**Abstract.** Large eddy simulation (LES) provides an optimal tool to examine air pollutant concentrations at high temporal and spatial resolutions within urban neighborhoods. The local mixing conditions are to a large extent a result of building morphology and thermal conditions impacting mechanically and thermally driven turbulence. However, the impact of thermal conditions on local air pollutant concentrations in real urban environments is not well understood nor the importance of including thermal processes in LES. Furthermore, LES of aerosol particle concentrations in urban areas rarely include aerosol processes, but rather aerosols are treated as passive scalars. The aim of this study is to examine the importance of radiative heating and aerosol processes in simulating local aerosol particle concentrations in a wide street canyon and its surroundings in Helsinki under morning rush hour with calm wind conditions using the LES model PALM. The model outputs are evaluated against mobile laboratory measurements of air temperature and total particle number concentration ( $N_{tot}$ ), and drone measurements of lung deposited surface area (LDSA).

The inclusion of radiation interaction in LES has a significant impact on simulated near surface temperatures in our study domain increasing them on average by 3.8 °C from 8.6 °C to 12.4 °C. The thermal processes further strengthen the flow field, and enhance the ventilation of air pollutants from the street canyon by altering the canyon vortex. The enhanced ventilation reduces the pedestrian level (4 m)  $N_{tot}$  by 53%. The reduction of  $N_{tot}$  due to aerosol processes is smaller, only 18%. Aerosol processes have a larger effect in the smallest particle range, decreasing particle concentrations below 10 nm by up to 2.5 orders of magnitude whereas radiation interaction is more important in the larger particle range. Aerosol processes have a stronger impact than ventilation on LDSA, whereas radiation interaction shows a larger decrease in  $PM_{2.5}$  than in other aerosol metrics. The inclusion of radiation interaction in PALM improves the modelled near-surface temperatures and  $N_{tot}$  when compared to mobile laboratory measurements reducing the bias between the modelled and measured temperatures from -3.9 °C to +0.2 °C, and concentrations from +98% to -13%. With both aerosol and radiation interaction on, the underestimation was 16 %, which might be due to overestimation of the ventilation. The results show how inclusion of radiative interaction, and to a lesser

extent aerosol processes, on LES are important for realistic simulation of near surface aerosol particle concentrations. This particularly in a calm wind situation such as modelled in this study.

## 1 Introduction

25 Urban air pollution has been recognized to be one of the major global challenges as it has been estimated to result annually up to 0.8 million premature deaths in Europe (Lelieveld et al., 2019) and 3 million deaths worldwide (Lelieveld et al., 2015; WHO, 2016). The numbers are expected to increase further in future as the number of global population living in urban areas is projected to increase from current 55% (2018) to 68% by 2050 (United Nations, 2019). Often the poorest air quality is observed at pedestrian level in street-canyons due to vicinity of road traffic and degraded ventilation (Kurppa et al., 2020).  
30 Ventilation of a street-canyon or a wider urban area depends on building morphology but also on radiative processes resulting in increased turbulent production and mixing of air when solar radiation is present (Tominaga and Stathopoulos, 2013; Nazarian and Kleissl, 2016; Park et al., 2017). Understanding the effect thermal turbulence production can have on urban air is thus important to accurately describe urban ventilation and air quality.

Turbulence and street canyon flows have been researched intensively in recent years through computational fluid dynamics (CFD) modelling (e.g. Letzel et al., 2012; Park and Baik, 2013; Kwak et al., 2015; Kurppa et al., 2020). From the two main  
35 modelling methods, Reynolds-averaged Navier–Stokes (RANS) and Large-Eddy Simulation (LES), LES has been found to perform better in resolving instantaneous turbulence in realistic complex urban settings (Salim et al., 2011; García-Sánchez et al., 2018). In LES the subgrid scale turbulence is parameterised but otherwise the three-dimensional wind field and scalar variables describing boundary layer flows are solved with high spatial and temporal resolution (Maronga et al., 2020). LES  
40 has been used to examine the impact of thermal effects on urban ventilation in idealised urban areas (Nazarian and Kleissl, 2016; Nazarian et al., 2018; Duan and Ngan, 2020; Wang et al., 2021; Zhou et al., 2021; Cintolesi et al., 2021) whereas most simulations in realistic urban settings have not yet included the effect of solar radiation induced thermal turbulence on street canyon flow patterns and ventilation (e.g. Salim et al., 2011; Kurppa et al., 2020; Karttunen et al., 2020). Earlier simulations  
45 over realistic neighbourhoods have rather focused on simplified radiation schemes or heating parameterization through other means (Park and Baik, 2013; Nazarian et al., 2020). Implementing a radiation scheme to an LES model offers a way to model the complex radiative transfer processes in urban areas, such as multiple reflections, diffuse radiation and the effect of shading, and further the resulting thermal effects on flow structures (Resler et al., 2017).

Mechanically and thermally driven turbulence modifies ventilation and thus urban air pollutant concentrations, but for realistic simulation of air pollutants and particularly aerosol particle concentrations, aerosol particle dynamics accounting for their  
50 chemical and physical processes need to be considered (Kurppa et al., 2019, 2020). However, only a few LES models allow detailed description of aerosol particles, their size distributions and dynamic processes (Steffens et al., 2013; Kurppa et al., 2019; Zhong et al., 2020).

The main aim of this study is to examine the impact of radiative effects on flow field, temperature distributions and local aerosol particle concentrations in an built-up neighbourhood in Helsinki under calm wind conditions during morning rush

55 hour. In addition, the relative importance of including radiative effects and aerosol processes in simulating aerosol particle  
concentrations and distributions will be examined. The LES model PALM (Maronga et al., 2020) will be used in the simulations  
as it allows for realistic description of the urban surface and aerosol dynamics, and it can be coupled with the radiation module  
RRTMG (Rapid Radiative Transfer Model for Global models, Krč et al., 2021) to account for radiative interaction. Model  
outputs will be compared against LDSA concentrations of aerosol particles measured using a drone, and total particle number  
60 concentration and air temperature measured using a mobile laboratory (Järvi et al., 2023).

## 2 Methods

### 2.1 PALM

PALM is an LES model used to study atmospheric and oceanic boundary layer dynamics (Maronga et al., 2020). PALM  
solves the non-hydrostatic, filtered and incompressible Navier–Stokes equations of wind ( $u$ ,  $v$ , and  $w$ ) and scalar variables,  
65 including turbulent kinetic energy, potential temperature and specific humidity, in a Boussinesq-approximated form. As the  
model is well-scalable on massively parallel computer architectures, it is particularly well-suited for urban simulations on  
domains up to a city-scale with a fine grid resolution. PALM has also a self-nesting capability allowing a fine grid resolution  
within the main domain of interest (i.e. child domain), and coarser resolution in parent and root domains allowing large total  
modelling domain (Hellsten et al., 2021). Moreover, PALM has multiple features which enhance its usability to examine urban  
70 turbulence. First of all, it utilises surface models such as the Land-Surface Model (LSM) and the Urban Surface Model (USM)  
solving the energy balance for each surface (Resler et al., 2017; Gehrke et al., 2020). LSM requires the use of a radiation  
scheme, which is provided by the external RRTMG library embedded in PALM and enabled in these simulations (Krč et al.,  
2021). Secondly, PALM has a plant canopy model (PCM) which is used to model the interaction between vegetation and flow  
(Karttunen et al., 2020). Finally, the Sectional Aerosol module for Large Scale Systems (SALSA) is used to solve the aerosol  
75 processes responsible for modifying the size distribution and pollutant interaction with the surface in PALM (Kurppa et al.,  
2019, 2020). The most important modules for this study are RRTMG and SALSA.

#### 2.1.1 RRTMG

RRTMG (Rapid Radiative Transfer Model for Global models) is an external library, which can be used with PALM to provide  
the variables responsible for describing the radiative interaction between the surface and the atmosphere. It supplies the surface  
80 models USM and LSM with the necessary components to solve the energy balance over all surfaces (Resler et al., 2017; Salim  
et al., 2020; Gehrke et al., 2020). RRTMG takes in information about the time of day and coordinates, which it then uses to  
calculate incoming solar radiation to be fed into the radiation scheme of USM and LSM. It is capable of calculating multiple  
reflections, diffuse radiation and absorbed radiation on different surfaces. Sky-view factors are calculated at each radiation  
timestep and on both vertical and horizontal grid points, which describe the amount of sky visible from a given surface as a  
85 fractional number between 0 - 1 (Salim et al., 2020; Krč et al., 2021).

