Abstract. The sensitivity of satellites to air pollution close to the sea surface is decreased by scattering of light in the atmosphere and low sea surface albedo. To reliably retrieve tropospheric nitrogen dioxide (NO₂) columns using the Tropospheric Monitoring Instrument (TROPOMI), it is therefore necessary to have good a priori knowledge of the vertical distribution of NO₂. In this study, we use an aircraft of the Royal Belgian Institute of Natural Sciences, which was already equipped with a sniffer sensor system, measuring NO_x (= NO + NO₂), CO₂ and SO₂. This instrumentation enables us to evaluate vertical profile shapes from several chemical transport models and to validate TROPOMI tropospheric NO₂ columns over the polluted North Sea in the summer of 2021. We observe multiple clear signatures of ship plumes from seconds after emission to multiple kilometers downwind. Besides that, our results show that the chemical transport model TM5-MP, which is used in the retrieval of the operational TROPOMI NO₂ data, tends to underestimate surface level pollution while overestimating NO₂ at higher levels over the study region. The higher horizontal resolution in the regional CAMS ensemble mean and LOTOS-EUROS model improve the surface level pollution estimates, but the models still systematically overestimate NO₂ levels at higher altitudes, indicating exaggerated vertical mixing in the models over the North Sea. When replacing the TM5 a priori NO₂ profiles with the aircraft-measured NO₂ profiles in the air mass factor (AMF) calculation, we find smaller recalculated AMFs. Subsequently, the retrieved NO₂ columns increase by 20%, indicating a significant negative bias in the operational TROPOMI NO₂ data product (up to v2.3.1) over the North Sea. This negative bias has important implications for estimating emissions over the sea. While TROPOMI NO₂ negative biases caused by the TM5 a priori profiles have also been reported over land, the reduced vertical mixing and smaller surface albedo over sea makes this issue especially relevant over sea and coastal regions.

Keywords. NO₂, TROPOMI, validation, shipping, profile, aircraft

1 Introduction

20 Satellite data of air pollutants is increasingly used for policy making, which requires reliable retrievals. This paper evaluates TROPOMI tropospheric NO₂ columns by comparing aircraft measurements of NO₂ profiles over the polluted North Sea to chemical transport models and studying uncertainty and bias in the TROPOMI NO₂ retrieval from modeled profile shapes.

Nitrogen oxides (NO_x = NO+NO₂) decrease air quality, having negative impact on human health and environment. NO₂ is known to cause cardiovascular and respiratory diseases (Luo et al., 2016). Depending on chemical regime, nitrogen oxides also lead to surface O₃ formation which in turn harm the human respiratory system and plant growth. The international shipping sector is responsible for at least 15% of anthropogenic nitrogen oxides emissions globally (Crippa et al., 2018; Eyring et al., 2010; Johansson et al., 2017) while causing 3% of anthropogenic CO₂ emission (IMO, 2020; European Commission, 2022).

While NO_x emissions from most anthropogenic sectors have been decreasing in recent years in western countries (e.g Zara et al. (2021); Fortems-Cheiney et al. (2021); Jiang et al. (2022) and references therein), intensity of ocean going ships has been and is expected to keep rising (IMO, 2020) and individual ships' NO_x emissions have been observed to increase (Van Roy et al., 2022b). NO_x emissions from shipping can lead to high background pollution levels in often densely populated coastal areas, limiting the impact of emission reductions in land-based sources. For all the above reasons, international regulations for (newly build) ships constrain emissions with incremental limits. For example, the NO_x Emission Control Area (NECA) in the North and Baltic Sea came into effect on 1st January 2021, requiring that newly build ships sailing in these seas comply with International Maritime Organization (IMO) Tier III, which should result in 75% lower NO_x emissions compared to ships build since 2011 (IMO, 2013). Details in emission limits depend on engine speed. For these regulations to be effective, monitoring of ship emissions is essential. Current monitoring routines include airplanes equipped with sniffer sensors (Van Roy et al., 2022b) or other remote sensing devices. Aircraft monitoring is costly, time consuming and practically feasible in coastal regions only. For a consistent and temporally and spatially complete approach current and upcoming satellite remote sensing missions offer promising options.

