding is becoming more difficult. Transgenic (genetic modification) technologies have a proven record of more than a decade of safe and environmentally sound use, and thus offer huge potential to address
655   critical biotic and abiotic stresses in the developing world. However, expected yield gains, costs of further developing these technologies, and the political acceptance of genetically modified foods are all highly uncertain.

To quantify the extent to which the advances in crop technology can further boost agricultural yields over the next century, we first need to assess the magnitude of existing yield gaps at the global scale. In a comprehensive study, Lobell et al. (2009) report a significant variation in the ratios of actual to potential yields for major food crops across the world, ranging from 0.16 for tropical lowland maize in Sub-Saharan Africa to 0.95 for wheat in Haryana, India. For the purposes of this study, we employ the results of Licker et al. (2010), who conduct comprehensive yield gap analysis using global crop dataset of harvested areas and yields for 175 crops on a 0.5° geographic grid of the planet for the year 2000. Using these estimates, we calculate the global yield gap as the grid-level output-weighted yield gap of the four most important food crops (wheat, maize, soybeans, and rice). The resulting estimate suggests that average yields are 53% of potential yields, which is close to the median estimates by Lobell et al. (2009). As a further robustness check we employ the Decision Support System for Agrotechnology Transfer (DSSAT) crop simulation model (Jones et al., 2003), run globally on a 0.5 degree grid in the parallel System for Integrating Impacts Models and Sectors (pSIMS; Elliott et al. 2014b) to simulate yields of the same four major food crops under best agricultural management conditions and compare simulated yields to their observed yields. The resulting yield gap estimates were not substantially different.

In the optimistic (i.e., "good") state of advances in crop technology, we assume that yields continue to grow linearly throughout the coming century, eliminating the yield gap by 2100. This high yield scenario rests on the assumption of continued strong growth in investment in agricultural research and development, widespread acceptance of genetically modified crops, continuing institutional reforms in developing countries, and public and private investments in the dissemination of new technologies. The erosion of any one of these component assumptions will likely result in a slowing of crop technology improvements. And there are some grounds for pessimism. In a comprehensive statistical analysis of historical crop production trends, Grassini et al. (2013) note that

> "despite the increase in investment in agricultural R&D and education [...] the relative rate of yield gain for the major food crops has decreased over time together with evidence of upper yield plateaus in some of the most productive domains. For example, investment in R&D in agriculture in China has increased threefold from 1981 to 2000. However, rates of increase in crop yields in China have remained constant in wheat, decreased by 64% in maize as a relative rate and are negligible in rice. Likewise, despite a 58% increase in investment in agricultural R&D in the United States from 1981 to 2000 (sum of public and private sectors), the rate of maize yield gain has remained strongly linear."

To capture the possibility of much slower technological improvement in the coming century, we specify two more pessimistic scenarios. In the "medium" state of technology, rather than closing the yield gap by 2100, average yields in 2100 are just three-quarters of yield potential at that point in time. In the "bad" state of technology, there is no technological progress, and the crop yields stay the same as at the beginning of the coming century. This is the path on which we begin the simulation in 2004. As previously noted, we then specify probabilities with which the crop technology index evolves across the different states of technology.

B2 Uncertainty in Climate Change Impacts

In addition to crop technology uncertainty, there is great uncertainty about the physical environment in which this technology will be deployed. In particular, long-run changes in temperature and precipitation are likely to have an important impact on land productivity in agriculture (IPCC, 2014), and, therefore, the global pattern of land use. Quantification of the impact of climate change on agricultural yields requires coming to grips with three interconnected factors (Alexandratos, 2011). First, there is significant uncertainty in future GHG concentrations along the long-run growth path of the global economy. Second, the General Circulation Models (GCMs) developed by climate scientists to translate these uncertain GHG concentrations into climate outcomes disagree about the spatially disaggregated deviations of temperature and precipitation from baseline levels. Finally, there is significant uncertainty in the biophysical models used to determine how changes in temperature and precipitation will affect plant growth and the productivity of agriculture in different agroecological conditions. The impact of climate change on food crop yields depends critically on their phenological development, which, in turn, depends on the accumulation of heat units, typically measured as growing degree days (GDDs). More rapid accumulation of GDDs due to climate change speeds up phenological development, thereby shortening key growth stages, such as the grain-filling stage, hence reducing potential yields (Long, 1991). However, rising concentrations of CO_2 in the atmosphere result in an increase in potential yields due to improved water use efficiency, often dubbed the "CO_2 fertilization effect" (Long et al., 2006). Sorting out the relative importance of these effects and achieving greater confidence in evaluations of climate impacts on agricultural yields remains an important research question in the agronomic literature (Cassman et al., 2010; Rosenzweig et al., 2014).