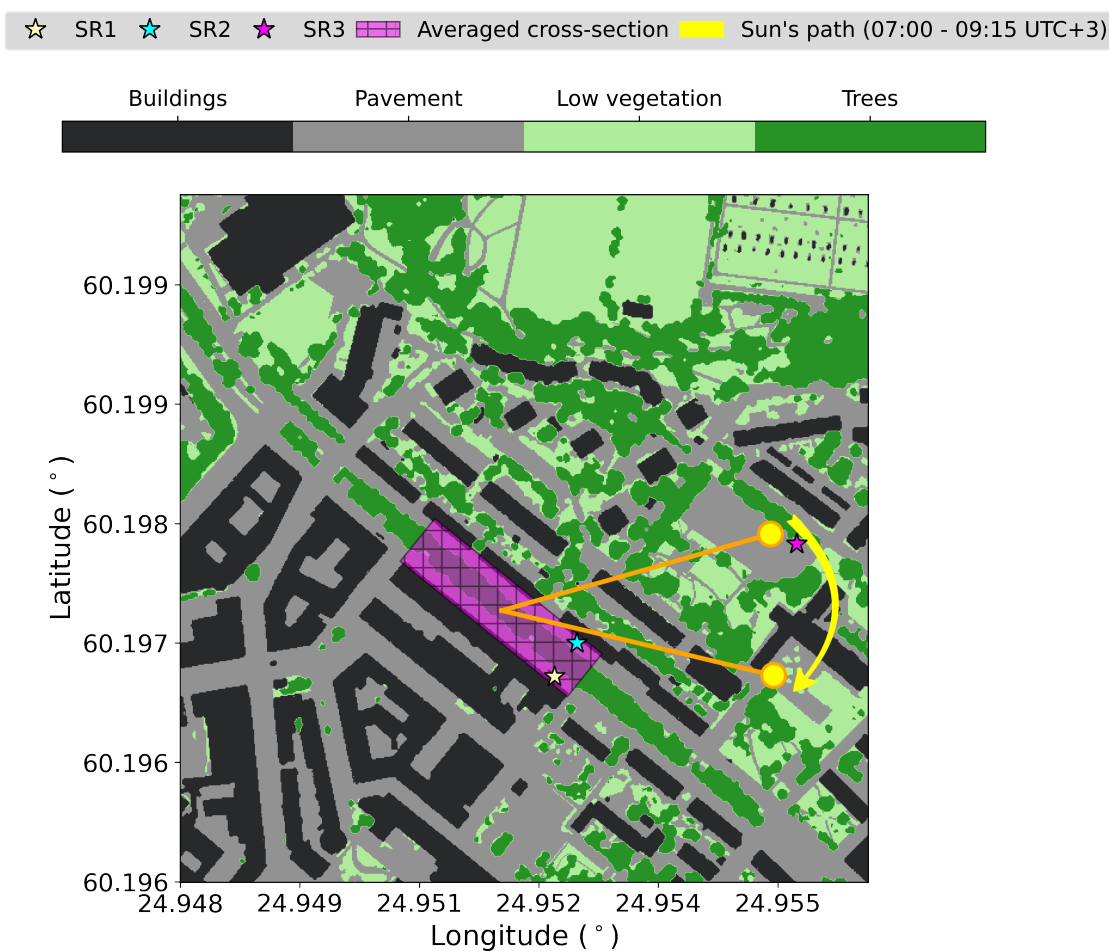

### 2.1.2 SALSA

The sectional aerosol module SALSA (Kokkola et al., 2008), which has embedded in the PALM model system (Kurppa et al., 2019), is employed to describe the aerosol population by discretizing the aerosol number size distribution into several size bins based on the geometric mean dry particle diameter. Each bin can be composed of different chemical components including sulphate, organic carbon, black carbon, nitrate, ammonium, sea salt, mineral dust, and water. The hybrid bin method is used for the update of aerosol size distribution in both two subranges (Kokkola et al., 2018). SALSA is designed to resolve aerosol microphysical processes in a very large number of grid points, comprising of nucleation, coagulation, condensation, dissolution, as well as dry deposition on horizontal and vertical surfaces and resolved-scale vegetation. The implementation of SALSA is flexible so that the user can decide the number of size bins, diameter range of aerosols, specific chemical components, and involved aerosol dynamic processes.

## 2.2 Model setup

Our study area is a 42-meter wide street canyon (average height to width  $H/W=0.45$ ) and its immediate surroundings in Helsinki, Finland (Figure 1), on an early summer morning on the 9th of June, 2017. The street canyon has pavement and three lanes for both directions with the outermost lanes next to the pavement reserved for public transport. In the middle there are two tram lines with street tree rows separating them from the lanes. An urban air quality monitoring supersite operated by the Helsinki Region Environmental Services Authority is located on the southern side of the street canyon. The simulation setup consists of a root (768,768 cells), parent (768,768 cells) and child (576, 576 cells) domain, each with an increase in horizontal resolution by a factor of 3 when moving from root (9 m) to the smaller domains (3 m in parent and 1 m in child). The surface energy balance and flow are solved in each domain whereas SALSA is only enabled in the child domain. Dynamic boundary conditions are supplied by numerical weather prediction data from the MetCoOp Ensemble Prediction System (MEPS, Bengtsson et al., 2017; Müller et al., 2017) which provides the necessary forcing for initializing the large scale motions in the atmosphere. The trajectory model for Aerosol Dynamics, gas and particle phase CHEMistry (ADCHEM, Roldin et al., 2011b), provides the background trace gas concentrations, particle number concentrations and chemical composition of aerosol particles for SALSA. Emissions from road traffic within the child domain are estimated by combining information on hourly vehicle fleet composition, and particle number and gaseous unit emissions factors. In SALSA the aerosol particle size distribution is described by 10 bins ranging from 2.5 nm to 1  $\mu\text{m}$ , and the particles contain sulphate, organic carbon, black carbon, nitrate, and ammonium. The aerosol processes of condensation, coagulation, and dry deposition are included and calculated per second. More information on the model setup can be found from Kurppa et al. (2020).

RRTMG uses information about the usage and built time-period of buildings (Appendix A1), pavement materials (Appendix A3) and vegetation types (Appendix A2) to model the thermal and radiative properties of each surface. Building usage for our study area and the time-period they were built were obtained from the City of Helsinki open database (HRI, 2017, see Supplementary material). Soil information (Appendix A4) needed by the LSM was retrieved from the national land survey of Finland (GTK, 2018).

**Figure 1.** Child domain of the model setup including the location of three statistical regions (SRs), area used to calculate street canyon cross-section and the Sun's path during the main run.

### 2.3 Model runs

120 In order to understand the effect of radiation (R) and aerosol processes (A) on aerosol particle distributions both together and separately, four model runs are performed.  $R_0A_0$  is the base run, with both aerosol processes and radiation turned off. This run purely solves the flow and aerosol dispersion as passive scalars, and the spatial distribution of particles and ventilation is only affected by the mechanical processes.  $R_0A_1$  increases the level of complexity by including the aerosol processes (condensation,

coagulation and deposition) while leaving the radiation out.  $R_1A_0$  on the other hand has radiation turned on, but only simulates  
 125 the transport of the aerosols, without any aerosol processes affecting their size distribution.  $R_1A_1$  combines the two processes  
 together and simulates both radiation and aerosol processes being the most complex in terms of the amount of processes  
 affecting the simulation.  $R_0A_1$  is the same model setup as in Kurppa et al. (2020). The PALM revision used in this study is  
 r4734.

**Table 1.** Summary of the model runs discussed in this study. R (radiation) and A (aerosol processes) describe the changing conditions  
 between the runs and the subscript under them tells if that part of the simulation is turned on (1) or off (0).