TROPOMI (TROPOspheric Measurement Instrument) on the European Sentinel-5 Precursor (S5P) is one of these satellite instruments and has been used to study emissions patterns within cities (Beirle et al., 2019; Goldberg et al., 2020; Lorente et al., 2019) as well as urban OH concentrations (Lama et al., 2022). While NO₂ over shipping lanes and its trends were previously studied on long-time averages of TROPOMI's predecessors GOME, SCIAMACHY & OMI (Richter et al., 2004; Beirle et al., 2004; Vinken et al., 2014), the higher spatial resolution and lower noise of TROPOMI make single ship plume detection possible (Georgoulas et al., 2020). Recent studies succeeded to discriminate NO₂ ship plume signatures from the background using TROPOMI tropospheric NO₂ columns (Kurchaba et al. (2021); Finch et al. (2022)). However, the validity of TROPOMI NO₂ and its uncertainties needs to be studied further to be able to reliably determine a ship's emissions and monitor compliance.

Prior knowledge of the state of the atmosphere during satellite remote sensing of trace gases such as NO₂ is key for the retrieval process. This includes surface radiative properties, radiative transfer in the atmosphere and vertical distribution of the trace gas. Much attention is therefore given to improve these aspects: recent updates in the cloud retrieval used for TROPOMI NO₂ columns lead to better agreement with independent data and reduce the known negative bias in tropospheric NO₂

columns (Van Geffen et al., 2022; Riess et al., 2022). Likewise, Riess et al. (2022) have shown that columns retrieved under sun glint conditions are reliable and enhance the instruments sensitivity to low altitude NO_2 . Glint conditions are therefore in principle beneficial for the monitoring of NO_x emissions over sea. On the other hand, a priori profiles remain a source of uncertainty. The profiles from the Transport Model 5 (TM5-MP) with a resolution of $1^\circ \times 1^\circ$ used in the operational TROPOMI NO_2 product are very coarse compared to the ground pixel size of the measurements ($3.5 \times 5.5 \text{ km}^2$ at nadir) while NO_2 profiles close to spatially confined emission sources such as ships are expected to vary significantly within kilometers (Douros et al., 2023; Griffin et al., 2019; Ialongo et al., 2020; Chen et al., 2005). Additionally, uncertainties in the vertical mixing and thus in the a priori profile shapes, combined with the satellite's non-linear decreasing sensitivity towards the surface, pose a source of error. Furthermore, the model assumes temporally averaged emissions which does not hold for varying emission sources such as moving ships, adding to uncertainties in the a priori NO_2 profiles.

The TROPOMI NO_2 product allows the user to replace the a priori profiles with their own modelled or measured profiles (e.g. Visser et al. (2019); Douros et al. (2023)). Douros et al. (2023) used the high-resolution CAMS ensemble mean NO_2 profile to replace the TM5-MP a priori NO_2 profiles in the calculation of the air mass factor (AMF) and to create an improved European TROPOMI NO_2 product. They found significant changes in resulting tropospheric columns with increases at hot-spot regions of up to 30%. A similar study found a 20% increase in tropospheric columns over Europe when using LOTOS-EUROS profiles as a priori (Pseftogkas et al., 2022). For the above reasons, validation of these modelled a priori profiles is very important. In the past, validation has focused on land (Ialongo et al., 2020) and clean background over sea (Boersma et al., 2008; Shah et al., 2022; Wang et al., 2020). However, evaluation over shipping lanes is missing from literature.

In this study, we investigate aircraft-based in-situ measurements of NO_x (and more) over a polluted area with major shipping routes and nearby industrial and densely populated centres: the North Sea. We combine ten spiral flights with three horizontal scans to obtain vertical NO_2 profiles in the lower 1.5 km of the troposphere. The aircraft is routinely used by the Belgian coast guard for compliance monitoring of ship emissions and is equipped for measuring NO_x over sea. The aircraft measurements of 3-D NO_2 distributions over the North Sea provide a new means for satellite and model NO_2 profile validation. The aircraft profiles are representative of areas comparable to the TROPOMI ground pixel size. We compare the profiles to (temporally and spatially) coinciding modelled profiles from TM5-MP (as used in the operational TROPOMI NO_2 product), CAMS ensemble mean (as used in the European product by Douros et al. (2023)), and LOTOS-EUROS. As a contrasting case, we show co-sampled model profiles over land close to the Cabauw tower in the Netherlands and compare the lowest 200 m to measured NO_2 concentrations, highlighting the special challenge of of satellite trace gas retrieval over sea. In the last step, we present re-calculated TROPOMI NO_2 columns replacing the TM5-MP a priori NO_2 profile with the aircraft measured profile, accounting for the vertical sensitivity of the NO_2 retrieval and quantifying the error caused by a priori profiles modelled using coarse spatial resolution and time-averaged emissions.