To quantify the uncertainty in climate impacts on agricultural yields, we use ISIMIP fast-track crop simulation model data (Rosenzweig et al., 2014). Specifically, we obtain results of four crop simulation models: GEPIC (Liu et al., 2007), LPJmL (Bondeau et al., 2007), pDSSAT (Jones et al., 2003), and PEGASUS (Deryng et al., 2011). All models are run globally on a $0.5°$ grid over the period between 1971 and 2099 and weighted by the output of four major food crops (maize, soybeans, wheat, and rice). Since the FABLE model is not spatially explicit, we further aggregate gridded crop yields at a global scale using weights of the size of the aggregate crop output per grid cell. To ensure simulation results' comparability with the structural parameters of the FABLE model, all models are run under Representative Concentration Pathways $6.0 \mathrm{W/m^2}$ (RCP6) GHG forcing scenario (Moss et al., 2008). We also consider alternative assumptions on CO_2 fertilization effects. Observe that our results are based on four crop simulation models though Rosenzweig et al. (2014) consider seven crop simulation models. The remaining three models have fewer crops and/or temporal frames for model baseline and are thus omitted. Rosenzweig et al. (2014) find that five models, including GEPIC, LPJmL, and pDSSAT models considered in this analysis, yield broadly similar predictions. One model (LPJ-GUESS) not covered here has much higher variation in predicted crop yields under different climate scenarios. Our results may, therefore, understate the range of uncertainty of climate change impacts on potential crop yields.

To quantify uncertainty in temperature increases due to climate change, we employ outputs for five global climate models (GCM): GFDL-ESM2M (Dunne et al., 2013), HadGEM2-ES (Collins et al., 2008), IPSL-CM5A-LR (Dufresne et al., 2012),

MIROC-ESM-CHEM (Watanabe et al., 2011), and NorESM1-M (Bentsen et al., 2012). For each of the simulations, we fit a linear trend to parsimoniously characterize the evolution of crop yields in the face of climate change over the coming century.

725   Figure A1 summarizes simulation results for four crop simulation models and five climate models (with and without fertilization effects) in 2100, normalized relative to assumed yield potential in the absence of climate change. There is significant heterogeneity in terms of both direction and magnitude of climate impacts on agricultural yields across global climate models when the CO_2 fertilization effect is considered.[13] Regardless of the chosen climate model, for the scenario with fertilization effects, two out of four crop simulation models (LPJmL and pDSSAT) predict a moderate increase in potential yields (5-15 percent), whereas the PEGASUS model predicts a large decline in potential yields (20-30 percent). The GEPIC model predicts that on average crop yields will be little changed, showing a small increase in crop yields for some climate models and a small decline for other models. The predictions of LPJmL and pDSSAT models are reversed when CO_2 fertilization effects are removed, showing a decline of about 10-15 percent in potential yields. The PEGASUS model predicts an even larger decline in potential yields (30-35 percent), whereas the predictions of GEPIC model show a moderate decline of about 5-10 percent in potential yields.

Given a large variation in model predictions, we construct 5 states for potential crop yields under uncertain climate change. These states correspond to quintiles of the distribution of different model outcomes for potential crop yields by 2100. Under two optimistic states of the world, we observe a 2 and 15 percent increases in potential crop yields relative to the model baseline whereby significant CO_2 fertilization effects offset the negative effects of climate change. For the next two states, we see a 15 and 19 percent declines in potential crop yields relative to model baseline whereby CO_2 fertilization effects are either small or nonexistent, and the negative effects of climate change tend to prevail. Finally, under the most pessimistic states of the world, drastic adverse effects of climate change combined with the absence of any CO_2 fertilization effects result in a 36 percent decline in potential crop yields relative to the model baseline.