	$R_0A_0$	$R_0A_1$	$R_1A_0$	$R_1A_1$
Radiation on	✗	✗	✓	✓
Aerosol processes on	✗	✓	✗	✓

## 2.4 Initialisation

130 Simulation time of the model runs is separated into three parts: spin-up, precursor and main run (Figure 2). The main run of  
 all modelled processes including SALSA covers the time period 07:00 - 09:15 UTC+3, which was chosen as observations  
 from an intensive observational campaign of local air quality are available for model evaluation (Järvi et al., 2023). Before the  
 main run, a precursor run to initialise flow and turbulence (06:00 - 07:00 UTC+3) is performed (Kurppa et al., 2020). From  
 the restart data provided by the precursor run, PALM is able to start the main run to get the final output data. In addition, the  
 135 runs with radiation enabled require an additional spin-up run of 24 hours (full diurnal cycle of solar radiation) for realistic  
 development of surface temperatures to accurately model the heat exchanges with the atmosphere (Resler et al., 2017; Krč  
 et al., 2021). For the spin-up run (8 June 06:00 – 9th June 06:00 UTC+3), PALM needs the mean and variation amplitude of  
 the potential temperature, which were calculated to be 12°C and 3°C using the Finnish Meteorological Institute (FMI, 2017)  
 weather station data, and taking the 24-hour mean temperature and difference between minimum and maximum temperatures  
 140 during the precursor period. The precursor run period is cloudy, with little diurnal variation in air temperature (Figure 2). The  
 morning at the time of the main run is less cloudy and solar radiation is already at the same level at 8 am as the maximum of the  
 previous day. Wind is from the west and during the main run, the wind turns from 273° to 305° and the wind speed increases  
 due to the rising sun.

## 2.5 Data analysis

145 Data with greater temporal and spatial resolution than what is saved from the full domains are saved from specific statistical  
 regions between 0.1 s intervals at 1 m resolution. In our analysis we use four such regions (see also Figure 1). Statistical  
 regions SR1 and SR2 cover 5 m×5 m areas from ground level to height of 144 m on opposite sides of the main street canyon  
 named hereafter supersite and opposite supersite (Kurppa et al., 2020). Similarly, SR3 is a 5 m×5 m×144 m column repre-

**Figure 2.** Meteorological conditions during the whole simulation period as measured on the Finnish Meteorological Institute weather station located at Kumpula every 10 minutes. Variables plotted are wind arrows (a), temperature ( $T$ ) (b), wind speed ( $WS$ ) and gusts ( $WG$ ) (c), cloud cover (d) and global radiation (e). Grey area highlights the spinup run, blue the precursor run and red the main run.

150 sending a background measurement site away from the main street canyon. All three statistical regions save profile information about wind components, fluxes, air temperature and available SALSA output of particle number size distribution, total particle number concentration ( $N_{tot}$ ), number concentration for ultrafine particle (UFP, particles with aerodynamic diameter less than  $0.1 \mu\text{m}$ ), particulate mass for particles with aerodynamic diameter below  $2.5 \mu\text{m}$  ( $\text{PM}_{2.5}$ ), and LDSA. Different aerosol metrics

are analysed as they reflect the characteristics of particles with different sizes. It has been reported that dispersion is somewhat different for smaller and larger particles (Rivas et al., 2017; Karttunen et al., 2020). The statistical regions SR1 and SR2 are  
155 chosen to get model output data with higher temporal resolution enabling comparison to LDSA observations made using a drone, and SR3 to get comparison how the vertical profiles of aerosol particles look like outside the emission sources.

Additionally, a fourth area of interest is calculated for the cross-section of the main street canyon covering a 176 m long section (Figure 1). This is not saved as a separate statistical region but rather taken as a subset from a mask area slightly smaller than the child domain containing only the main street and its immediate surroundings. The street canyon section is chosen as  
160 it follows the long building on the southwestern side and is between two side streets coming from the west. The area is chosen to provide an overall understanding of the flow and aerosol fields within the street canyon. The mean cross-section for this area is calculated by applying a  $51^\circ$  coordinate rotation to the horizontal wind components in order to align the street with the y-coordinate direction. The cross-sectional wind analysis and  $N_{tot}$  analysis use data from 2 to 32 meters above the ground that follow the terrain. Analysed data cover the time period 7:00-9:15 when only modelled data are analysed, and time period 7:15-  
165 9:15 when modelled data are compared to drone observations. Additionally, colourblind-friendly colour maps were provided by Crameri (2021).

## 2.6 Observations

During the measurement campaign, observations with a mobile laboratory Sniffer (Pirjola et al., 2004) and a drone were conducted (Järvi et al., 2023). The mobile laboratory measured  $N_{tot}$  using a Condensation Particle Counter (CPC, TSI 3776,  
170 TSI Ltd, USA) and a 2-meter air temperature using a temperature and humidity probe (HMP45A, Vaisala Oyj, Finland) with a 1-s resolution. The inlet for the aerosol instrument was located above the windshield at 2.9 m. The van speed and position were recorded using a global positioning system (model GPS V, Garmin). The van was driving along the main street canyon and its side streets, and standing at the background, supersite and opposite supersite (i.e. matching with the statistical regions). Mean temperature and  $N_{tot}$  were calculated for 5 m x 5 m grids for 07:15–09:15 within the area where the mobile laboratory  
175 was driving (Kurppa et al., 2020).

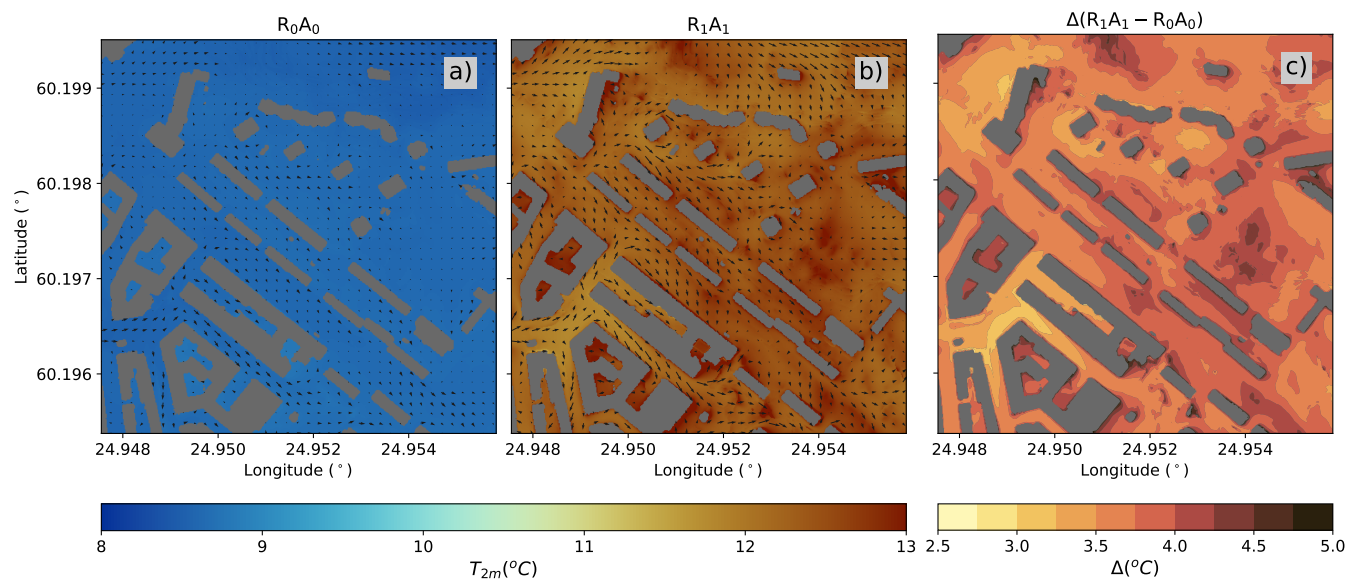

At the same time with the mobile laboratory, a multi-rotor drone (X8, VideoDrone Finland Ltd) was measuring the vertical distribution of the alveolar LDSA of aerosol particles using an electrical particle sensor (Partector, Naneos GmbH, Switzerland). The measurements were done within the statistical subregions SR1 and SR2 located on both sides of the street canyon. The drone flew 10 times up and down between  $z = 2$  and 50 m during one 30-min measurement interval, after which measure-  
180 ments were repeated on the other side. Geometric mean profiles from the 10 repetitions for the supersite (opposite supersite) were calculated for time periods 07:16-07:44 (07:54-08:14) and 08:23-08:44 (08:51-09:15). More details of the drone measurements and data analysis can be found from Kuuluvainen et al. (2018).

