Abstract. Surface ozone (O₃) is well known to pose significant threats to both human health and crop production worldwide. However, a multi-decadal assessment of O₃ impacts on public health and crop yields in China is lacking due to insufficient long-term continuous O₃ observations. In this study, we used a machine learning (ML) algorithm to correct the biases of O₃ concentrations simulated by the chemical transport model from 1981–2019 by integrating multi-source datasets. The ML-enabled bias correction offers improved performance in reproducing observed O₃ concentrations, and thus further improves our estimates of O₃ impacts on human health and crop yields. The warm-season increasing trend of O₃ in Beijing-Tianjin-Hebei and its surroundings (BTHs), Yangtze River Delta (YRD), Sichuan Basin (SCB) and Pearl River Delta (PRD) regions are 0.32 μg m⁻³ yr⁻¹, 0.63 μg m⁻³ yr⁻¹, 0.84 μg m⁻³ yr⁻¹, and 0.81 μg m⁻³ yr⁻¹ from 1981 to 2019, respectively. In more recent years, O₃ concentrations experience more fluctuations in the four major regions. Our results show that only BTHs have a perceptible increasing trend of 0.81 μg m⁻³ yr⁻¹ during 2013–2019. Using AOT40-China exposure-yield response relationships, the estimated relative yield losses (RYLs) for wheat, rice, soybean and maize are 17.6%, 13.8%, 11.3% and 7.3% in 1981, and increases to 24.2%, 17.5%, 16.3% and 9.8% in 2019, with an increasing rate of +0.03% yr⁻¹, +0.04% yr⁻¹, +0.27% yr⁻¹ and +0.13% yr⁻¹, respectively. The estimated annual all-cause premature deaths induced by O₃ increase from ~55,900 in 1981 to ~162,000 in 2019 with an increasing trend of ~2,980 deaths yr⁻¹. The annual premature deaths related to respiratory and cardiovascular disease are ~34,200 and ~40,300 in 1998, and ~26,500 and ~79,000 in 2019, having a rate of change of -546 and +1,770 deaths yr⁻¹ during 1998–2019, respectively. Our study, for the first time, used ML to provide a robust dataset of O₃ concentrations over the past four decades in China, enabling a long-term evaluation of O₃-induced crop losses and health impacts. These findings are expected to fill the gap of the long-term O₃ trend and impact assessment in China.

1 Introduction

Surface ozone (O₃), an important secondary air pollutant, is mainly generated through photochemical reaction of volatile organic compounds (VOCs), carbon monoxide (CO), and nitrogen oxides (NO_x) in the presence of sunlight. As a strong oxidant, O₃ at the ground level is detrimental to human health and vegetation. More recently, due to the rapid

38 urbanization and industrialization, the summertime O₃ pollution has become an emerging concern in China. Li et al. (2020)
39 reported that the mean summer 2013–2019 trend in maximum daily 8-h average surface O₃ (MDA8-O₃) was +1.9 ppb yr⁻¹
40 in China, with high values widely observed in the North China Plain (NCP), Yangtze River Delta (YRD), and Pearl River
41 Delta (PRD) regions. On the regional scale, the exposure of humans and vegetation to O₃ is greater in China than in other
42 developed regions of the world (Lu et al., 2018). Several studies have suggested the important roles of climate and land
43 cover changes on O₃ pollution in addition to anthropogenic emissions (Fu and Tai, 2015; Wang et al., 2020). It has been
44 suggested that global warming and the changing land use may further increase surface O₃ by the late 21st century (Kawase
45 et al., 2011; Wang et al., 2020), which can pose greater threats to human health and food security.

46 Meteorological factors can modulate the temporal and spatial patterns of O₃ via affecting the physical and chemical
47 processes within the atmosphere (Liu et al., 2019; Mao et al., 2020; Yin and Ma, 2020). High temperature, low relative
48 humidity and low planetary boundary height are conducive to the photochemical production and O₃ accumulation. Jacob
49 and Winner (2009) summarized that the enhanced O₃ levels at higher temperatures are primarily driven by increased
50 biogenic VOC emissions from vegetation and reduced lifetimes of peroxyacetyl nitrate (PAN) due to accelerated
51 decomposition of PAN into NO_x. Besides, the changes in wind speed and direction can affect O₃ concentrations through
52 transport. Land cover and land use change affects O₃ air quality by perturbing surface fluxes, hydrometeorology, and
53 concentrations of atmospheric chemical components (Tai et al., 2013; Fu and Tai, 2015; Liu et al., 2020; Ma et al., 2021).
54 For instance, the terrestrial biosphere is a major source of isoprene, which plays a significant role in modulating O₃
55 concentrations. In the Intergovernmental Panel on Climate Change (IPCC) A1B scenario, Tai et al. (2013) found that
56 widespread crop expansion could reduce isoprene emission by ~10 % globally compared with the present land use. Such
57 a reduction could decrease O₃ by up to 4 ppb in the eastern US and increase O₃ by up to 6 ppb in South and Southeast Asia,
58 whereby the difference in the sign of responses is primarily determined by the different O₃ production regimes.

59 The increasing health burden due to air pollution has become an important contributor to global disease burden. Some
60 recent studies have demonstrated that short-term O₃ exposure negatively impacts human health, especially via respiratory,
61 and cardiovascular mortality (Shang et al., 2013; Yin et al., 2017b; Feng et al., 2019; Zhang et al., 2022a). In 2015–2018,
62 the estimated annual total premature mortality related to O₃ pollution in 334 Chinese cities was 0.27 million for 2015, 0.28
63 million for 2016, 0.39 million for 2017, and 0.32 million for 2018 (Zhang et al., 2021). Maji and Namdeo (2021) reported
64 that short-term all-cause, cardiovascular and respiratory premature mortalities attributed to the ambient 4th highest MDA8-
65 O₃ exposure were 156,000, 73,500 and 28,600 in 2019, showing increases of 19.6%, 19.8% and 21.2%, respectively,
66 compared to 2015. Zhang et al. (2022b) reported that each 10 µg m⁻³ increase in the MDA8-O₃ can lead to a rise of 0.41 %
67 (95 % CI: 0.35 %–0.48 %) in all-cause, 0.60 % (95 % CI: 0.51 %–0.68 %) in cardiovascular and 0.45 % (95 % CI: 0.28 %–
68 0.62 %) in respiratory mortality.

69 The damage to plants induced by O₃ is mainly caused by the stomatal uptake of O₃ into the leaf interior instead of
70 direct plant surface deposition (e.g., Clifton et al., 2020). In previous studies, a variety of concentration-based metrics have
71 been widely used to assess the O₃ risks to crop yield and ecosystem functions. Initially, a 7-hour (09:00–15:59) mean metric
72 (M7) was proposed, which was later extended to a 12-hour (08:00–19:59; referred to M12) to include late-day O₃
73 concentrations. Cumulative metrics have also been developed to evaluate the impacts of O₃ on crops. The accumulated O₃
74 over a threshold of 40 ppb (AOT40) is a widely used metric to evaluate the phytotoxic effects of O₃. Compared to AOT40
75 using a linear function, another metrics, W126, considers the nonlinear response of yield loss to O₃ exposure whereby
76 higher O₃ concentrations will progressively induce more severe yield losses. However, many studies have suggested that
77 the stomatal uptake of O₃ is more related to vegetation damage than O₃ exposure per se (Feng et al., 2012; Feng et al., 2018;
78 Pleijel et al., 2022). In the recent two decades, the flux-based approach therefore has been developed and increasingly used
79 to assess the relationships between the stomatal O₃ uptake and crop yields. Tai et al. (2021) compared the results of the
80 estimated global crop yield losses using three concentration-based and two flux-based O₃ exposure metrics, and showed
81 that the concentration-based metrics differ greatly among themselves, while the two flux-based metrics are generally close

82 to each other, which lie close to the middle of the range covered by all metrics.

83 At present, a comprehensive long-term assessment of O₃ impacts is hindered by a lack of continuous O₃ observations
84 in China (Lu et al., 2018; Gong et al., 2021). From both health and food perspectives, reliable long-term estimates of O₃
85 are critically needed to better understand the O₃ damage over the past few decades since the beginning of rapid industrial
86 transformation in the 1980s. In previous studies, various alternative approaches have been used to address the problem of
87 insufficient observations. The multiple linear regression (MLR) model is often used for extrapolation to construct
88 spatiotemporal distributions of air pollutants (Moustris et al., 2012; Abdullah et al., 2017). However, the linear statistical
89 methods are generally limited by their incapability to capture the nonlinear relationships between air pollutants and
90 precursors as well as meteorological fields. Chemical transport models (CTMs), based on mathematical representation of
91 atmospheric physical and chemical processes, are also the common tool to simulate air pollutant concentrations
92 spatiotemporally (Fusco and Logan, 2003; Liu and Wang, 2020a; Wang et al., 2022a). Taking the advantages of the CTM,
93 Fu and Tai (2015) investigated the impacts of historical climate and land cover changes on tropospheric O₃ in East Asia
94 between 1980 and 2010. However, the utility of CTMs is often limited by their high computational cost when conducting
95 long-term simulations at high spatiotemporal resolutions. Large biases also exist due to uncertainties in historical emission
96 inventories, parameterization of physical and chemical processes, and initial and/or boundary conditions, and these errors
97 tend to increase at finer spatiotemporal scales.