B3   Transition probabilities

745   The five possible values of the climate state $J_{1,t}$ are $\mathcal{J}_{1,1} = 0.64$, $\mathcal{J}_{1,2} = 0.85$, $\mathcal{J}_{1,3} = 0.89$, $\mathcal{J}_{1,4} = 1.02$, and $\mathcal{J}_{1,5} = 1.15$, and its probability transition matrix is

$$
P_1 = \begin{bmatrix}
0.5 & 0.25 & & & \\
0.5 & 0.5 & 0.25 & & \\
& 0.25 & 0.5 & 0.25 & \\
& & 0.25 & 0.5 & 0.5 \\
& & & 0.25 & 0.5
\end{bmatrix}
$$

---

[13]Field trials show that higher atmospheric CO_2 concentrations enhance photosynthesis and reduce crop water stress (Deryng et al., 2016). This fertilization effect interacts with other factors such as nutrient availability, and current-generation crop models are characterized by large uncertainties regarding net CO_2 fertilization potentials at larger spatial scales. In line with previous studies (Rosenzweig et al., 2014; Elliott et al., 2014a; Jägermeyr et al., 2016) we use a constant CO_2 case as pessimistic assumption regarding climate change effects, and a transient CO_2 case according to the RCP concentration pathways to reflect a more optimistic case.

where $P_{1,i,j}$ represents the probability from the j-th value of $J_{1,t}$ to the i-th value, for $1 \leq i,j \leq 5$. The three possible values of the technological state $J_{2,t}$ are $\mathcal{J}_{2,1} = 1.45$, $\mathcal{J}_{2,2} = 1.675$, and $\mathcal{J}_{2,3} = 1.9$, and its probability transition matrix is

750
$$P_2 = \begin{bmatrix} 0.4423 & 0.1416 & 0.1311 \\ 0.4139 & 0.669 & 0.4367 \\ 0.1438 & 0.1894 & 0.4322 \end{bmatrix},$$

where $P_{2,i,j}$ represents the probability from the j-th value of $J_{2,t}$ to the i-th value for $1 \leq i,j \leq 3$. We assume that $J_{2,t}$ is independent of $J_{1,t}$.

B4   Model

After we add the risks, the state vector becomes

755    $\mathbf{S} := (\mathbf{L}, \mathbf{X}, \mathbf{J})$

where $\mathbf{J}_t = (J_{1,t}, J_{2,t})$. And $\mathbf{J}$ is a Markov chain so it can be represented as $\mathbf{J}_{t+1} = \mathbf{G}_t^J(\mathbf{J}_t, \epsilon_t)$ where ϵ_t is a vector of shocks with zero means. The problem is

$$\max_{\mathbf{a}} \mathbb{E} \left\{ \sum_{t=0}^{\infty} \delta^t \mathcal{U}(\mathbf{S}_t, \mathbf{a}_t) \right\} \tag{B1}$$

subject to

760    $\mathbf{L}_{t+1} = \mathbf{G}_t^L(\mathbf{S}_t, \mathbf{a}_t)$
$\mathbf{X}_{t+1} = \mathbf{G}_t^X(\mathbf{S}_t, \mathbf{a}_t)$
$\mathbf{J}_{t+1} = \mathbf{G}_t^J(\mathbf{J}_t, \epsilon_t)$

and $\mathbf{a}_t \in \mathcal{D}_t(\mathbf{S}_t)$ representing the feasibility constraints, that is, inequality constraints and the equations other than the above transition laws. The above transition laws are just a special case of

765    $\mathbf{S}_{t+1} = \mathbf{G}_t(\mathbf{S}_t, \mathbf{a}_t, \epsilon_t)$

in the notations of Section 2 of this Appendix, so we can implement the SCEQ method to solve the dynamic stochastic programming problem. Since our time of interest is $T^* = 100$ years, we change the problem (B1) to have a finite horizon with $T = 400$ years as a larger T has little impact on our solution in the first 100 years.

In the step 2 of Algorithm 1 for the solution at time s, we replace ϵ_t by its zero mean to have $\mathbf{S}_{t+1} = \mathbf{G}_t(\mathbf{S}_t, \mathbf{a}_t, 0)$, that is,
770    $\mathbf{J}_{t+1} = \mathbf{G}_t^J(\mathbf{J}_t, 0)$. But this $\mathbf{J}_{t+1} = \mathbf{G}_t^J(\mathbf{J}_t, 0)$ is only for simplicity in notations. In fact, since $\mathbf{J}$ is a Markov chain, we replace $\mathbf{J}_t$ by its mean conditional on the realized value of $\mathbf{J}_s$ (i.e., its certainty equivalent approximation):