### 3 Results and discussion

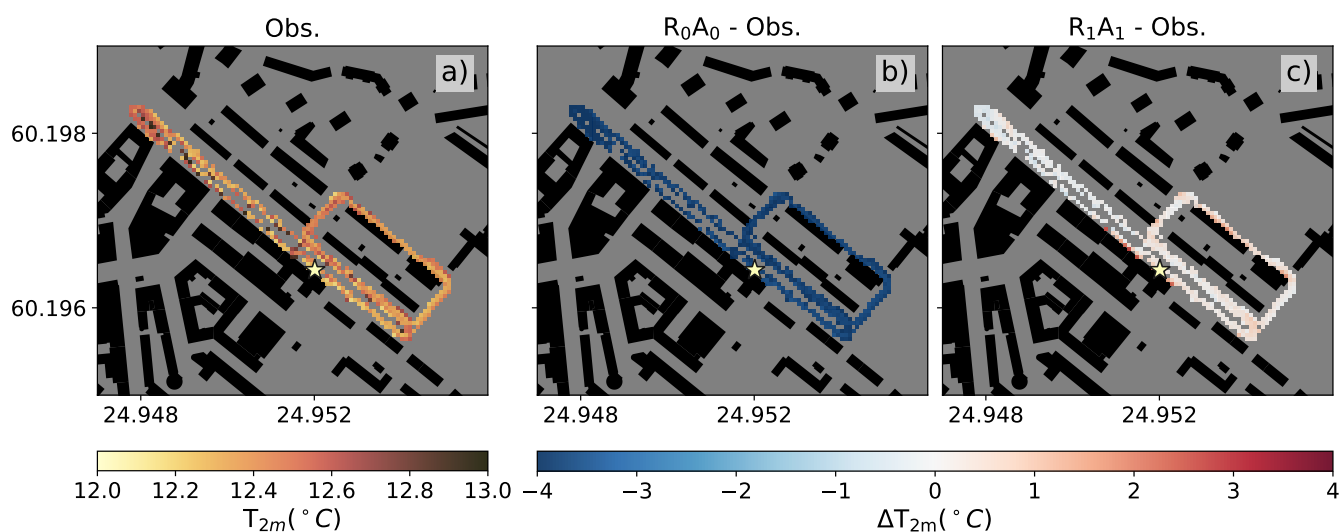

#### 3.1 Near surface air temperature

185 Figure 3 shows the overall change in the mean near surface air temperature at a height of 2 metres ( $T_{2m}$ ) for the base run  $R_0A_0$   
without radiation interaction and aerosol processes, and for the model run with both aerosol and radiation interaction on ( $R_1A_1$ )  
within the child domain. In the base run  $R_0A_0$ , the mean  $T_{2m}$  over the child domain is  $8.6^\circ\text{C}$  and varies spatially between  $8.4$  to  
 $8.9^\circ\text{C}$  (Figure 3a) whereas in  $R_1A_1$ , the mean overall  $T_{2m}$  is  $12.4^\circ\text{C}$ , and ranges spatially between  $11.2$  and  $17.9^\circ\text{C}$ . Thus, there  
is an average increase of  $3.8^\circ\text{C}$  within the entire child domain in  $R_1A_1$  when compared to  $R_0A_0$ . The largest  $T_{2m}$  increase is  
190 observed close to the eastward facing building walls in the main street canyon. This is due to the early morning sun heating the  
walls and creating a more heterogeneous temperature distribution compared to  $R_0A_0$ . Aerosol processes do not affect radiation,  
but they impact the flow (Sühling, 2022), which in turn affects near surface air temperatures. This impact is however minor  
with  $-0.6\%$  difference in  $T_{2m}$  between  $R_1A_0$  and  $R_1A_1$ . Thus, we can say that the difference between  $R_0A_0$  and  $R_1A_1$  is caused  
by radiation interaction.

**Figure 3.** Near surface ( $z = 2$  m) mean air temperature ( $T_{2m}$ ,  $^\circ\text{C}$ ) and flow field (arrows) for the base run  $R_0A_0$  without radiation interaction and aerosol processes (a) and for run  $R_1A_1$  with both radiation interaction and aerosol processes on (b), and the difference of  $R_0A_0$  and  $R_1A_1$  (c) averaged over 7:00-9:15 in the child domain.

195 The observed  $T_{2m}$  measured by the mobile laboratory are in the range of  $12$ - $13^\circ\text{C}$  with a spatial mean of  $12.4^\circ\text{C}$  (Figure 4a).  
When compared to the modelled temperatures (Figure 4b,c),  $R_0A_0$  underestimates  $T_{2m}$  by  $3.9^\circ\text{C}$  due to lack of heat exchange  
between the surface and atmosphere, and the absence of solar radiation (Gehrke et al., 2020). When comparing these to  $R_1A_1$ ,  
an immediate improvement is visible, with a decrease in the bias from  $-3.9^\circ\text{C}$  to  $+0.2^\circ\text{C}$ . With radiation interaction turned

**Figure 4.** Observed 2-m air temperature ( $T_{2m}$ , °C) (a), the temperature difference between the base run ( $R_0A_0$ ) without radiation interaction and aerosol processes on and observations (b), and the temperature difference between  $R_1A_1$  with radiation interaction and aerosol processes on and observations (c). Negative values indicate underestimation and positive values overestimation of the observations.

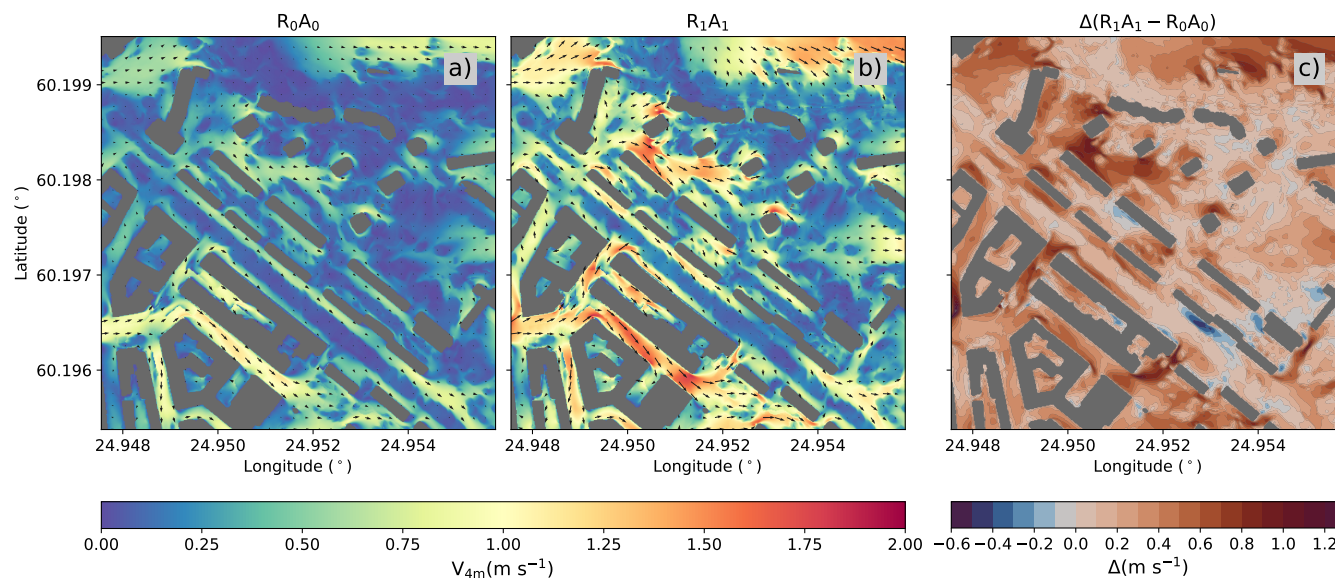

on, the overall spatial distribution of air temperature falls in the same range at 12.7°C for the whole area. This shows the  
 200 model describes heating of the surfaces correctly. There are some areas with slightly larger air temperatures compared to the  
 observations close to western side wall next to the supersite. Similar behaviour of the highest temperatures on one side of a  
 street canyon is also reported in Jiang and Yoshie (2018). This can be attributed to the amount of solar radiation received, as  
 a large gap between buildings on the opposite side of the street combined with low azimuth angles of the sun cause this strip  
 of wall to receive more incoming shortwave radiation than the rest of Mäkeläinkatu (Oke, 1988). The used revision of PALM  
 205 (r4734) is known to overestimate heat input at vertical walls by roughly 20%, which can at least partially explain this near 1°C  
 maximum difference (PALM Model System, 2021).