2 Materials

85 The following section gives an overview of the data used and their sources, starting with the TROPOMI instrument in Sect. 2.1 and followed by the aircraft, LOTOS-EUROS model data & ship location data in subsections 2.2, 2.3 & 2.4, respectively.

Table 1. Overview of the TROPOMI products used and their key differences.

NO ₂ Retrieval	Processor version	Period covered	A priori profile	Adjustment of surface albedo
Operational product	v1.4	April 2018 - July 2021	TM5 1°x1°	No
	v2.2	July 2021 - present		
Reprocessed PAL	v2.3.1	April 2018 - present	TM5 1°x1°	Yes
TROPOMI _{CAMS}	v2.3.1	April 2018 - present	CAMS 0.1°x0.1°	Yes

2.1 TROPOMI NO₂ satellite data

Table 1 lists three different TROPOMI tropospheric NO₂ column data products used in this study. TROPOMI (Veefkind et al., 2012) is the single payload of the Sentinel-5 Precursor (S5P) satellite, which was launched in October 2017, and provides scientific quality retrievals of various trace gases since April 2018. S5P is flying in a sun-synchronous, ascending orbit with an equator overpass time of 13:30 local time. With a swath width of approximately 2600 km TROPOMI has near daily coverage at the equator, and at the latitude of the North Sea (52°N) the instrument frequently overpasses the same ground scene multiple times per day. The spatial resolution is 5.5 x 3.5 km² for nadir pixels, and 5.5 x 14 km² for pixels at the edge of TROPOMI's swath.

95 The retrieval of tropospheric NO₂ columns follows a three-step procedure: retrieval of a slant column density (N_s) with the DOAS-method in the visible spectrum (405-465 nm) (Platt and Stutz, 2008), separation of the stratospheric and tropospheric contributions ($N_{s,trop}$), and conversion of the tropospheric slant column into a vertical column ($N_{v,trop}$) by application of the air mass factor (AMF, M): $N_{v,trop} = N_{s,trop}/M$. The single-pixel slant column detection limit ($0.5 \cdot 10^{15}$ molec/cm²) is determined by the uncertainty in the spectral fitting procedure and has been validated in Tack et al. (2021). Of most interest for this study is the calculation of the tropospheric AMFs, which is the dominant error source in the retrieval (Lorente et al., 2017; Boersma et al., 2018). The AMF depends on the solar zenith angle, the satellite viewing zenith angle, on the scattering properties of the atmosphere and the surface, and on the vertical profile of the NO₂ in the troposphere (Martin et al., 2002; Boersma et al., 2004). For the TROPOMI NO₂ retrievals used here, the AMFs are calculated with the DAK radiative transfer model v3.3 (Lorente et al., 2017), based on pixel-specific input data on viewing geometry, surface albedo, residual cloud fraction and height, and the a priori vertical NO₂ profile. Scattering of light in the atmosphere together with the low sea surface albedo in the visible part of the spectrum decrease TROPOMI's sensitivity to NO₂ close to the sea surface (e.g. Eskes and Boersma (2003); Vinken et al. (2014)). Good knowledge of these a priori profiles as well as cloud coverage and surface albedo are therefore key for a good quality retrieval. While the cloud algorithm used in the TROPOMI operational NO₂ retrieval has

recently been improved to better account for residual cloud scattering (FRESCO+ wide) (Riess et al., 2022; Van Geffen et al.,
110 2022), the a priori vertical NO₂ profiles remain a major source of AMF uncertainty, especially over sea.

2.2 Aircraft campaign over the North Sea

The Britten Norman Island (BN2) aircraft from the Royal Belgian Institute of Natural Sciences, operating from Antwerp
airport, flew six missions over the North Sea between 2 June and 9 September 2021. The missions provided unique sampling
of the marine mixed layer, intercepting outflow from land, and vertical profiles from the sea surface to the lower troposphere
115 (±1500 m).