$[\mathcal{J}_1 \pi_{1,t,s}, \ \mathcal{J}_2 \pi_{2,t,s}]$

for all $t \geq s$, where $\mathcal{J}_1 = (\mathcal{J}_{1,1}, ..., \mathcal{J}_{1,5})$, $\mathcal{J}_2 = (\mathcal{J}_{2,1}, \mathcal{J}_{2,2}, \mathcal{J}_{2,3})$, $\pi_{1,t,s}$ and $\pi_{2,t,s}$ are two column vectors representing probability distributions of $J_{1,t}$ and $J_{2,t}$ conditional on the realized values of $J_{1,s}$ and $J_{2,s}$ respectively. If the realized values of $J_{1,s}$ and $J_{2,s}$ are $\mathcal{J}_{1,i}$ and $\mathcal{J}_{2,j}$ respectively, then we have $\pi_{1,t,s} = P_1^{t-s}\pi_{1,s,s}$ and $\pi_{2,t,s} = P_2^{t-s}\pi_{2,s,s}$, where $\pi_{1,s,s}$ is a length-5 column vector with 1 at the ith element and 0 everywhere else, and $\pi_{2,s,s}$ is a length-3 column vector with 1 at the jth element and 0 everywhere else.

Appendix C: Model Equations, Variables and Parameters

C1 Equations

Land Use

$$L = \sum_{i=A,P,C,N,R} L_t^i \tag{C1}$$

$$L_{t+1}^N = L_t^N - \Delta_t^{N,A} - \Delta_t^{N,R} + \Delta_t^{C,N} \tag{C2}$$

$$L_t^A = L_t^{A,c} + L_t^{A,b2} \tag{C3}$$

$$L_{t+1}^A = L_t^A + \Delta_t^{N,A} - \Delta_t^{A,P} + \Delta_t^{C,A} \tag{C4}$$

$$L_{t+1}^P = L_t^P + \Delta_t^{A,P} \tag{C5}$$

$$L_{t+1}^R = L_t^R + \Delta_t^{N,R} \tag{C6}$$

$$L_t^C = \sum_{v=1}^{v_{\max}} L_{v,t}^C, \tag{C7}$$

$$L_{v+1,t+1}^C = L_{v,t}^C - \Delta_{v,t}^{C,H}, \quad v < v_{\max} - 1 \tag{C8}$$

$$L^C_{v_{\max},t+1} = L^C_{v_{\max},t} - \Delta^{C,H}_{v_{\max},t} - \Delta^{C,N}_t + L^C_{v_{\max}-1,t} - \Delta^{C,H}_{v_{\max}-1,t},$$ 790 (C9)

$$L^C_{1,t+1} = \Delta^{C,C}_t$$ (C10)

$$\Delta^{C,H}_{v,t} \leq L^C_{v,t}, \quad v < v_{\max}$$

$$\Delta^{C,H}_{v_{\max},t} + \Delta^{C,N}_t \leq L^C_{v_{\max},t}$$

$$\Delta^{C,A}_t = \sum_{v=1}^{v_{\max}} \Delta^{C,H}_{v,t} - \Delta^{C,C}_t$$

795   *Fossil Fuels*

Table A1. Model Exogenous Variables

Parameter	Description	Units

Exogenous Variables

Parameter	Description	Units
$\Delta_t^{F,D}$	Flow of Newly Discovered Fossil Fuels	trillion toe
X_t^O	Other Primary Goods	trillion USD
A_t	Crop Technology Index	
$\theta_t^{c,b2}$	2G biofuels Crop Technology Index	
$\theta_t^{b2,K}$	2G Biofuels Fixed Factor Decay Index	
$\theta_{v,t}^w$	Logging Productivity Index	
θ_t^f	Food Processing Productivity Index	
θ_t^e	Energy Efficiency Index	
θ_t^l	Livestock Processing Productivity Index	
$\theta_t^{y^w}$	Wood Processing Productivity Index	
θ_t^o	Total Factor Productivity Index	
C_t^F	Fossil Fuel Extraction Cost	share of X_t^O
C_t^N	Natural Land Access Cost	share of X_t^O
C_t^R	Natural Land Protection Cost	share of X_t^O
C_t^H	Managed Forest Conversion Cost	share of X_t^O
C_t^P	Pasture Land Conversion Cost	share of X_t^O
$C_t^{C,N}$	Natural Land Restoration Cost	share of X_t^O
Π_t	Population	billion people