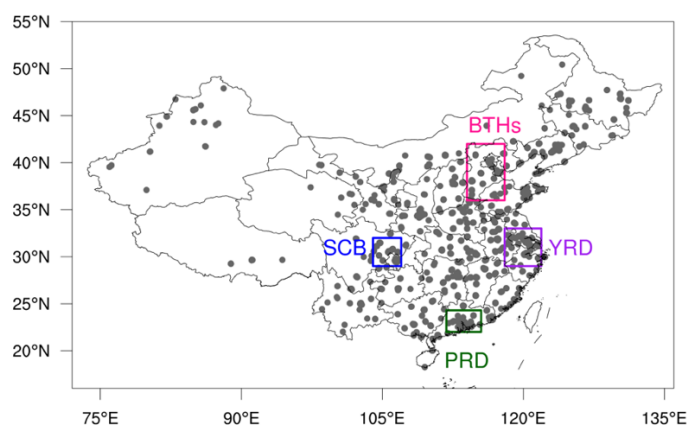

98 In recent years, machine learning (ML) methods have gained increasing popularity in air pollution studies (Liu et al.,
99 2020; Ma et al., 2021). In the early stage of applying ML to atmospheric chemistry, ML methods were usually used as an
100 independent method from CTMs (Hu et al., 2017; Zhan et al., 2017), for instance, to predict O₃ concentrations by mapping
101 the nonlinear relationships between observed O₃ concentrations and their possible shaping factors. These applications are
102 usually purely data-driven, whereby the ML algorithms do not involve any representation of the physical mechanisms
103 behind the relevant processes. With powerful algorithms and user-friendly hyperparameter tuning processes, some well-
104 trained ML models, driven by data from multiple sources including reanalysis and satellite data, have shown even higher
105 predictive capacity than process-based models. The advantages of ML methods over CTMs include more flexible choices
106 for input data and spatiotemporal resolution, and substantially lower computational costs (Bi et al., 2022). However, purely
107 data-driven ML methods are known to suffer a lack of transparency and interpretability, which renders it more difficult to
108 offer adequate scientific interpretation for the physical mechanisms behind. Thus, a hybrid approach combining ML
109 algorithms and CTM-simulated results have been increasingly used to predict air pollutants and understand their trends in
110 recent years. Integrating data from various sources, ML methods have been used as a tool to correct the biases in the lower-
111 resolution simulated results from CTMs (Di et al., 2017; Ivatt and Evans, 2020; Ma et al., 2021). Based on process-based
112 CTMs integrating decades of accumulated knowledge in Earth system science, while taking advantage of ML to address
113 still-existing model errors, the hybrid approach has great potential in tackling air quality problems (Irrgang et al., 2021).

114 In this work, we incorporated the O₃ concentrations directly simulated by the Goddard Earth Observing System
115 coupled with Chemistry (GEOS-Chem) model at a lower resolution into a bias-corrected, finer-resolution dataset by
116 integrating them with O₃ observations from 2016 to 2018 (for validation purpose), high-resolution meteorological fields,
117 land use data and other geographical information from multiple sources using a tree-based ML algorithm, LightGBM. The
118 final high-resolution hourly O₃ dataset with a resolution of 0.25°×0.25° from 1981 to 2019 was further used to assess the
119 impacts of O₃ on human health and crop yields over the past four decades. The simultaneous analysis of the combined
120 impacts of O₃ on agriculture and human health can offer more comprehensive policy implications for the mitigation of O₃-
121 related impacts across China.

122 2 Data and methods

123 2.1 Air quality, meteorological, land and crop data

124 Hourly surface O₃ observations (μg m⁻³) from 2016 to 2018 were obtained from the China National Environment
125 Monitoring Center Network (<http://106.37.208.233:20035/>) established by the Ministry of Ecology and Environment of
126 China. The MDA8-O₃ of each site was calculated with at least 14 valid hourly values from 08:00 to 24:00 local time. A
127 total of 1016 sites were selected after deleting the missing and abnormal data (**Fig. 1**).

128
129 **Figure 1. Study domain and locations of the selected monitoring sites. The pink, blue, purple and green rectangles**
130 **indicate the Beijing-Tianjin-Hebei and its surroundings (BTHs), Sichuan Basin (SCB), Yangtze River Delta (YRD),**
131 **and Pearl River Delta (PRD) regions, respectively, for more detailed analysis.**

132 The surface meteorological fields used in this study include sea surface pressure, horizontal wind at 10 m, air
133 temperature at 2 m, downward solar radiation, surface albedo, and total precipitation. The variables selected at 850 hPa
134 and 100 hPa include relative humidity, horizontal and vertical velocity. These meteorological variables have been shown
135 by many previous studies to correlate strongly with surface O₃ concentrations as discussed above. Hourly reanalysis data
136 for meteorological variables were obtained from the fifth generation European Center for Medium-Range Weather
137 Forecasts (ECMWF) reanalysis dataset (ERA5) with a spatial resolution of 0.25°×0.25° from 1981 to 2019
138 (<https://cds.climate.copernicus.eu/>). This spatial resolution sets the highest limit of resolution for our hybrid O₃ product.

139 The national land use data with a spatial resolution of 1 km×1 km for 2013 were obtained from the Resource and
140 Environment Science Data Center of the Chinese Academy of Sciences (RESDC) (<http://www.resdc.cn>). Six primary types
141 of land use are considered: cultivated land, forestland, grassland, water bodies, construction land, and unused land.
142 Nationwide elevation data were also provided by the RESDC (<https://www.resdc.cn/data.aspx?DATAID=123>), which is
143 resampled based on the latest Shuttle Radar Topography Mission (SRTM) V4.1 data developed in 2000.

144 The spatial distribution of the harvested areas for four staple crops (wheat, rice, maize, soybean) for China was
145 obtained from the Global Agro-Ecological Zones 2015 dataset (<https://doi.org/10.7910/DVN/KJFUO1>). Crop harvesting
146 dates with a resolution of 0.5°×0.5° were provided by the Center for Sustainability and the Global Environment (Sacks et
147 al., 2010). For crops having more than one growing season in a year, only the primary growing period was considered.

148 2.2 GEOS-Chem model

149 We used the GEOS-Chem global 3-D chemical transport model version 12.2.0 (<http://acmg.seas.harvard.edu/geos/>),
150 driven by assimilated meteorological data from Modern Era Retrospective-analysis for Research and Applications, Version
151 2 (MERRA2) (<https://gmao.gsfc.nasa.gov/reanalysis/MERRA-2/>) with a horizontal resolution of 2.0° latitude by 2.5°

152 longitude and reduced vertical resolution of 47 levels. GEOS-Chem incorporates meteorological conditions, emissions,
153 chemical information, and surface conditions to simulate the formation, transport, mixing and deposition of ambient O₃. It
154 performs fully coupled simulations of O₃-NO_x-VOC-aerosol chemistry (Bey et al., 2001). Previous studies have
155 demonstrated the ability of GEOS-Chem to reasonably reproduce the magnitudes and seasonal variations of surface O₃
156 East Asia (Wang et al., 2011; He et al., 2012). To provide long-term simulated O₃ fields for incorporation into the ML
157 model (see below), we conducted GEOS-Chem simulations at a resolution of 2.0°×2.5°; higher resolutions of GEOS-Chem
158 in nested grids are available but computationally prohibitive for multi-decadal simulations. The original unit of GEOS-
159 Chem-simulated O₃ is ppb, which was converted to μg m⁻³ assuming a constant temperature of 25°C and pressure of
160 1013.25 hPa (1 μg m⁻³ is approximately 0.5 ppb) when compared with observations (Yin et al., 2017b; Gong and Liao,
161 2019).

162 Global anthropogenic emissions of CO, NO_x, SO₂ and VOCs are from Community Emissions Data System (CEDS),
163 which has coverage over the simulation years of 1950–2014 (Hoesly et al., 2018). Biomass burning emissions are from the
164 GFED-4 inventory (van der Werf et al., 2017). Biogenic VOC emissions are computed by the Model of Emissions of Gases
165 and Aerosols from Nature (MEGAN) v2.1 (Guenther et al., 2012), which is embedded in GEOS-Chem. Emissions of
166 biogenic VOC species in each grid cell, including isoprene, monoterpenes, methyl butenol, sesquiterpenes, acetone and
167 various alkenes, are simulated as a function of canopy-scale emission factors modulated by environmental activity factors
168 to account for changing temperature, light, leaf age, leaf area index (LAI), soil moisture and CO₂ concentrations
169 (Sindelarova et al., 2014).