The aircraft is equipped with a sniffer sensor system measuring NO₂, SO₂, and CO₂. This system is developed for the purpose
of monitoring of compliance by ships to emission regulations (Mellqvist et al., 2017), specifically the MARPOL Annex VI
regulation 13 on NO_x emission strength and MARPOL Annex VI regulation 14 on sulphur fuel content from ships. The detailed
technical setup is described in Van Roy et al. (2022b, a, c). Of interest to our study is the NO_x sensor (Ecotech Serinus 40),
120 which operates with two separate paths to determine the NO and NO_x concentration almost simultaneously and is in use since
2020. In the first path, the concentration of NO in the air sample is determined from the observed chemiluminescent intensity
emitted by activated NO₂*, which is produced when the air sample passes through a reaction cell filled with O₃ and proceeds
through NO+O₃ -> NO₂*+ O₂ (Ecotech, 2023). The NO_x concentration in the air sample is determined by first converting
125 all NO₂ to NO, and then letting the total NO (NO + converted NO₂) in the second path react with ozone in the reaction cell,
resulting in a chemiluminescence signal from activated NO₂*. The NO₂ is then calculated as the difference between NO_x and
NO over the measurement time interval of 10 s. A delay loop is installed between the two loops to make sure they sample the
same air mass. A small mismatch can however not be ruled out. With an aircraft ground speed of 30-50 m/s, the horizontal
scale at which NO₂ gradients can be detected is on the order of several hundred meters. The reported detection limit of the
chemiluminescence analyser is 0.4 ppb (Ecotech, 2023). The sensor is equipped with an optical bandpass filter to avoid the
130 measurement of interfering species and has successfully been used in previous scientific studies (e.g. Wong et al. (2022);
Namdar-Khojasteh et al. (2022); Van Roy et al. (2022b)).

The aircraft NO₂ campaign served two purposes. The first goal was to obtain vertical profiles of NO₂ in the vicinity of ships
sailing the North Sea. The software on board the BN2 aircraft showed the live locations and tracks of ships within AIS range, as
well as the expected location of the ship's exhaust plume based on wind conditions and the speed and course of the ship. After
135 visual detection and approaching of a ship, at least one transect through the ship's plume was flown, followed by a spiraling
climb from < 30 m to 1500 m altitude, continuously measuring NO and NO_x concentrations with a temporal resolution of
10 s. These vertical spirals were executed such that they coincide within 30 minutes of the TROPOMI overpass time on
that day. The second goal of the campaign was to sample the horizontal distribution of air pollution within the lower marine
boundary layer. On 8 September 2021, three zig-zag patterns were flown through the exhaust plume of ships at a constant
140 altitude of approximately 40 m. The measurements of NO_x during these in- and out of plume patterns serve the purpose to
better understand the spatial representativeness and distribution of NO_x concentrations in the presence of emitting ships at the
scale of a TROPOMI pixel. Fig. 1 shows an overview of the campaign: The left panel shows the spatial extend of the flights as