### 3.2 Flow field

In order to examine differences in the flow fields,  $R_0A_0$  and  $R_1A_1$  are examined at a height of 4 metres ( $V_{4m}$ ) (Figure 5). In the  
 base run  $R_0A_0$ , the highest  $V_{4m}$  are visible at the side street Southwest of the main street canyon reaching 1.3 m s<sup>-1</sup> and over  
 210 an open flat terrain in the northern part of the child domain reaching 0.9 m s<sup>-1</sup> (Figure 5a). In  $R_1A_1$ , the flow field stays similar  
 to  $R_0A_0$  (Figure 5b) but an increase in the overall  $V_{4m}$  is seen (Figure 5c). In this case, the smaller street canyon southwest of  
 the main street canyon experiences stronger winds reaching 2.1 m s<sup>-1</sup>. Some spots such as the eastern side of the main street  
 show slight decrease in  $V_{4m}$  by 0.6 m s<sup>-1</sup>. The smallest difference in  $V_{4m}$  between the two model runs is found at the location  
 of the trees, where the tree canopies slow down the flow. Overall the mean flow increases by 89% in the child domain from 0.29

215 ( $R_0A_0$ ) to  $0.54 \text{ m s}^{-1}$  ( $R_1A_1$ ) at the 4-meter height due to enhanced circulation from radiative warming and cooling (Figure 6). Aerosol processes have minor impact on the flow causing a minor increase of 0.1% from  $R_0A_0$  to  $R_0A_1$  and 4.8% from  $R_1A_0$  to  $R_1A_1$  in  $V_{4m}$ . During the main run, the mean wind direction in the beginning of the simulation period is from the west but turns northwesterly during the simulation. The wind turning is greater in the base run compared to  $R_1A_1$ . The increase in wind speeds with heated surfaces has been commonly reported in previous studies (Li et al., 2010; Cheng and Liu, 2011; Li et al., 220 2012), which have reported an increase of 100%, 150% and 150% from neutral to a slightly unstable case in idealised street canyon configurations. In these studies, no changes in wind direction were seen likely due to fixed wind direction relative to idealised street canyons. In our simulations, the wind direction changes during the simulation period presenting more realistic wind pattern.

**Figure 5.** Mean horizontal wind speed at 4-m height ( $V_{4m}$ ) between 07:00 - 09:15 for the base run ( $R_0A_0$ ) when radiation effects are turned off (a) and for run with radiation effects turned on  $R_1A_1$  (b), and the absolute change in horizontal wind speed between the two model runs (c).

Figure 6 shows the street canyon vortex within the main street canyon (see Figure 1) for  $R_0A_0$  and  $R_1A_1$ .  $R_1A_1$  shows the 225 effect of radiative forcing with stronger opposing wind speeds. Maximum ascent (descent) increased from  $0.15 \text{ m s}^{-1}$  ( $-0.13 \text{ m s}^{-1}$ ) in  $R_0A_0$  to  $0.69 \text{ m s}^{-1}$  ( $-0.33 \text{ m s}^{-1}$ ) in  $R_1A_1$ , due to radiative cooling and warming on opposite sides of the street canyon. In the middle of the canyon, the effect of street trees is visible with enhanced ascent due to warming canopy, which spreads the area of ascent more toward the middle of the canyon. Similar changes to vortex were reported by Xie et al. (2005) and Bottillo et al. (2014) in idealised street canyon setups. As mentioned already above, the mean wind direction remains more westerly in 230  $R_1A_1$  when compared to  $R_0A_0$ . This increases the cross-flow component over the canyon in  $R_1A_1$  and is one possible cause for the more organized canyon vortex (Offerle et al., 2007; Dimitrova et al., 2009). This change in both the vortex structure

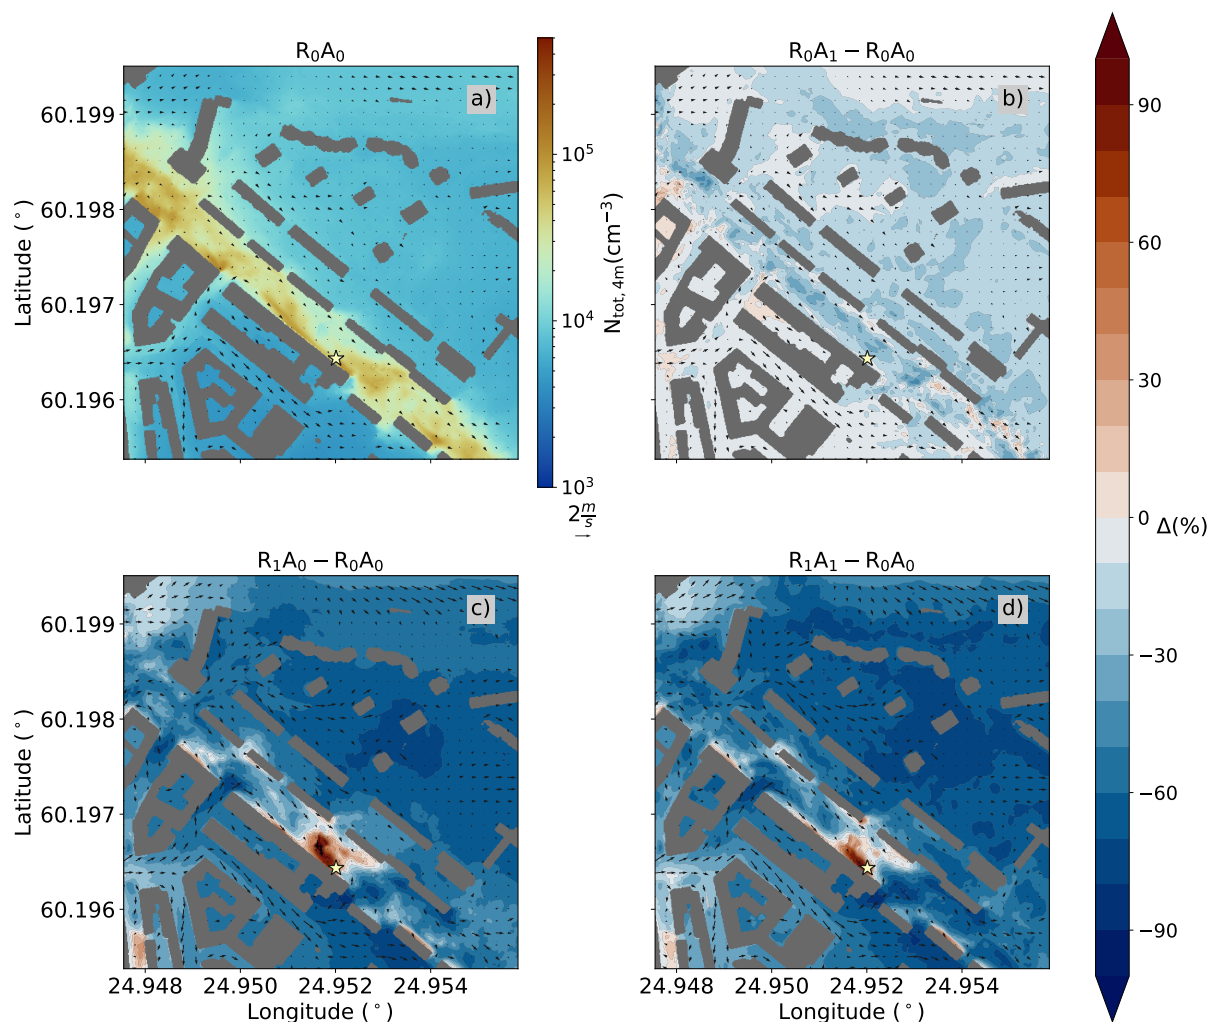

**Figure 6.** Street canyon vortex mean flow for the base run  $R_0A_0$  with no radiation interaction (a) and  $R_1A_1$  when the radiation model is turned on (b), averaged along the canyon over the shaded area shown in Figure 1. The streamlines describe the flow rotating around the y-axis aligned with the street and the colors describe the vertical wind speed. Black areas represent buildings on both sides of the street, with an additional measurement container on the western side.

and strength in an unstable case compared to a neutral one has been shown in numerous studies (Nezis et al., 2011; Mei et al., 2016; Guo et al., 2020). Previous studies suggest also that canyon vortices in wide street canyons are sensitive to the time of day, since heating of the windward wall would hinder the vortex instead of strengthening it, causing an entirely different flow structure in the canopy layer (Sini et al., 1996; Xie et al., 2005). As this is a calm wind case (mean wind  $0.54 \text{ m s}^{-1}$ ), the effect of solar heating induced thermal turbulence has a larger effect on the flow than what would be with higher wind speeds (Bottillo et al., 2014). On the other hand, we simulate an early morning when solar radiation is around  $240 \text{ W m}^{-2}$  when compared to midday radiation levels reaching  $920 \text{ W m}^{-2}$  when the radiative heating is going to be even stronger.