170 Dry deposition follows the resistance-in-series scheme of Wesely (1989), which depends on species properties, land
171 cover types and meteorological conditions, and uses the Olson land cover classes with 76 land types reclassified into 11
172 land types. Although transpiration is a potential mechanism via which the land cover affects ozone, we do not address it in
173 this study because water vapor concentration in GEOS-Chem is prescribed from assimilated relative humidity (i.e., not
174 computed online from evapotranspiration).

175 **2.3 LightGBM machine-learning model**

176 The primary purpose of utilizing ML here was to minimize the biases of model output as compared with observations,
177 whereby the biases could arise from incomplete model physics, input and parameter errors, numerical errors, coding errors,
178 as well as representation errors (i.e., mismatch in spatial scales between model grid cells and site observations), so that the
179 output of the hybrid model could have the closest values to the observations and enable more accurate impact evaluation.
180 In this study, we used the LightGBM ML algorithm to integrate GEOS-Chem-simulated O₃ at a lower resolution with
181 higher-resolution multi-source data to produce higher-resolution hourly O₃ and MDA8-O₃ fields.

182 LightGBM is a ML algorithm based on the gradient boosting decision tree (Chen and Guestrin, 2016), which has a
183 high training efficiency and lower memory footprint, and thus is suitable for processing massive high-dimensional data
184 (Zhang et al., 2019). The general steps to build a ML model can be summarized as follows: (1) choose an algorithm
185 appropriate for the problem (e.g., regression or classification); (2) clean the data and split them into training and test data;
186 (3) train and tune the model with training data to well capture prediction patterns; (4) evaluate model performance on test
187 data; and (5) return to step (3) and (4) until an optimal predictive ability is reached. The training and evaluation processes
188 are both performed at the site level in accordance with the observations, whereby the predictor variables and model
189 responses were first sampled at the same locations using the bilinear interpolation approach (Accadia et al., 2003). This
190 approach of handling spatial scale mismatch between model grid cells and site observations has been commonly used in
191 previous studies (e.g., Li et al., 2021). When predicting the gridded O₃ concentrations with the trained model, predictor
192 variables at different spatial resolutions were all regridded to the same resolution of 0.25°×0.25° consistent with the ERA5
193 meteorological fields. By taking the advantage of these higher-resolution datasets, the hybrid approach can not only correct

194 the biases of the GEOS-Chem-simulated O₃, but also refine them into a finer resolution. To evaluate if the hybrid approach
195 truly benefits from using a higher-resolution meteorological fields, we also repeated the whole training exercise with the
196 input meteorology of GEOS-Chem (MERRA2 at 2.0°×2.5°) instead of ERA5.

197 During the model training process, the model was evaluated with 10-fold cross-validation to ensure the robustness
198 and reliability of the model, whereby the training data were randomly partitioned into 10 subsets of approximately the same
199 size, with 90% of data used to train individual models and the ensemble model, and the remaining 10% of data used to
200 examine model performance (Xiao et al., 2018). This process was repeated 10 times so that each data record was left for
201 testing once. The tuning of the hyperparameters was optimized using grid search optimization to improve detection
202 performance and diagnostic accuracy (Wang et al., 2019). Statistical indicators, including the coefficient of determination
203 (R^2) and root-mean-square error (RMSE), were used in subsequent assessment of model performance for GEOS-Chem
204 alone and for the hybrid approach.

205 Our analysis revealed that training the model with one year or more of data results in only marginal reductions in
206 RMSE and enhancements in R^2 (Fig. S1); thus a timescale of two years appears to strike a good balance between
207 computational burden and model accuracy. These results align with the findings of Ivatt and Evans (2020), who suggested
208 that much of the variability in the power spectrum of surface O₃ can be captured by timescales of a year or less. Therefore,
209 here we utilized observations from the period 2016-2017 as the training data, which offered a more economical computing
210 cost and improved training time efficiency, and observations in 2018 as the independent test data to evaluate model
211 performance.

212 2.4 Ozone exposure metric and exposure–yield response functions

213 Among O₃ exposure indices, AOT40 has been used widely during the last two decades as it has been found to have a
214 strong relationship with relative yield of many crop species (Mills et al., 2007), and thus was used to quantify the impacts
215 of surface O₃ on crop yields in this study. The flux-based metrics, which require long-term simulations using a process-
216 based stomatal uptake model, were beyond the scope of this study. The AOT40 (ppm-h) is defined as follows:

$$217 \text{AOT40} = \sum_{i=1}^n ([\text{O}_3]_i - 0.04) \quad (1)$$

218 where the $[\text{O}_3]_i$ is the hourly mean O₃ concentration (ppm) during the 12 hours of local daytime (08:00–19:59); n is the
219 number of hours in the growing season defined as the 90 days prior to the start of the harvesting period according to the
220 crop calendar.

221 The exposure–yield response functions based on extensive field experimental studies have been established to relate
222 a quantifiable O₃-exposure metrics to crop yields. It has been suggested that responses of crop yields were found greater
223 in Asian experiments than the American and European counterparts, indicating possibly higher O₃ sensitivity of Asian crop
224 varieties (Emberson et al., 2009; Feng et al., 2022). To better understand O₃-induced risks to crops in China, the AOT40
225 exposure-yield functions developed based on field experiments in China are used in this study, which are named as AOT40-
226 China. The exposure–yield response functions for soybean is from Zhang et al. (2017), and for other three crops are from
227 Feng et al. (2022). The statistical exposure-yield relationships used in this study are summarized in **Table S1**.

228 2.5 Analysis of health impacts

229 All-cause mortality, cardiovascular disease mortality and respiratory disease mortality are selected as the health
230 outcomes of our study due to the high correlation between these endpoints and short-term O₃ exposure in previous studies.
231 A log-linear exposure-response function is widely adopted and recommended by the World Health Organization (WHO)
232 for health impact assessment in areas with severe air pollution. In particular, the log-linear model is the most widely applied

233 exposure-response model at present in China (Lelieveld et al., 2015; Yin et al., 2017a; Zhang et al., 2022b). The premature
234 mortality is calculated following:

$$235 \quad \Delta M = \delta c * \left[\frac{(RR - 1)}{RR} \right] * P \quad (2)$$

236 where ΔM is the excess mortality attributable to O₃ exposure; δc is the baseline mortality rate for a particular health endpoint
237 (Yin et al., 2017b; Madaniyazi et al., 2016); P is the exposed population; and RR is the relative risk defined as:

$$238 \quad RR = \exp((X - X_0) * \beta) \quad (3)$$

239 where β is the exposure-response coefficient derived from epidemiological cohort studies (Shang et al., 2013); X represents
240 the model-calculated O₃ concentration; the value of X_0 is the threshold concentration below which no additional risk is
241 assumed. Consistent with previous studies (Lelieveld et al., 2015; Liu et al., 2018), we used $X_0 = 75.2 \mu\text{g m}^{-3}$.

242 In this study, the mean MDA8-O₃ concentrations in warm season (May-September) were used to estimate the disease-
243 specific health impacts of short-term exposure to O₃. The province-level population and national baseline mortality rate for
244 particular diseases were provided by the National Bureau of Statistics (<http://www.stats.gov.cn/>). The spatial differences of
245 baseline mortality in China were not considered without provincial-level data, which means that we assume the baseline
246 mortality is evenly distributed across China (Dedoussi et al., 2020). The exposure-response coefficients were obtained from
247 existing epidemiological studies in China (**Table S2**). If the corresponding coefficient of a province could not be found in
248 published epidemiological studies, the datum closest to that province would be selected as a substitute. If there were no
249 neighboring provinces, the results of national meta-analysis would be used (Zhang et al., 2021).

250 **3 Results**

251 **3.1 Model development and validation**

252 The finally selected features and their importance estimated by the LightGBM algorithm based on 10-fold cross
253 validation are shown in **Fig. 2**. GEOS-Chem-simulated O₃ is the top predictor for predicting surface O₃ concentrations,
254 accounting for 61% and 58% of all relative importance in the ML algorithm predicting hourly O₃ and daily MD8A-O₃,
255 respectively. The result indicates that process-based GEOS-Chem simulations have high utility for O₃ predictions under
256 the hybrid approach (Ma et al., 2021). The meteorological variables with high contribution to both the daily and hourly
257 models are downward surface solar radiation (SSRD), relative humidity at 1000 hpa (RH_1000hpa) and 10-m horizontal
258 wind (U10 and V10). Other special features, including location (latitude and longitude), elevation and diurnal and monthly
259 pattern of O₃, also contribute to ambient O₃ estimations. The spatial distributions of bias-corrected O₃ are consistent with
260 observations for both training and test datasets (**Fig. S2**), indicating that there is no obvious overfitting, i.e., the model is
261 able to generalize from the training set to the test set. The good generalization ability of the model gives us confidence in
262 its ability to make accurate predictions based on new data. In general, the hybrid approach can yield good O₃ estimates in
263 the data-intensive regions, including eastern and central China that are the hotspot areas of O₃ pollution.