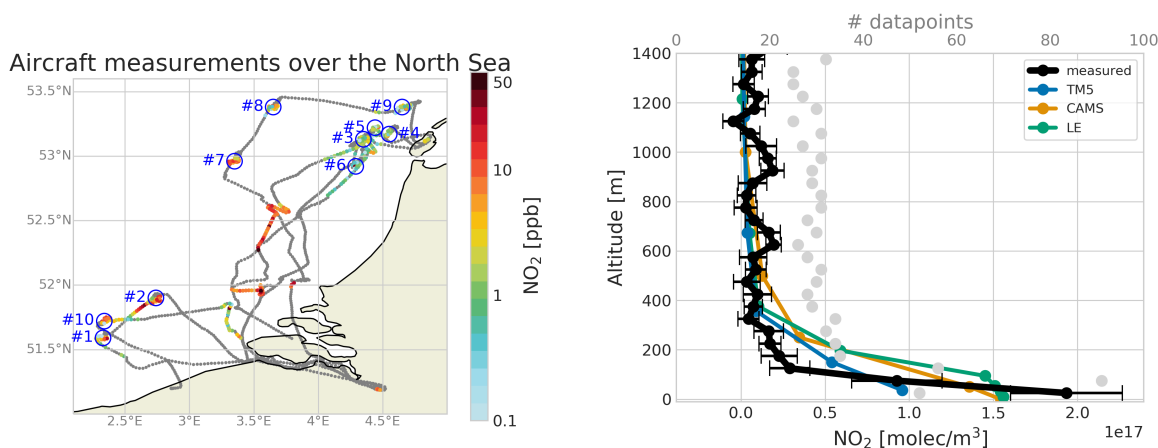

Figure 1. Left: Routes of all aircraft flights during the campaign. The 30 second mean NO_2 mixing ratio is shown as color for the flight below 200 m. Blue circles indicate the locations of the aircraft profiles. Right: Mean vertical NO_2 profiles for the aircraft data (black), co-sampled TM5 (blue, Eskes and van Geffen (2021); Huijnen et al. (2010)), CAMS (yellow, METEO FRANCE et al. (2022)) and LOTOS-EUROS (green). The light gray dots indicate the number of 10 second NO_2 measurements at each height in the top x-axis. The aircraft profiles and their mean can be found in the dataset associated with this publication (see below).

well as the NO_2 range measured, the right panel shows the mean measured NO_2 profiles as well as co-sampled model profiles. A detailed description of the weather and chemical conditions during the flights can be found in the supplementary materials

145 S1.

2.3 LOTOS-EUROS model simulations

We use LOTOS-EUROS version 2.2.002 (LE, Manders et al. (2017); Thürkow et al. (2021)) at $2 \times 2 \text{ km}^2$ resolution with 12 vertical levels (of which 7 are typically below 1500 m altitude) reaching up to around 9 km altitude. This model setup is similar to the model version operated within the CAMS ensemble and typically performs well in intercomparison studies, and is typically near the ensemble mean. The runs were performed over/around the Dutch North Sea for an area between $50.5\text{--}54.5^\circ\text{N}$ and $1.5\text{--}5.0^\circ\text{E}$ with a spin up time of one month. To ensure appropriate boundary conditions the model was nested within a LOTOS-EUROS run covering a part of north-western Europe ($1\text{--}16^\circ\text{E}$, $47\text{--}56^\circ\text{N}$), which itself was nested within an European domain ($15^\circ\text{W}\text{--}35^\circ\text{E}$, $35\text{--}70^\circ\text{N}$) both run for a similar period and spin-up time.

Key characteristics of LOTOS-EUROS and other model data used in this study can be found in Table 2.

155 2.4 Ship location and course

To interpret the measured data we use AIS (Automatic Identification System) data on ship location, speed and heading to predict the location of pollution plumes. The IMO requires all large ships (> 300 tonnes) to broadcast static (e.g. identity) as