### 3.3 Aerosol particle number concentration

The spatial variability of total particle number concentration at 4 metres height ( $N_{tot,4m}$ ) for the base run  $R_0A_0$ , and the differences of model runs  $R_0A_1$ ,  $R_1A_0$  and  $R_1A_1$  compared to the base run are shown in Figure 7.  $R_0A_0$  shows the largest concentrations on the Western side of the main street canyon reaching up to  $155.4 \cdot 10^3 \text{ cm}^{-3}$ . This is due to the canyon vortex transporting traffic emissions to leeward side of the street canyon (Nezis et al., 2011; Jiang and Yoshie, 2018; Chen et al., 2020; Kurppa et al., 2020). Slightly smaller concentrations are seen when moving towards the southeast compared to other parts of the street canyon (Figure 7a). The side streets and surrounding areas away from the main street traffic emissions show the smallest concentrations staying above  $3.6 \cdot 10^3 \text{ cm}^{-3}$ . When only aerosol processes are turned on ( $R_0A_1$ ), there is generally a decrease in  $N_{tot,4m}$  where trees in the main street canyon are located (Figure 7b). This is due to dry deposition removing

**Figure 7.** Mean total particle number concentration ( $N_{tot,4m}$ ) and horizontal wind speed (arrows) at 4 metre height for the base run  $R_0A_0$  (a), and the change in percentages of  $R_0A_1$  (b),  $R_1A_0$  (c) and  $R_1A_1$  (d) compared to  $R_0A_0$ . Supersite is marked with a yellow star.

particles from the air (Buccolieri et al., 2011; Karttunen et al., 2020). With only radiation interaction turned on ( $R_1A_0$ ),  $N_{tot,4}$  decreases on average by 53% from  $15.7 \cdot 10^3 \text{ cm}^{-3}$  to  $7.0 \cdot 10^3 \text{ cm}^{-3}$  in the child domain as the increased wind speed enhances the particle transport from the 4-metre height upward (Figure 7c). An exception is seen close to building walls along the main street canyon in the central area. A small area of stagnating horizontal flow is formed in the middle close to the supersite (SR1), which combined with the overall pollutant transport to the leeward side of the street results in the largest increase in total particle concentrations. This transport of pollutants to the leeward side has also been reported by Jiang and Yoshie (2018) and Chen et al. (2020). The upward transport of pollutants starts at 4-meters height and particles are then swept away above the canopy by the free flow.

Aerosol processes ( $R_0A_1$ ) alone decrease  $N_{tot,4m}$  in the child domain by 18%, while thermal turbulence alone ( $R_1A_0$ ) decreases the concentrations by 53%. When the combined effect from radiation and aerosol processes ( $R_1A_1$ ) are considered,  $N_{tot,4m}$  is decreased by 56%. Previous studies (Nezis et al., 2011; Li et al., 2012, 2015) have also concluded that under unstable stratification, the enhanced vertical motion and injections upward from the canyon reduce street canyon aerosol concentrations by up to 50% at low levels.

The modelled particle number concentrations at 2 metre height ( $N_{tot,2m}$ ) are compared with the mobile laboratory measurements in the child domain (Figure 8). The base run  $R_0A_0$  and the run with only aerosol processes on ( $R_0A_1$ ) show on average 98% and 74% larger  $N_{tot,2m}$ , respectively, than what is measured (Figure 8a).  $R_0A_1$  performs better compared to  $R_0A_0$  as the effect of aerosol processes decreases the overall particle concentrations. When introducing radiation interaction, the model performs much better, with 13% ( $R_1A_0$ ) and 16% ( $R_1A_1$ ) decrease in  $N_{tot,2m}$  compared to observations. The enhanced pollutant dispersion away from the surface decreases  $N_{tot,2m}$  at nearly all locations, especially along the side streets. This enhanced ventilation has also been reported in other studies using idealised street canyons (Mei et al., 2016; Guo et al., 2020). Thus, radiation decreases also the absolute difference when compared to measurements and performs better compared to when radiation interaction is absent. The base run ( $R_0A_0$ ) and the run with only aerosol processes on ( $R_0A_1$ ) perform better in the southern sector of the main street canyon, but due to the large overestimation at the northern end of the street,  $R_1A_0$  and  $R_1A_1$  perform better overall.

Figure 9 shows the averaged cross-section of  $N_{tot}$  in the main street canyon. In the base run  $R_0A_0$ , the highest concentrations reaching  $104 \cdot 10^3 \text{ cm}^{-3}$  are modelled at the ground level on the western side of the street canyon due to the street canyon vortex (Figure 9a). Introducing the aerosol processes reduces  $N_{tot}$  in the cross-section because of the combined effect of coagulation scavenging the small particles, and dry deposition to the building and canopy surfaces (Figure 9b). The reduction is around 15.6% near the ground, and 21.0% within the street canyon (below 16 metres). When radiation is involved (Figure 9c), there is a disparity between the amount of decreased pollutant concentrations when comparing the left and right side of the street, as the transport across the canyon is more pronounced and the canyon vortex is modified.  $R_1A_0$  shows an overall decrease of 27.1% in the canyon  $N_{tot}$  compared to the base run ( $R_0A_0$ ), and near surface concentrations decrease by 40.5%. This infers that the removal of pollutants is most effective near the ground at the centre of the canyon. Considering the combined effect of aerosol processes and radiative heating in  $R_1A_1$  (Figure 9d), a further decrease in particle concentrations appears in the middle and especially eastern side of the main street canyon from ground level to the top of the tree canopy. The particle concentrations are the lowest near the surface in the middle of the street with a decrease of 46.3%. Idealised simulations conducted by Xie et al. (2005), Nezis et al. (2011), Mei et al. (2016) and Mei et al. (2017) concluded that pollutant transport to the leeward side (southwest in our case) increases concentrations on this side due to the enhanced vortex, and overall pollutant concentrations are reduced in the canyon when the leeward wall is heated, whereas in our case there is an overall decrease at both sides, but the decrease is not as strong at the southwestern side.

**Figure 8.** Observed 2m total particle number concentration ( $N_{tot,2m}$ ) (a), and the difference of the base run ( $R_0A_0$ ) (b), aerosol processes on ( $R_0A_1$ ) (c), radiation interaction on ( $R_1A_0$ ) (d) and both on ( $R_1A_1$ ) (e) to the observed concentrations.