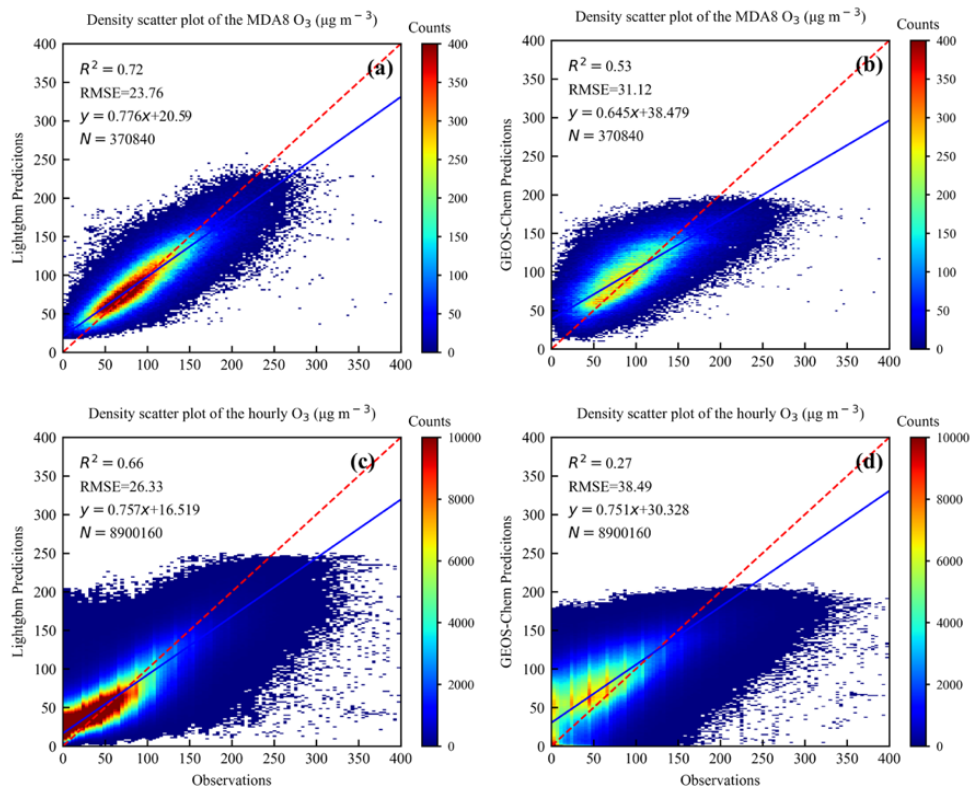

264
 265 **Figure 2. The feature importance plot for (a) MDA8-O₃ and (b) hourly O₃, respectively. The full list of candidate**
 266 **variables with their symbols, units, descriptions, and data sources are shown in Table S3.**

267 **Fig. 3** shows the density scatter plots between O₃ measurements and GEOS-Chem simulations, as well as the hybrid-
 268 approach predictions for 2018. The R^2 value of the hybrid approach and GEOS-Chem model are 0.66 and 0.27 at hourly
 269 level, and 0.72 and 0.53 at MDA8-O₃ level, respectively. Bias-corrected O₃ concentrations have lower RMSE in
 270 comparison with GEOS-Chem simulated O₃ concentrations, reduced from 31.1 to 23.8 $\mu\text{g m}^{-3}$ for MDA8-O₃ predictions,
 271 and from 38.5 to 26.3 $\mu\text{g m}^{-3}$ for hourly predictions. The MDA8-O₃ model performance is better than that of the hourly
 272 model, indicating reduced errors upon temporal averaging. To test if using the higher-resolution meteorological data offers
 273 better prediction accuracy compared with the original input meteorology of GEOS-Chem, the MERRA2 dataset driving
 274 GEOS-Chem was also used to train the model. We found that the higher-resolution ERA5 dataset performed better in
 275 reproducing observed O₃ concentrations with moderately smaller RMSE and larger R^2 (**Fig. S3**), demonstrating the level
 276 to which a higher-resolution meteorological dataset, despite not being strictly consistent with the input meteorology for the
 277 CTM, can help enhance the performance of the hybrid approach and help resolve finer spatial details within the original
 278 CTM grid cells. In summary, the result suggests that the CTM-simulated results can be substantially improved by applying
 279 ML with multi-source datasets, and the bias-corrected data can improve our understanding of long-term O₃ trends and its
 280 further implications on crop and human health over China, as discussed in the following sections.

281 In comparison with previous studies, Liu et al. (2020) used XGBoost to predict O₃ in major urban areas of China at a
 282 resolution of $0.1^\circ \times 0.1^\circ$, and the R^2 value and RMSE for MDA8-O₃ were 0.74 and 23.8 $\mu\text{g m}^{-3}$, respectively. Their result
 283 indicates that higher-resolution predictions may help enhance model accuracy, but represent a trade-off between model
 284 accuracy and time efficiency depending on the purpose. Instead of directly predicting O₃ concentrations, Ivatt and Evans
 285 (2020) predicted biases in GEOS-Chem-simulated O₃ concentrations and then corrected them with XGBoost. They also
 286 suggested that the corrected model performs considerably better than the uncorrected model, with RMSE reduced from
 287 32.4 to 15.0 $\mu\text{g m}^{-3}$ and Pearson's R raised from 0.48 to 0.84. Their greater improvement with larger reduced RMSE than
 288 our result is mainly because they selected fewer sites for training, with all the urban and mountain sites (observations made
 289 at a pressure < 850 hPa) removed. The removal of these sites can improve the overall apparent performance of the model
 290 because O₃ formation could have different characteristics in these areas. In general, ML methods have been proven to be a

291 promising tool to improve air pollutant forecasts when a process-level understanding is still incomplete.

299

300 3.2 Spatiotemporal distribution and trends of O₃ predictions

301 **Fig. 4** demonstrates the spatial patterns of averaged annual and warm-season (May-September) MDA8-O₃ from 1981
302 to 2019. When compared to the high concentrations in the warm season, MDA8-O₃ concentrations are relatively lower at
303 annual level. The annual and warm-season MDA8-O₃ concentrations have similar spatial distribution, and both present an
304 increasing trend over the past decades, with more substantial increase observed between 1981 and 2010. The O₃ levels in
305 southern China are lower than those in northern China, but they are still relatively high in the PRD region, which is
306 consistent to findings in previous studies (e.g. Liu and Wang, 2020a). During the first decade of 1981–1990, high O₃
307 concentration areas are mainly concentrated in the BTHs and northern Shandong. In the next two decades, O₃ pollution
308 extensively expands to most of East and North China, spreading northward to Jilin and Liaoning, westward to Shanxi and
309 Ningxia, and southward to northern Hunan, Shanxi and Zhejiang. Moreover, the SCB and PRD regions also experience
310 aggravated O₃ pollution during this period. In the last decade of the study period, O₃ concentrations remain at high levels
311 in BTHs and SCB without obvious changes. To understand the detailed changes and trends of O₃, next we analyze the
312 interannual variability.

313
 314 **Figure 4. Spatial distribution of the annual mean MDA8-O₃ concentrations (μg m⁻³) during: (a) 1981–1990; (b)**
 315 **1991–2000; (c) 2001–2010; and (d) 2011–2019. Spatial distribution of the warm-season (May–September) mean**
 316 **MDA8-O₃ concentrations of (e)1981–1990, (f) 1991–2000, (g) 2001–2010; and (h) 2011–2019.**

317 **Fig. 5** shows that the annual averaged MDA8-O₃ concentrations increase from 87 μg m⁻³ in 1981 to 98 μg m⁻³ in
 318 2019, with a growth rate of +0.26 μg m⁻³ yr⁻¹, while the warm-season averaged MDA8-O₃ concentrations increase from
 319 100 μg m⁻³ in 1981 to 117 μg m⁻³ in 2019, having a growth rate of +0.51 μg m⁻³ yr⁻¹. Moreover, the average annual and
 320 warm-season O₃ concentrations have a more obvious upward trend before 2000s, with a growth rate of 0.38 μg m⁻³ yr⁻¹
 321 and 0.71 μg m⁻³ yr⁻¹, compared to that after 2000s, when O₃ concentrations appear to fluctuate within a certain range.
 322 GEOS-Chem-simulated O₃ has a similar trend as the bias-corrected O₃, but it generally overestimates O₃ concentrations on
 323 national scale (**Fig. S4**). The annual and warm-season averaged MDA8-O₃ concentrations in BTHs, YRD, SCB and PRD
 324 regions are shown in **Fig. S5–S6**. The warm-season increasing trend for BTHs, YRD, SCB and PRD regions are 0.32 μg
 325 m⁻³ yr⁻¹, 0.63 μg m⁻³ yr⁻¹, 0.84 μg m⁻³ yr⁻¹, and 0.81 μg m⁻³ yr⁻¹ from the year 1981 to 2019.