Table A2. Model Endogenous Variables

Parameter	Description	Units
L_t^A	Agricultural Land Area	GHa
$L_t^{A,c}$	Agricultural Land Area, food crops	GHa
$L_t^{A,b2}$	Agricultural Land Area, 2G biofuels crops	GHa
L_t^P	Pasture Land Area	GHa
L_t^C	Commercial Forest Land Area	GHa
L_t^N	Unmanaged Natural Land Area	GHa
L_t^R	Protected Natural Land Area	GHa
$\Delta_t^{N,A}$	Flow of Deforested Natural Land	GHa
$\Delta_t^{N,R}$	Flow of Protected Natural Land	GHa
$\Delta_t^{C,N}$	Flow of Restored Natural Land	GHa
$\Delta_t^{C,A}$	Managed Forest Land Converted to Agriculture	GHa
$\Delta_t^{C,C}$	Replanted Forest Land Area	GHa
$\Delta_{v,t}^{C,H}$	Harvested Forest Land Area of Vintage v	GHa
$\Delta_t^{A,P}$	Agricultural Land Converted to Pasture	GHa
X_t^F	Stock of Fossil Fuels	Ttoe
$\Delta_t^{F,E}$	Flow of Fossil Fuels Converted to Petroleum	Ttoe
$\Delta_t^{F,n}$	Flow of Fossil Fuels Converted to Fertilizers	Ttoe
x_t^p	Petroleum Products	Gtoe
x_t^n	Fertilizers	Gton
x_t^c	Food Crops	Gton

Y_t^l	Services from Processed Livestock	billion USD
Y_t^w	Services from Processed Timber	billion USD
Y_t^r	Eco-system Services	billion USD
Y_t^o	Other Goods and Services	trillion USD

Table A3. Baseline Parameters

Parameter	Description	Units	Value
Population			
Π_0	Population in 2004	billion people	6.39
Π_T	Population in time T	billion people	10.1
κ^π	Population Convergence Rate		0.042
Land Use			
L	Total Land Area	billion Ha	8.56
L_0^A	Area of Agricultural Land in 2004	billion Ha	1.53
L_0^P	Area of Pasture Land in 2004	billion Ha	2.73
L_0^C	Area of Commercial Forest Land in 2004	billion Ha	1.62
L_0^N	Area of Unmanaged Natural Land in 2004	billion Ha	2.47
L_0^R	Area of Protected Natural Land in 2004	billion Ha	0.207
ξ_0^n	Access Cost Function Parameter		0.6
ξ_1^n	Access Cost Function Parameter		105
ξ_0^R	Protection Cost Function Parameter		4.5
ξ_1^R	Protection Cost Function Parameter		400
ξ_1^P	Pasture Conversion Cost Function Parameter		170
ξ_0^H	Forest Conversion Cost Function Parameter		80
ξ_1^H	Forest Conversion Cost Function Parameter		0.004
$\xi_0^{C,N}$	Natural Land Restoration Cost Parameter		0.8
$\xi_1^{C,N}$	Natural Land Restoration Cost Parameter		400
Fossil Fuels			
X_0^F	Endowment of Fossil fuels in 2004	trillion toe	0.343
$\Delta^{F,D}$	Flow of Newly Discovered Fossil Fuels	trillion toe	0.008
ξ_1^F	Fuel Extraction Cost Function Parameter		2000
Other Primary Goods			
X_0^O	Endowment of Other Primary Goods in 2004	USD $\times 10^{13}$	3.16
$\kappa^{o,X}$	Growth Rate of Physical Capital		0.0035
$\alpha^{o,l}$	Share of demographic factors in growth of X_t^O		0.39
Intermediate Products			
θ^p	Petroleum Conversion Factor	per toe of $\Delta_t^{F,E}$	0.5
$c^{o,p}$	Petroleum Conversion Cost	share of X_t^O	0.0157