### 3.4 Aerosol particle size distribution

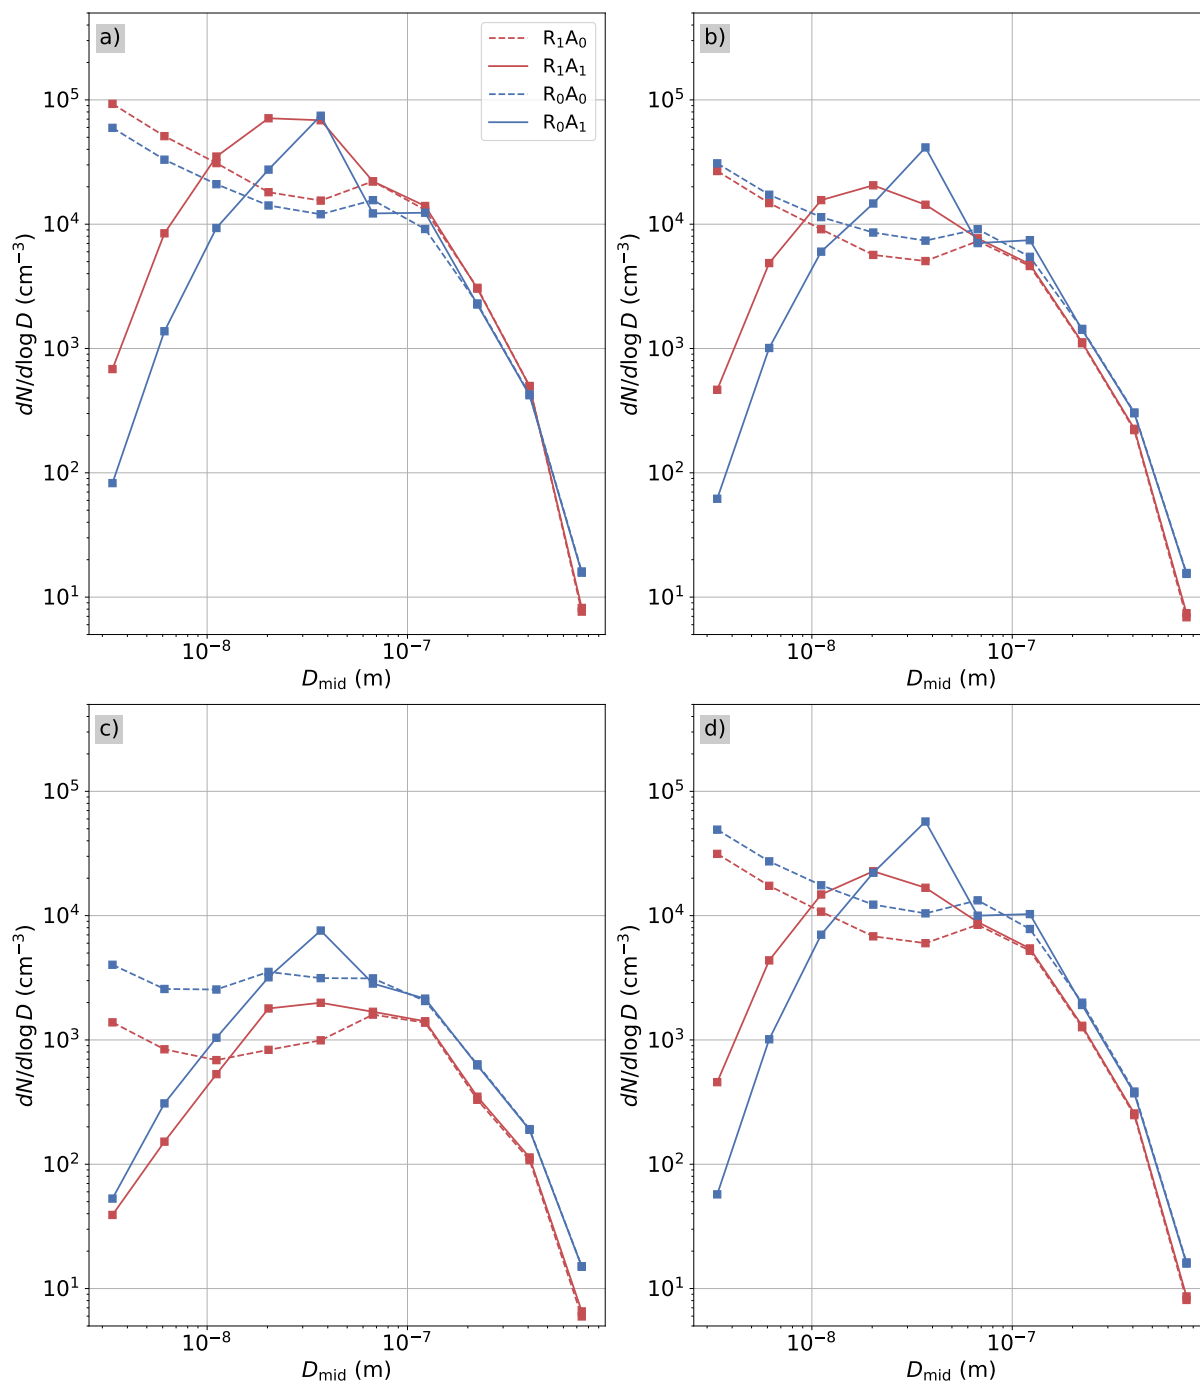

Focusing only on  $N_{tot}$  ignores the effect of the aerosol dynamic processes on the different size of aerosol particles. Figure 10 shows the particle size distribution at the statistical regions (see Figure 1). The dominant particle size shifts to larger size when the aerosol processes are introduced. The largest overall change appears in the range of the smallest particles (4-15 nm) between  $R_0A_0$  and  $R_0A_1$ . The number concentration of small particles is orders of magnitude larger when aerosol processes are off ( $R_0A_0$  and  $R_1A_0$ ) compared to that when aerosol processes are on ( $R_0A_1$  and  $R_1A_1$ ). This is due to coagulation and condensation which act as a sink for the smallest particles. The effect of coagulation is estimated to be minor as in a narrow street canyon in Cambridge, it was found to have an effect of 1% on total particle number concentration (Kurppa et al., 2019). At the supersite, the concentration of aerosol particles at all size bins is larger with radiation interaction on, whether or not aerosol processes are introduced. This is more pronounced for small particles. The combined effect of the stronger transport towards the leeward wall and the stagnant flow parallel to the canyon lead to this increment on particle concentration. At the opposite of the supersite, the effect of radiation on aerosol concentrations is not significant when the aerosol processes are absent. When the aerosol processes are switched on, the concentration of small particles is higher with radiation interaction on, which is probably related to the interaction of the flow field, temperature, and coagulation and condensation processes of small particles.  $R_1A_0$  and  $R_1A_1$  show generally higher concentrations at both sides of the main street canyon, with the largest change  $R_1A_1$  showing 8.2 times larger concentrations compared to  $R_0A_1$  at the southwestern side due to the leeward transport described in Xie et al. (2005) and Nezis et al. (2011). Meanwhile, the background particle concentration at all size bins is lower compared to the street canyon. Unlike the main street, particle concentrations in the background site are larger in  $R_0A_0$  and  $R_0A_1$ . The inclusion of radiation interaction reduces particle concentration for all particle size bins. The background site is at the edge of a gravel football field, so street canyon flows such as an enhanced vortex structure and the increased ventilation

**Figure 9.** Mean total particle number concentration ( $N_{tot}$ ) cross-section along the main street canyon in the base run  $R_0A_0$  (a), and the difference of the model runs with only aerosol processes on ( $R_0A_1$ ) (b), only radiation on ( $R_1A_0$ ) (c) and both on ( $R_1A_1$ ) (d) compared to the base run.

caused by it are not as evident here compared to the main street. In general, the street canyon average particle size distribution (Figure 10d) resembles the distribution on the northeastern side of the street (SR2).

**Figure 10.** 4 metre mean particle number size distributions for the supersite (SR1) (a), opposite supersite (SR2) (b), background (SR3) (c) and canyon average (d) for runs with radiation ( $R_1A_0$  and  $R_1A_1$ ) and without radiation ( $R_0A_0$  and  $R_0A_1$ ).

**Figure 11.** The geometric mean vertical profiles of total particle number concentration ( $N_{tot}$ ) (a-b) number of ultrafine particles (UFP) (c-d), particle mass below 2.5  $\mu\text{m}$  (PM<sub>2.5</sub>) (e-f) and lung deposited surface area (LDSA) of particles (g-h) at the supersite (a,c,e,g) and opposite the supersite (b,d,f,h).

### 310 3.5 Vertical profiles of pollutant concentrations

The vertical aerosol profiles from both sides of the main street canyon (statistical regions SR1 and SR2) are illustrated in Figure 11 for the different aerosol metrics  $N_{tot}$ , UFP,  $PM_{2.5}$  and LDSA. When radiation interaction is included in the simulations ( $R_1A_0$  and  $R_1A_1$ ), the removal of particles from the canyon is evident in all aerosol metrics at SR1. Particularly the metrics representing larger particles (LDSA and  $PM_{2.5}$ ) decrease below the roof-top. A change in stratification from near neutral to  
315 unstable, and the resulting reduction in pollutant concentrations within street level concentrations has also been reported by Nezis et al. (2011), Mei et al. (2016) and Jiang and Yoshie (2018). Above the roof-top the profiles of  $N_{tot}$  and UFP are similar between the runs, whereas  $PM_{2.5}$  and LDSA have more variability. Due to radiation interaction,  $PM_{2.5}$  decrease on both  $R_1A_0$  and  $R_1A_1$  whereas LDSA decreases only in the absence of aerosol processes. In SR2, there is a slight reduction in street canyon concentrations of  $N_{tot}$  and UFP, but a larger increase above the canopy in runs with radiation interaction on ( $R_1A_0$  and  
320  $R_1A_1$ ). This suggests that the modified canyon circulation enhances the transport of smaller particles above the roof-tops on the windward of the street canyon. A similar behavior in concentrations increasing above the canopy due to the expanding canyon vortex was reported by Mei et al. (2016) in idealised simulations with unstable stratification and similar aspect ratio (0.5) compared to our case (0.45).  $PM_{2.5}$  and LDSA have similar behaviour at SR2 than SR1 with  $PM_{2.5}$  systematically decreasing, and LDSA decreasing with radiation interaction and increasing with aerosol processes. The transport towards the leeward side of the canyon is seen as higher concentrations at SR1 compared to SR2. Again the increase in the crossing flow component in  
325  $R_1A_0$  and  $R_1A_1$  resulting in packing of the pollutants leeward side of the street canyon compared to  $R_0A_0$  and  $R_0A_1$  is visible.