326
 327 **Figure 5. The bias-corrected MDA8-O₃ predictions (black line; left y axis) and corresponding anomalies (colored**

328 **bar; right y axis) from 1981 to 2019: (a) annual mean; and (b) warm-season mean (May–September). The trends**
 329 **(growth rates) are obtained by ordinary linear regression on mean values of MDA8-O₃. The anomalies are defined**
 330 **as annual mean minus the multidecadal average over 1981–2019.**

331 In recent years, the worsening O₃ pollution has fueled numerous studies on ground-level O₃ spatial distribution and
 332 changes in China, which were conducted on local, regional and national scale using different O₃ fields from observations,
 333 CTMs and ML estimates. In this study, we mainly focus on the regional and national O₃ characteristics, and the reported
 334 O₃ trends in recent studies are listed in **Table 1**. By comparing the results of existing works, we find that source-varied O₃
 335 fields can induce great uncertainty of the O₃ trends. Moreover, the O₃ trends are found to be very sensitive to the study
 336 period even with the same O₃ fields (Wei et al., 2022), which indicates large interannual variability, mostly reflecting the
 337 changing anthropogenic emissions and meteorology (Lu et al., 2019; Li et al., 2020). In contrast to the perceptible O₃ trends,
 338 Liu et al. (2020) suggested that O₃ pollution in most parts of China has only modest changes between 2005 and 2017, and
 339 their trends were not spatially continuous. Wang et al. (2022b) also reported that O₃ has small positive increase rates for
 340 2013–2021 in many cities, and the O₃ increase rates greatly differ from site to site even within the same region.

341 In comparison, our results indicate no obvious increasing trends of national MDA8-O₃ within the same study period.
 342 On a regional scale, only BTHs have a perceptible increasing trend in more recent years, while no such trends are found
 343 over the YRD, SCB and PRD regions during the same period. The summertime MDA8-O₃ in BTHs has a change rate of
 344 +0.81 $\mu\text{g m}^{-3}\text{ yr}^{-1}$, which is much lower than the results using O₃ observations (Li et al., 2020). One possible reason is that
 345 most observational sites are in urban regions, which usually suffer more serious O₃ pollution, while the O₃ concentrations
 346 from model simulations and ML methods are calculated on the scale of a grid cell with lower domain-averaged values.
 347 Moreover, gridded data at a relatively coarse resolution may fail to capture larger site differences, leading to the larger
 348 discrepancy of between O₃ observations and gridded O₃ estimates.

349 **Table 1 Summary of reported regional and national MDA8-O₃ trends ($\mu\text{g m}^{-3}\text{ yr}^{-1}$).**

350

351 3.3 Seasonal characteristics of O₃ predictions

352 Differences in averaged annual and warm-season O₃ concentrations indicate that O₃ has distinctive seasonal
353 characteristics. **Fig. 6** shows the seasonal variations in O₃ concentrations from 2011–2019, and results for other past three
354 decades are shown in **Fig. S7-S9**. In winter, pollution is mainly concentrated in the coastal areas of southern China. In
355 spring, O₃ pollution primarily occurs in eastern China and the southern part of Yunnan Province. O₃ pollution continues to
356 aggravate over eastern China in summer, particularly in BTHs, and further extends to SCB. The air quality in eastern and
357 central China is greatly improved in fall, while southern China experiences the most pollution in this period. In general,
358 the peak and trough values of O₃ concentrations appear in summer and winter, respectively. However, O₃ concentrations
359 are found to be minimum in summer and maximum in fall over PRD, which is largely determined by the summer monsoon
360 (Zhou et al., 2013; Wang et al., 2018a). **Fig. S10** shows the seasonal averaged MDA8-O₃ concentrations in different regions
361 from 1981 to 2019. In winter, O₃ concentrations do not have much change across the four regions over the past decades,
362 staying mostly between 70–80 µg m⁻³. Moreover, wintertime O₃ concentrations after the 2000s are generally lower than
363 that before the 2000s in BTHs, YRD and SCB. In contrast, summertime O₃ concentrations have a dramatic increase over
364 the four regions. In spring and fall, O₃ concentrations have an increasing trend in PRD, while it mostly fluctuates within a
365 certain range in the other three regions. The results show that O₃ in non-winter seasons has a more pronounced increase
366 during 1981–2019 albeit with regional differences. The regional characteristics of O₃ and its influencing factors will be
367 further discussed in Section 3.4. The BTH, SCB, YRD, and PRD regions have been identified as hotspots of O₃ pollution
368 in China. These regions are characterized by high population density (Wang et al., 2018b) and are also major agricultural
369 areas (Monfreda et al., 2008), which may face greater burdens of crop yield and human health losses with high O₃
370 concentrations. Therefore, here we provide more detailed analysis and investigation of these regions.

371

396

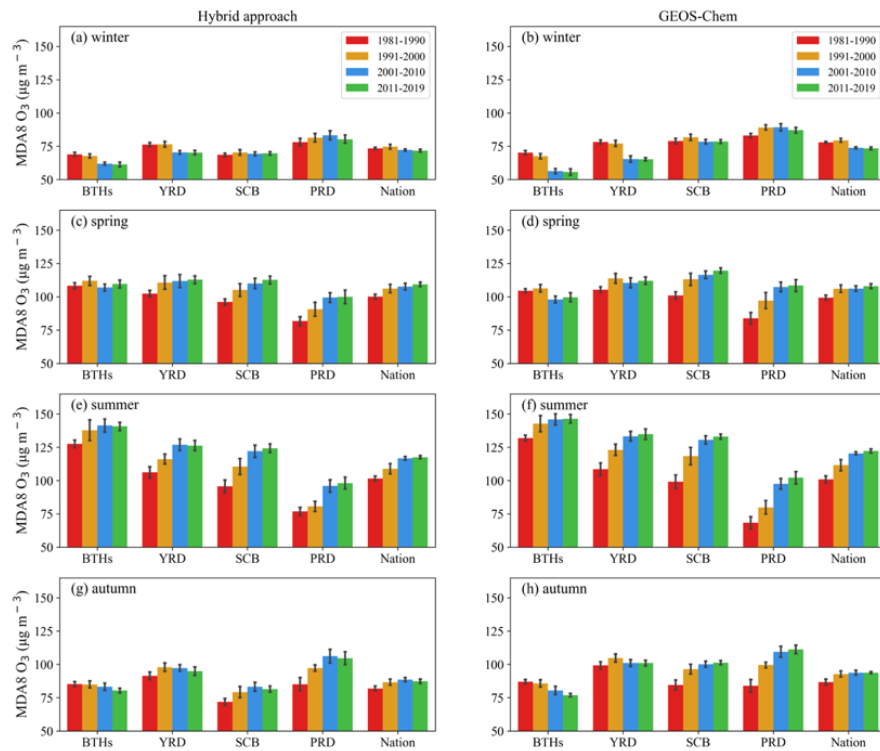

397

Fig. 7 shows the bar plots of the seasonal MDA8-O₃ concentrations in each region from 1981–2019 for bias-corrected and GEOS-Chem-simulated O₃. For the bias-corrected O₃, the averaged summertime MDA8-O₃ concentrations in BTHs, YRD, SCB and fall-time MDA8-O₃ concentrations in PRD are $137 \pm 8 \mu\text{g m}^{-3}$, $119 \pm 10 \mu\text{g m}^{-3}$, $113 \pm 12 \mu\text{g m}^{-3}$ and $98 \pm 10 \mu\text{g m}^{-3}$, with the increasing rate being $0.46 \mu\text{g m}^{-3} \text{yr}^{-1}$, $0.73 \mu\text{g m}^{-3} \text{yr}^{-1}$, $0.98 \mu\text{g m}^{-3} \text{yr}^{-1}$ and $0.69 \mu\text{g m}^{-3} \text{yr}^{-1}$ from 1981 to 2019, respectively (**Fig. S11**). For GEOS-Chem-simulated O₃, the averaged summertime MDA8-O₃ concentrations in BTHs, YRD, SCB and fall-time MDA8-O₃ concentrations in PRD are $141 \pm 7 \mu\text{g m}^{-3}$, $125 \pm 11 \mu\text{g m}^{-3}$, $120 \pm 14 \mu\text{g m}^{-3}$ and $100 \pm 12 \mu\text{g m}^{-3}$, respectively. It shows that O₃ concentrations of the four regions have a consistent upward trend in the summer over the past decades, but there are regional differences in other seasons. Compared to BTHs and YRD, PRD and SCB have more distinctive O₃ increases in spring and fall. Among these four regions, the O₃ concentrations in BTHs have the biggest seasonal differences, but have the smallest seasonal differences in PRD.