Parameter	Description	Units	Value
θ^n	Fertilizer Conversion Factor	Tton / Ttoe	1.071
$c^{o,n}$	Fertilizer Conversion Cost	share of X_t^O	0.0021
θ^{b1}	1G Biofuels Conversion Rate	toe/ton	0.283
θ^{b2}	2G Biofuels Conversion Rate	toe/ton	0.467
K	2G Biofuels Fixed Factor Index		0.005
$c^{o,b1}$	1G Biofuels Conversion Cost	share of X_t^O	0.00025
$c^{o,b2}$	2G Biofuels Conversion Cost	share of X_t^O	0.00033
a^n	Share of Agricultural Land in CES function		0.55
ρ_n	CES Parameter for Agricultural Land and Fertilizers		0.123
A_0	Crop Technology Index in 2004		13.89
κ^c	Logistic Growth Rate of Crop Technology Index		0.025
$c^{o,c}$	Food Crop Production Cost	share of X_t^O	0.016
$\theta_0^{c,b2}$	2G Biofuels Crop Technology Index in 2004		14.89
κ_{b2}	2G Biofuels Fixed Factor Decay Rate		0.05
α^{b2}	Fixed Factor Cost Share in 2G Biofuels Production		0.6
ρ_{b2}	CES Parameter for Fixed Factor and Agr. Land		-1.5
$c^{o,c}$	2G Biofuels Crops Production Cost	share of X_t^O	0.022
θ^P	Livestock Technology Index in 2004		0.69
a^l	Share of Pasture Land in CES function		0.35
ρ_l	CES Parameter for Pasture Land and Feed		-0.33
$c^{o,l}$	Livestock Production Cost	share of X_t^O	0.0055
ψ_a	Merchantable Timber Yield Parameter 1		5.62
ψ_b	Merchantable Timber Yield Parameter 2		76.5
$\overline{v}$	Minimum Age for Merchantable Timber	Years	11
κ_v^w	Timber Yield Gains of Vintage v	Share of Yield 0	0.011
c^p	Forest Planting Cost	share of X_t^O	0.0001
$c^{o,w}$	Forest Harvesting Cost	share of X_t^O	0.0021
Final Goods and Services			
θ_0^f	Food Processing Technology Index in 2004		1.5
κ^f	Food Processing Technology Index Growth Rate		0.0225
$c^{o,f}$	Food Processing Cost	share of X_t^O	0.015
θ_0^l	Livestock Processing Technology Index in 2004		1.7
κ^l	Livestock Processing Technology Growth Rate		0.0025
c^{o,y_l}	Livestock Processing Cost	share of X_t^O	0.0068

Parameter	Description	Units	Value
θ_0^e	Energy Technology Index in 2004		1.195
κ^e	Energy Technology Index Growth Rate		0.0225
ρ_e	CES Parameter for Petroleum and Biofuels		0.5
α^e	Share of Biofuels in CES Function		0.09
$\theta_0^{y_w}$	Timber Processing Technology Index in 2004		1.52
κ^{y_w}	Timber Processing Technology Growth Rate		0.0225
c^{o,y_w}	Timber Processing Cost	share of X_t^O	0.0224
θ^r	Ecosystem Services Technology Index		0.71
$\alpha^{A,r}$	Share of Agricultural Land in CES Function		0.02
$\alpha^{P,r}$	Share of Pasture Land in CES Function		0.14
$\alpha^{C,r}$	Share of Managed Forest Lands in CES Function		0.26
ρ_r	CES Parameter for Ecosystem Services		0.123
θ^R	Effectiveness Index of Protected Lands		10
$c^{o,r}$	Cost of Recreation Services		0.0296
θ_0^o	Total factor Productivity Index in 2004		1.854
κ^o	Total Factor Index Growth Rate		0.0225

Preferences and Welfare

Parameter	Description	Units	Value
α_f	AIDADS Marginal Budget Share at Subsistence Income for Services from Processed Food		0.189
α_l	AIDADS Marginal Budget Share at Subsistence Income for Services from Processed Livestock		0.035
α_e	AIDADS Marginal Budget Share at Subsistence Income for Energy Services		0.112
α_w	AIDADS Marginal Budget Share at Subsistence Income for Services from Processed Timber		0.036
α_r	AIDADS Marginal Budget Share at Subsistence Income for Ecosystem Services		0.049
α_o	AIDADS Marginal Budget Share at Subsistence Income for Other Goods and Services		0.579

Table A3: Baseline Parameters (continued)

Parameter	Description	Units	Value
β_f	AIDADS Marginal Budget Share at High Income for Services from Processed Food		0.028
β_l	AIDADS Marginal Budget Share at High Income for Services from Processed Livestock		0.011
β_e	AIDADS Marginal Budget Share at High Income for Energy Services		0.049
β_w	AIDADS Marginal Budget Share at High Income for Services from Processed Timber		0.032
β_r	AIDADS Marginal Budget Share at High Income for Ecosystem Services		0.104
β_o	AIDADS Marginal Budget Share at High Income for Other Goods and Services		0.776
γ^f	AIDADS Subsistence Parameter for Processed Food		0.45
γ^l	AIDADS Subsistence Parameter for Processed Livestock		0.003
γ^e	AIDADS Subsistence Parameter for Energy Services		0.026
γ^w	AIDADS Subsistence Parameter for Processed Timber Products		0.027
γ^r	AIDADS Subsistence Parameter for Ecosystem Services		0.028
γ^o	AIDADS Subsistence Parameter For Other Goods and Services		0.346
γ	Risk Aversion Parameter		2
δ	Social Discount Rate		0.95