Both at SR1 and SR2, the aerosol processes are more important ( $R_0A_1$  and  $R_1A_1$ ) for LDSA than for other aerosol metrics. Although the concentration of the smallest particles decreases, the increased concentration of particles larger than 20 nm due to aerosol processes is more important to LDSA (Kuula et al., 2020). Compared to the drone observations (Figure 11g,h), SR1  
330 shows most agreement with  $R_1A_0$  out of all the processes reducing LDSA at low levels, but is greater than any model runs above the canopy. This might indicate issues in the background forcing of the particles. At SR2 however, both  $R_0A_1$  and  $R_1A_1$  show better agreement with observations, which suggests that aerosol processes are more important on this side of the street canyon.

## 4 Conclusions

335 LES provides an optimal mean to examine flow and pollutant distributions in realistic urban areas as it can account for complex interactions between the surface and the air flow, radiation interaction and in some cases also aerosol particle dynamics, such as in the LES model PALM used in this study. The main aim of this work was to examine the effects that aerosol processes and radiation interaction have on ventilation, aerosol particle concentrations and size distributions in real urban neighbourhood in Helsinki, Finland. The effect of including radiation interaction in the model simulations on near surface temperatures and  
340 flow field, and the separate and joint effect of radiation and aerosol processes on aerosol particle distributions were examined. The model performance was evaluated against near surface temperature ( $T_{2m}$ ) and total aerosol particle number concentrations ( $N_{tot}$ ) measured by a mobile laboratory, and lung deposited surface area (LDSA) measured by a drone. Four main runs to

represent early summer morning on 6 June 2017 between 07:00 and 09:15 were performed. In the base run ( $R_0A_0$ ) neither radiation interaction nor aerosol processes were on.  $R_1A_0$  had only radiation interaction on,  $R_0A_1$  only aerosol processes, and finally  $R_1A_1$  radiation interaction and aerosol processes on.

In a calm wind case, such as the simulated summer morning, inclusion of radiation interaction improved the model performance in simulating the near-surface temperatures within the study area. In the base run,  $T_{2m}$  was underestimated by on average  $3.9^\circ\text{C}$ . In  $R_1A_1$ ,  $T_{2m}$  was overestimated by  $0.2^\circ\text{C}$ , being on average  $12.4^\circ\text{C}$ . This change in temperatures affected also the flow fields. The 4-metre wind speeds increased on average from  $0.29\text{ m s}^{-1}$  to  $0.55\text{ m s}^{-1}$  within the study area. Radiation provides additional energy increasing the mean wind speed, which combined with thermal turbulence production increases turbulent mixing.

Changes in flow increased ventilation and decreased particle concentrations close to the ground. The 4-metre  $N_{tot}$  were reduced by 53% with radiation interaction included ( $R_1A_0$ ). The inclusion of radiation interaction in LES is more important than adding the aerosol process which decreased the 4-metre  $N_{tot}$  concentrations by 18% ( $R_0A_1$ ). Together with both the aerosol processes and radiation interaction included the concentrations decreased by 56%. Compared to observations at the 2-metre modelling height, the near surface particle number concentration bias was reduced from 98% overestimation ( $R_0A_0$ ) to 16% underestimation ( $R_1A_1$ ). The bias is particularly reduced by inclusion of radiation interaction in the model runs.

Aerosol processes and their response to changes in flow altered the size distribution of particles. The size distribution in  $R_0A_1$  and  $R_1A_1$  showed larger particle sizes dominating, whereas in  $R_0A_0$  and  $R_1A_0$ , the fraction of particles between 4-15 nm in diameter increased significantly due to the absence of processes such as deposition, coagulation and condensation. Radiation interaction and the enhanced flow field had a larger impact on the size distribution at the supersite, where the concentrations of all size bins increased by up to 8.2 times with  $R_1A_1$  compared to  $R_0A_1$  at the pedestrian level. Overall radiation interaction had the largest effect in medium to small particle size range at this height.

The change in stratification affected also the aerosol vertical profiles. All aerosol concentrations decrease in the street canyon when radiation interaction is considered, the effect being larger for  $\text{PM}_{2.5}$  and LDSA on both sides of the canyon. Above the canopy  $N_{tot}$  and UFP increase at the windward side of the canyon due to modified street canyon vortex by radiation interaction. Supersite shows higher concentrations overall compared to the opposite side due to the leeward transport described before. Aerosol processes have larger effect on the vertical profiles of  $\text{PM}_{2.5}$  and LDSA than  $N_{tot}$  and UFP, with the effect being particularly pronounced in LDSA. When taking into account both sides of the main canyon,  $R_1A_0$  performs the best in terms of LDSA, as the change in flow alone is enough to bring LDSA closer to observations.

The results show that radiation interaction is more important to be considered in LES than aerosol processes when simulating pollutant distributions within urban neighbourhood in low wind conditions. Without radiation interaction, near surface air temperature and flow are underestimated and pollutant concentrations overestimated. Aerosol processes are however critical when aerosol particle size distributions, particularly the smallest size ranges, or vertical profiles of larger particles are examined. In our simulations with weak prevailing wind speed, the impact of radiation interaction on reducing the street-level concentrations can be greater than with stronger wind speeds. On the other hand, we simulated early morning when the radiative effects are

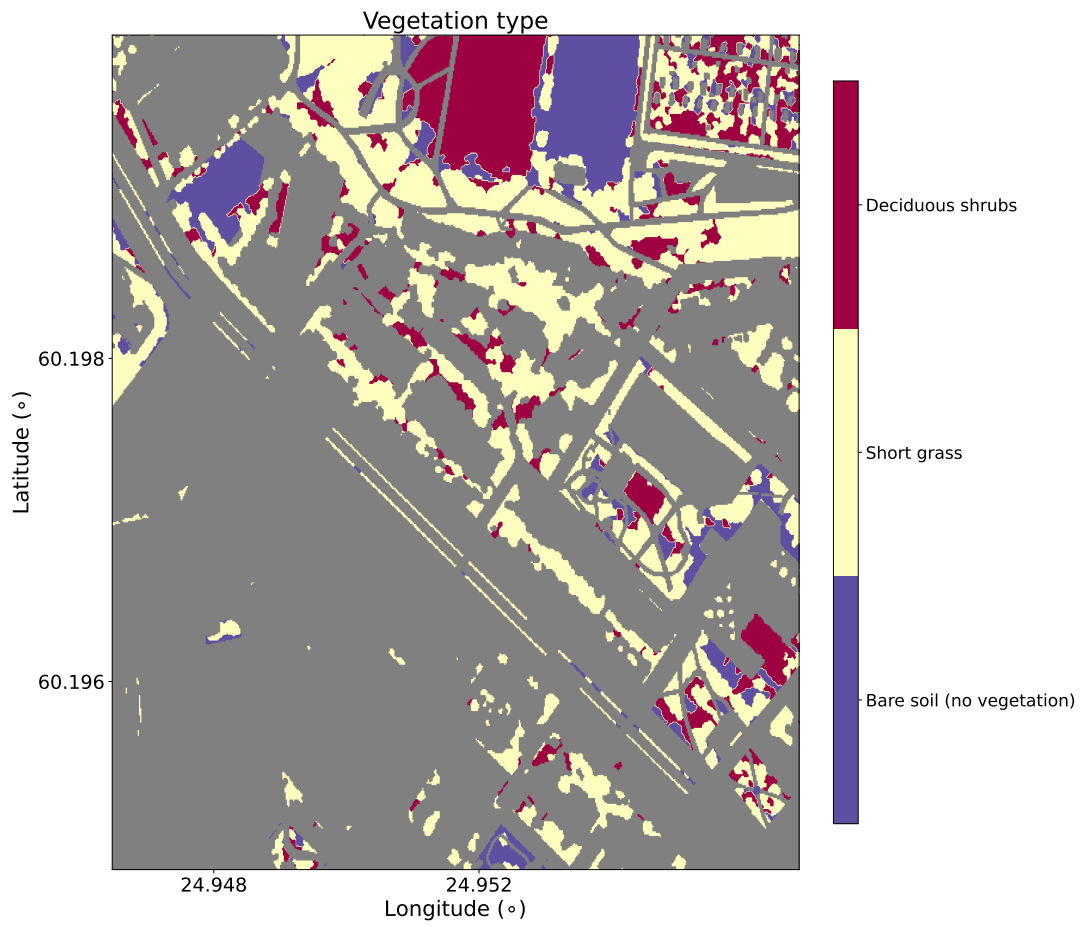

not the strongest. In the future more meteorological conditions with varying wind speed and direction scenarios and time of day should be made to understand the effect of radiation interaction and aerosol processes in detail.