The spatiotemporal patterns of O₃ in China have been proven to largely depend on both emissions and meteorology. The regional O₃ pollution is usually found to be triggered by specific circulation patterns as local meteorological factors are modulated by synoptic-scale circulation patterns. China has a large territory and is affected by different weather systems. The continental high-pressure systems, components of East Asian summer monsoon (EASM) and tropical cyclones, among others, are critical synoptic conditions leading to O₃ formation and transport in China (Wang et al., 2022b; Han et al., 2020). For instance, regional O₃ pollution in North China usually occurs under a typical weather pattern of an anomalous high-pressure system at 500 hPa (Gong and Liao, 2019), which creates favorable meteorological conditions for high O₃ levels with high temperature, low relative humidity, anomalous southerlies and divergence in the lower troposphere. As one of the most important components of EASM, the Western Pacific subtropical high (WPSH) strongly influences summertime precipitation and atmospheric conditions in East China. A strong WPSH can decrease O₃ levels over YRD as enhanced moisture is transported into YRD under prevailing southwesterly winds (Zhao and Wang, 2017). Located on the southern coast of China, PRD features a typical subtropical monsoon climate. There O₃ concentrations are usually the lowest in summer due to the prevailing southerlies with clean air from the ocean and the associated large rainfall, while the worst O₃

398 pollution usually happens in fall mainly due to the occasional northerly winds during the monsoonal transition, thereby
 399 importing precursors from the north, and stable and still relatively warm and sunny weather conditions before the winter
 400 starts. Downdrafts in the periphery circulation of a typhoon system can also strongly enhance surface O₃ before typhoon
 401 landing (Jiang et al., 2015; Lu et al., 2021; Li et al., 2022). On one the hand, the poor ventilation in the peripheral subsidence
 402 region of typhoons favors the accumulation of O₃ and its precursors. On the other hand, the deep subsidence can transport
 403 the O₃ in the upper troposphere and lower stratosphere to surface, causing aggravated O₃ pollution. Moreover, smaller-
 404 scale circulation patterns, such as land-sea and mountain-valley breezes, also influence O₃ in coastal regions (Ding et al.,
 405 2004; Zhou et al., 2013; Wang et al., 2018a).

406 When compared to the hybrid approach, GEOS-Chem generally has similar O₃ distribution and trends over each
 407 region, while overestimating O₃ concentrations (**Table S4**). GEOS-Chem particularly overestimates wintertime and fall-
 408 time O₃ concentrations in SCB, which are $10 \pm 1 \mu\text{g m}^{-3}$ and $17 \pm 3 \mu\text{g m}^{-3}$ higher than those of the hybrid approach,
 409 respectively. Previous studies reported such model overestimates and proposed a number of explanations involving
 410 precursor emissions, dry deposition, and vertical mixing in the planetary boundary layer (PBL) (Lin et al., 2008; Travis et
 411 al., 2016; Fiore et al., 2005). Both observational analyses and inter-model comparisons suggested that the summertime dry
 412 deposition of O₃ calculated by the Wesely scheme in GEOS-Chem could be underestimated, which has been invoked as a
 413 cause for model overestimates of O₃. The biased emissions in the model, as consistent with the biased-high tropospheric
 414 NO_x columns, result in overestimated O₃. Travis et al. (2016) showed that GEOS-Chem with reduced NO_x emissions
 415 provides an unbiased simulation of O₃ observations from the aircraft and reproduces the observed O₃ production efficiency
 416 in the boundary layer. Lin et al. (2008) suggested that the excessive PBL mixing can lead to the biased-high O₃
 417 concentrations. The fully mixed O₃ throughout the PBL means that the higher O₃ concentrations in the upper PBL are
 418 brought down to the surface much more efficiently. Moreover, the excessive spatial averaging of emissions at coarser
 419 resolutions could also lead to systematic overestimation of regional O₃ production (Wild and Prather, 2006). In summary,
 420 with a higher prediction accuracy, the hybrid approach lends greater credence to using model simulations to extrapolate
 421 historical O₃ further back in time, which can furthermore provide us with more accurate estimates of O₃ impacts on crop
 422 production and human health.

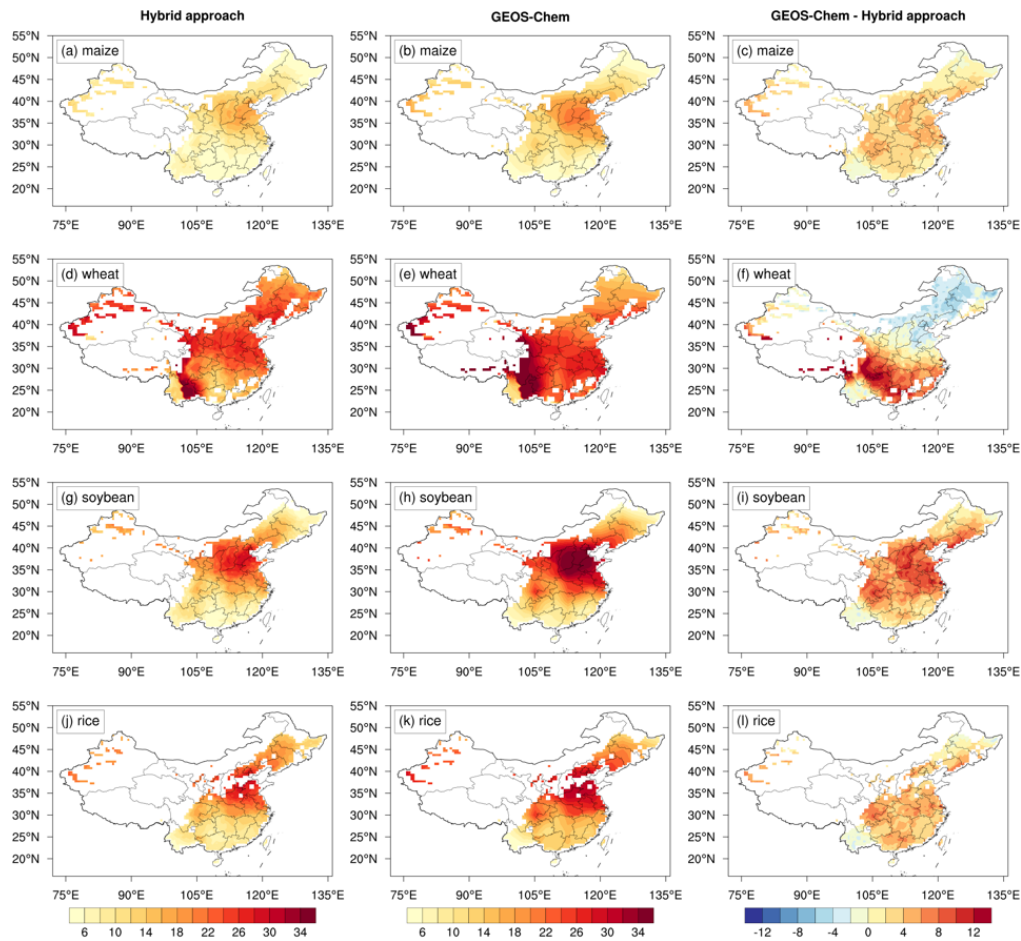

423

424 **Figure 7. The seasonal mean MDA8-O₃ concentrations ($\mu\text{g m}^{-3}$) in different regions during 1981-2019. Bias-**
 425 **corrected MDA8-O₃ in: (a) winter; (c) spring; (e) summer; and (g) fall. GEOS-Chem MDA8-O₃ in: (b) winter; (d)**
 426 **spring; (f) summer; and (h) fall. The error bar represents the standard deviation.**

427 3.5 Crop production losses attributable to O₃ pollution

428 **Fig. 8** shows the relative yield losses (RYLs; $\text{RYL} = 1 - \text{RY}$, where RY is the relative yield defined as the ratio of the
 429 O₃-affected yield to the yield without O₃ exposure) calculated with GEOS-Chem and bias-corrected O₃ using AOT40-
 430 China metric. For a given crop, the RYLs show generally consistent spatial distribution across the metrics, with BTHs
 431 having the most serious crop yield losses due to high O₃ concentrations. Compared to the bias-corrected O₃, using GEOS-
 432 Chem-simulated O₃ generally leads to larger yield losses, especially over BTHs and SCB, reflecting overestimated O₃
 433 concentrations by GEOS-Chem in cropland areas during the growing seasons (**Fig. S12**), primarily in spring and summer,
 434 which is consistent to the above analysis. GEOS-Chem-simulated O₃ leads to slightly underestimated wheat yield loss only
 435 over some parts of BTHs, mostly because the primary growing period of wheat there is in winter and spring, and GEOS-
 436 Chem has lower O₃ estimates than the hybrid approach during this period there (**Table S4**).

437 **Figure 8. Estimated annual mean relative yield losses (RYLs, in %) of four staple crops from 1981–2019 using the**
 438 **AOT40-China metric. The estimated RYLs using bias-corrected O₃: (a) maize; (d) wheat; (g) soybean; and (j) rice.**
 439 **The estimated RYLs using GEOS-Chem-simulated O₃: (b) maize; (e) wheat; (h) soybean; and (k) rice. The**
 440 **differences in estimated RYLs between GEOS-Chem-simulated and bias-corrected O₃: (c) maize; (f) wheat; (i)**
 441 **soybean; and (l) rice. The GEOS-Chem-simulated O₃ were regridded to $0.5^\circ \times 0.5^\circ$ for comparison with bias-**
 442 **corrected O₃.**

444 **Fig. 9** shows the bar plots of the relative yield for each crop using AOT40-China exposure-yield response relationship.
445 Crop yield losses are generally consistent with the O₃ trends as the exposure-yield relationships used here are essentially a
446 set of linear functions. Most crops experience aggravated yield losses over the past four decades due to enhanced O₃
447 concentrations, except for wheat, which has the largest yield loss during the period 1991 to 2000. The reason could be that
448 BTHs have the highest O₃ concentrations in spring during the 1990s, which is the primary growing season for wheat (**Fig.**
449 **S13**). Noticeable uncertainties of crop yield losses are found across metrics.

450 The average annual crop RYLs from 1981 to 2019 for wheat, rice, soybean and maize range from 1.1 to 13.4%, 2.7 to
451 13.4%, 6.3 to 24.8% and 0.8 to 7.4%, respectively. The differences in yield losses across crops reflect the dependence on
452 crop-specific phenology and ecophysiology. The estimated annual RYLs using bias-corrected O₃ for wheat, rice, soybean
453 and maize from 1981 to 2019 range from 17.5–25.5%, 10.7–19.1%, 7.3–17.9% and 7.1–12.7%, with a growth rate of 0.03%
454 yr⁻¹, 0.04% yr⁻¹, 0.27% yr⁻¹ and 0.13% yr⁻¹. Wheat is the most sensitive crop to the O₃ concentrations, whereas maize is
455 the least sensitive. Using GEOS-Chem-simulated O₃, the estimated annual RYLs for wheat, rice, soybean and maize from
456 1981 to 2019 are 18.7–28.7%, 14.0–22.0%, 12.4–23.1%, and 7.9–13.2%, having a growth rate of 0.08% yr⁻¹, 0.14% yr⁻¹,
457 0.23% yr⁻¹ and 0.11% yr⁻¹. There are noticeable differences in crop yield estimates using the bias-corrected and GEOS-
458 Chem O₃, indicating again the importance of the bias-corrected high-resolution O₃ data in related crop issues.

459 In existing studies evaluating the O₃-induced crop losses in China, which also use exposure-yield relationship derived
460 from the experiments conducted in Asia, Zhang et al. (2017) reported that the ambient O₃ concentrations in Northeast China
461 cause substantial annual yield loss of soybean ranging from 23.4% to 30.2% during 2013 and 2014, depending on the O₃
462 metric used (including AOT40, W126, SUM06 and a flux-based metric). Feng et al. (2022), using AOT40, indicated that
463 the annual average RYLs of wheat (33%), rice (23%) and maize (9%) from 2017 to 2019. Our correspondingly estimated
464 RYLs for rice (18.0%) and maize (10.0%) are generally consistent to their results, while the RYLs for soybean (16.4%)
465 and wheat (23.4%) are much lower than the estimates. Since we used the same exposure-yield response relationships in
466 their studies, the discrepancies are primarily attributed to the differences in used metrics (only for soybean), O₃ fields and
467 sensitivity of crop to the changes of O₃ concentrations (Mukherjee et al., 2021; Feng et al., 2022; Mills et al., 2018). In
468 Zhang et al. (2017), the O₃ measurements are obtained from the experimental field (45°73'N, 126°61'E), and in Feng et al.
469 (2022), the measured O₃ concentrations are from over 3,000 monitoring sites across East Asia. The results of comparison
470 are consistent to the previous analysis of O₃ trends and variability from different sources, where the domain-average values
471 of O₃ observations are larger than gridded O₃ from model simulations (**Section 3.2**) and thus lead to larger estimates of
472 RYLs. On one hand, it indicates that O₃ fields should be considered as a great source of uncertainty when comparing the
473 results of previous studies using source-varied O₃ fields. Moreover, different degrees of importance should be given for
474 specific crops, for example, the changes in O₃ concentrations have a larger impact on wheat crop. On the other hand, it
475 highlights again the necessity and importance of bias correction for model-simulated O₃ when O₃-induced crop reduction.

476

 480 **represents the standard deviation.**

481 **3.6 Health impacts attributable to O₃ pollution**

482 The estimated annual all-cause premature deaths induced by O₃ increase from 55,876 in 1981 to 162,370 in 2019 with
 483 an increasing trend of +2,979 deaths yr⁻¹. The annual premature deaths related to respiratory and cardiovascular diseases
 484 are 34,155 and 40,323 in 1998, and 26,471 and 79,021 in 2019, having a rate of change of -546 and +1,773 deaths yr⁻¹
 485 during 1998–2019, respectively (**Fig. 10a**). Among three types of health outcomes, only respiratory diseases experienced
 486 a decreasing trend in premature mortality, and the premature mortality is constantly below 40,000. The decreasing trend of
 487 the respiration-related mortality primarily results from the decreased annual baseline mortality rate over the past decades
 488 (**Fig. S14**). As the total respiratory-related deaths decreased over the past decades, respiratory O₃ deaths are decreasing
 489 even under aggravated O₃ pollution. Based on GEOS-Chem-simulated O₃, the corresponding estimated change rate for all-
 490 cause disease is +3,516 deaths yr⁻¹ from 50,384 in 1981 to 176,741 in 2019. Premature mortality induced by respiratory
 491 disease decreases from 37,822 in 1998 to 29,079 in 2019 with a change rate of -584 deaths yr⁻¹, while cardiovascular
 492 disease increases from 44,516 in 1998 to 85,980 in 2019 with a change rate of +1,977 deaths yr⁻¹ (**Fig. S15**). The result
 493 shows that using GEOS-Chem-simulated O₃ generally gives higher estimates of mortality than using the bias-corrected
 494 data. **Fig. 10b** shows the provincial annual average premature mortality of different health endpoints. The five provinces
 495 with the highest all-cause mortality are Jiangsu [14,510 (95% CI: 9,022–19,935)], Shandong [12,684 (95% CI: 4,258–
 496 20,990)], Henan [12,290 (95% CI: 4,125–20,343)], Guangdong [9,268 (95% CI: 7,224–11,416)] and Hebei [8,276 (95%
 497 CI: 2,776–13,706)], which are generally consistent with previous studies for China (Zhang et al., 2021; Zhang et al., 2022a).
 498 Similar distribution can be found for respiratory and cardiovascular diseases but with a different ranking order. Generally,
 499 those provinces in densely populated areas (**Fig. 10c**) with higher O₃ concentrations, such as BTHs, YRD and PRD, have
 500 higher health burdens. In contrast, the northeastern and southern China (excluding Guangdong) suffer the least life losses

501 induced by O₃ exposure (**Fig. S16**).

502 When compared with estimates from previous studies, our estimates of are generally quite consistent with that given
503 by Maji and Namdeo (2021), which reported that the short-term all-cause, cardiovascular and respiratory premature
504 mortalities attributed to ambient O₃ exposure were 156,000, 73,500 and 28,600 in 2019. Based on O₃ observations in 334
505 Chinese cities, Zhang et al. (2021) suggested that the national all-cause, respiratory, cardiovascular mortalities attributable
506 to O₃ are 270,000 to 390,000, 49,000 to 63,000, and 150,000 to 220,000 across 2015–2018, which are much higher than
507 most existing results. Since the methodological approaches are largely similar and we use the log-linear exposure-response
508 function, we ascribe that the very high estimated mortalities are mainly due to concentration–response threshold X_0 assumed
509 to be zero in their study. A lower X_0 means that O₃ can cause more adverse impacts on human health even at low
510 concentrations, thus leading to higher mortalities.

511 **Figure 10. (a) Annual premature mortality (thousand) for different diseases over the past decades; (b) annual mean**
512 **province-based mortality (thousand) attributed to different health endpoints; and (c) annual mean province-based**
513 **population (million). The mortality is calculated using the bias-corrected O₃.**
514

515 4. Conclusions and discussion

516 In this study, to have a more accurate characterization of O₃ spatiotemporal distribution and trends as well as their
517 impacts on agriculture and human health, we used a hybrid approach to generate bias-corrected O₃ data across China from
518 1981 to 2019. The hybrid approach helps improve O₃ predictions by taking advantage of a chemical transport model, a ML
519 algorithm and increasing availability of high-resolution environmental and meteorological data. In the model training
520 process, we found that utilizing a higher-resolution meteorological dataset, albeit one that is not the same as the default
521 CTM input meteorology, has high potential to enhance the performance of the hybrid model in reproducing observed O₃
522 concentrations. The validation shows that the bias-corrected O₃ can achieve a higher prediction accuracy than GEOS-
523 Chem-simulated O₃ alone when compared with historical in-situ measurements. Before being corrected, the GEOS-
524 Chem-simulated O₃ concentrations tend to be overestimated and lead to higher crop yield losses and larger O₃-induced mortalities.

525 Noticeable differences in crop RYLs and mortality estimates highlight the advantages of using high-resolution O₃ data to
526 improve our understanding of long-term O₃ impacts.

527 When examining the regional and national O₃ trends, we found that MDA8-O₃ concentrations have a perceptible
528 increasing trend before 2000s, but fluctuate within a certain range with large interannual variabilities in more recent years.
529 The large discrepancies in previous studies indicate that the regional and national O₃ trends in China still suffer with great
530 uncertainties, particularly when different approaches are used to produce the O₃ estimates. However, these studies using
531 source-varied O₃ fields consistently show the great interannual variabilities of O₃ concentrations. Some insights can be
532 obtained from existing findings, which need to be carefully considered when examining O₃ trends and comparing them
533 with existing results. First, given the large site differences, the calculation of observational O₃ trends is very sensitive to
534 the subsets of data from networks. Thus, great uncertainty could still exist even using O₃ observations from the same source
535 depending on the chosen subsets of data. Second, different formats of O₃ fields (e.g., site-based and gridded) could lead to
536 large uncertainties of the O₃ trend estimates. A higher resolution of gridded O₃ estimates from CTMs and ML may reduce
537 the differences between O₃ observational results. Third, the calculated O₃ trends are very sensitive to the chosen study
538 period due to large interannual variability and seasonal differences. The changing meteorological conditions are the major
539 factor causing the large interannual O₃ variations, and reductions in the emissions of NO_x, SO₂ and PM also have complex
540 effects on ground-level O₃ concentrations (Wang et al., 2022b). Liu and Wang (2020a) suggested that the meteorological
541 impacts on O₃ trends vary region by region and year by year and could be comparable with or even larger than the impacts
542 of changes in anthropogenic emissions.

543 Our estimated RYLs for maize and rice and soybean in China are generally consistent to existing studies, while the
544 RYLs for soybean and wheat are lower than their estimates mainly due to the differences in used metrics, O₃ fields and
545 crop sensitivity to ambient O₃ concentrations. It suggests that plating O₃-resistant cultivars could be an effective approach
546 to increase total crop production to meet the increasing food demands. In addition to the metrics and O₃ fields, uncertainties
547 of estimated O₃-induced crop losses could be also from other sources (e.g., exposure-yield relationships). Though some
548 other metrics (e.g., M7/M12 and W126) have also been used in some studies (Van Dingenen et al., 2009; Avnery et al.,
549 2013; Wang et al., 2022c), there are not available exposure-yield relationships for all four major crops specific for China.
550 The estimated RYLs for crops could be largely biased using metrics with exposure-yield relationships developed for U.S.
551 or Europe (**Fig. S17**), as they are inadequate to represent Asian crop genotypes and environmental conditions. So, the
552 region-specific exposure-yield relationships are highly recommended to be used in future study estimating the O₃-induced
553 crop reduction, especially for the regional study.

554 In recent years, although existing studies have made efforts to quantify the O₃-related health impacts in China, only a
555 few focused on the nationwide acute O₃ health burden assessment, particularly for assessment over multiple decades (Maji
556 and Namdeo, 2021; Sahu et al., 2021; Zhang et al., 2021; Zhang et al., 2022a). There are some remaining issues to be
557 addressed regarding O₃ health impacts. For instance, the existence of a “safe” threshold of O₃ levels still remains debated.
558 A recent study reported that no consistent evidence was found for a threshold in the O₃-mortality concentration-response
559 relationship in seven cities of Jiangsu Province, China during 2013–2014 (Chen et al., 2017; Maji and Namdeo, 2021).
560 Given the importance of the threshold assumption in assessing health effects of air pollution, more studies are needed to
561 determine a most likely threshold for O₃-mortality association in the future. Moreover, the multiple temporal O₃ metrics
562 (e.g., 1-h maximum and daytime average O₃ concentrations) have also been proved to play an important role in the
563 variability of estimated health effects, even though standard ratios are used to convert among multiple metrics (Anderson
564 and Bell, 2010). In addition to the uncertainties from varying methodologies, interpretation of the O₃ epidemiological
565 impact is also constrained by the variability in geographical, seasonal, and demographic characteristics (Yin et al., 2017b).
566 Liu et al. (2013) suggested that associations between O₃ and mortality appeared to be more evident during the cool season
567 than in the warm season, and stronger in the oldest age group and among those with less education. The effect modification

568 by population susceptibility and the confounding effects of concomitant exposures (temperature, particulate matter, etc.)
569 should be further considered in future works.

570 A major limitation of our study lies in the uncertain predictions in regions where monitoring data are scarce (e.g., the
571 western half of China). The monitoring sites are sparsely distributed in those areas, which may fail to capture the accurate
572 association between O₃ concentrations and various predictors there, especially considering that the ML algorithm has likely
573 over-emphasized such relationships in the data-intensive eastern regions. Second, the land use data were prescribed in 2013
574 due to the limited availability of data, and this may neglect some major land use changes in China over the past decades.
575 Though the land use data were found by the ML algorithm to contribute little to the overall model, more detailed land use
576 data are expected to further increase model accuracy. In addition, though concentration-based metrics are easy to calculate
577 and ensured to be scientifically sound in some experiments (Fuhrer et al., 1997; Mills et al., 2007), they do not consider
578 the active responses of plant ecophysiology to ambient climatic and environmental changes and thus likely inadequate for
579 examining yield losses in a future climate and atmospheric environment (Tai et al., 2021). So, flux-based metrics are
580 recommended in future studies to better understand the long-term evolution of crop losses over China (Feng et al., 2012;
581 Zhang et al., 2017; Tai et al., 2021; Pleijel et al., 2022), wherein more crop- and region-specific experiments and trials are
582 needed to acquire appropriate metrics and exposure-yield response functions and calibrate the process-based crop model.

583 Despite these limitations, our study represents important progress in evaluating the long-term, multidecadal health
584 burdens and agricultural losses resulting from O₃ pollution in China. Across the four major regions, BTHs experience the
585 highest RYLs for major crops due to elevated O₃. On the other hand, the YRD and PRD regions have greater human health
586 losses primarily due to their large population size. The results can provide important references for governments and
587 agencies when making related national or regional policies to meet the imperative environment, health, and food security
588 demands. To effectively address O₃ impacts, collaborative efforts can be made in multifaceted aspects: (1) to implement
589 stricter regulations and specific emission control measures for major ozone precursors from industrial, vehicular and
590 agricultural sources that account for region-specific chemical, meteorological and terrestrial conditions; (2) to encourage
591 the adoption of more sustainable and adaptive agricultural practices that minimize O₃ exposure and its damage on crops
592 (e.g., cultivating O₃-resistant crop varieties); (3) to improve short-range O₃ forecast capabilities of regional models,
593 especially with the enhancement of artificial intelligence technology, which may enable better early warning systems to
594 prepare the public and farmers for O₃ episodes; (4) to raise public awareness via promotional campaigns and educational
595 programs to inform individuals, communities, and farmers about the risks associated with O₃. It is important for
596 policymakers to consider these suggestions and act to effectively mitigate the negative O₃ impacts.

597 **Data availability.** Model output data used for analysis and plotting are available on the open-access online repository:
598 [ml_simulated_ozone_China](#).

599 **Competing interests.** The authors declare that neither they nor their co-authors have any competing interests. At least one
600 of the (co-)authors is a member of the editorial board of Atmospheric Chemistry and Physics.

601 **Author contributions.** APKT designed the study and supervised the writing of the paper. JM conducted model simulation,
602 analyzed results, and wrote the draft with the assistance of TGY and KTC. DHYY performed the GEOS-Chem simulations.
603 ZZF assisted in the interpretation of the results. All authors contributed to the discussion and improvement of the paper.

604 **Acknowledgements.** This work was supported by the National Natural Science Foundation of China (NSFC)/Research
605 Grants Council (RGC) Joint Research Scheme (reference #: N_CUHK440/20, 42061160479) awarded to A. P. K. Tai and