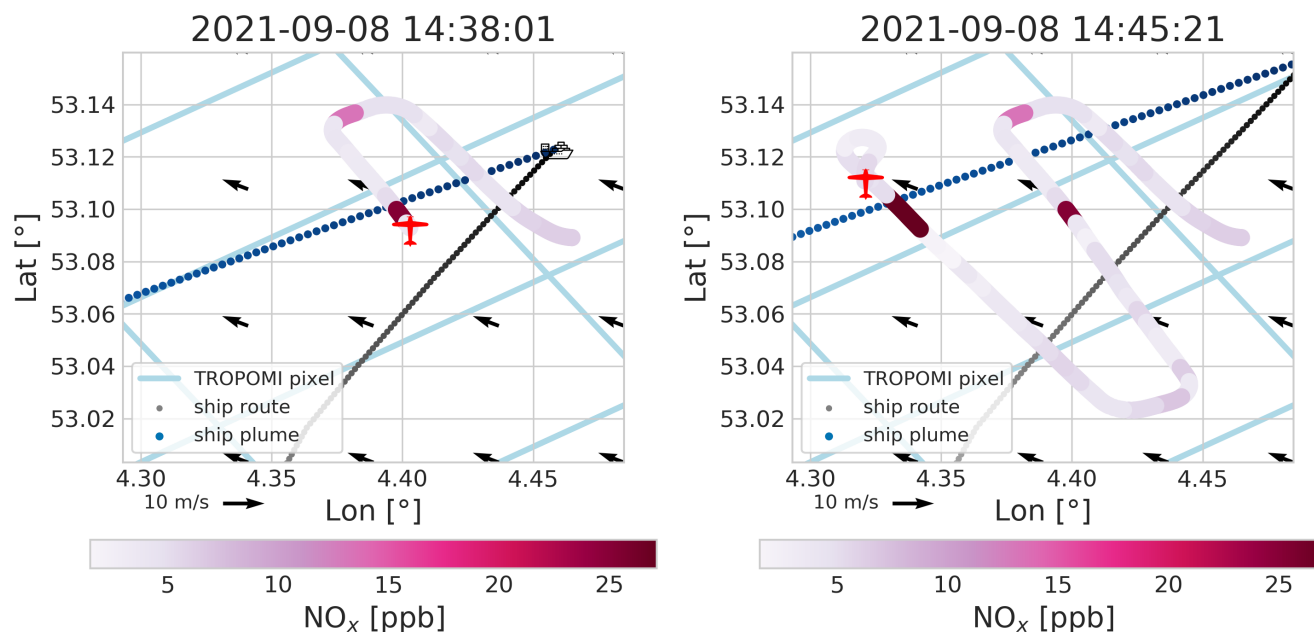

Figure 2. Two snapshots of one of the horizontal scans: Black and blue dots show ship path and plume center location at the moment indicated by the timestamp, respectively, with lighter colors indicated older locations. In pink we see the flight path with the color indicating the measured NO_x concentration. The light blue lines show the edges of TROPOMI pixels for the coinciding orbit. An animated version - illustrating the dynamics and highlighting the match between expected and observed plume location - is available in the supplement.

Table 2. Main characteristics of the model products used.

model	LOTOS-EUROS	CAMS	TM5
horizontal resolution	2x2 km ²	0.1°x0.1°	1°x1°
emissions	CAMS-REG-AP_v5.1	CAMS-REG-AP	see Williams et al. (2017)
meteorology	IFS	IFS	ERA-Interim re-analysis
vertical mixing scheme	see ECMWF (2015) with Monin–Obukhov length calculated as in Golder (1972)	model dependent	see Holtslag and Boville (1993)
full description	Manders et al. (2017)	METEO FRANCE et al. (2022)	Williams et al. (2017)

well as dynamic (position, speed) data, which can be received by other ships, shore stations, and satellites (IMO, 2014). The historic AIS data set used here was made available to the Dutch Human Environment and Transport.

Table 3. Overview of vertical profile flights taken during this campaign. Times are in UTC. Latitude and Longitude columns indicate the center of the profile.

Profile number	date	time	TROPOMI orbit	TROPOMI overpass	Latitude [°N]	Longitude [°E]
#1	02.06.2021	11:03-11:18	18842	12:00:15	51.59	2.33

160 3 Aircraft NO₂ interpretation and representation at the scale of a TROPOMI pixel

The comparison of satellite retrievals with aircraft measurements requires that differences in sampling characteristics are reconciled first. Individual flights were not uniformly stretched out over a TROPOMI pixel, and the measured horizontal patterns in NO₂ concentrations reveal substantial variability within the spatial extent of a TROPOMI pixel. The spatial heterogeneity of NO₂ within a pixel is driven by the fraction of time the aircraft spent within ship plumes, and by the age of the plume at the moment of intercept (e.g. Chen et al., 2005). In general, aircraft spatial sampling characteristics are not uniform across a TROPOMI pixel as evident from Fig. 2. Additionally, the chosen aircraft operation and instrumentation requires post-processing of the measured data as detailed in the following section and Supplement S3.

3.1 Representative NO₂ vertical profile measurements

Pixel-scale aircraft NO₂ profiles

170 We first take care to represent the aircraft NO₂ measurements at the scale of a TROPOMI pixel. The coastguard flights approached ships and their plumes in order to measure the composition of the exhaust. The measurements are therefore not necessarily representative of the mean NO₂ concentrations over the pixel: the aircraft may have spent a relatively large fraction of its measurement time within ship plumes compared to the fraction of the pixel filled with those plumes. Such a situation would lead to an overestimation of mean NO₂ concentration in a pixel. For each vertical profile flight listed in Table 3, we
 175 therefore calculated the ratio of the predicted fraction of the pixel covered by ship pollution plumes to the proportion of in-plume to overall time spent by the aircraft in a pixel. Fig. 4(a) illustrates the approach: the predicted plume-covered area is taken as the ratio of the grey area to the overall (grey and white) area, and the in-plume aircraft proportion is taken as the ratio of the time spent in the plume (red) to the total time spent below 100 m (all solid lines). Ideally, the two ratios would be iden-

tical, and a correction would not be needed. Using the AIS data we can calculate the expected presence of ship plumes for all
 180 profile flights and with the help of the three horizontal scans we predict the plume-covered area. On average, we over-sample
 plumes by a factor of 1.9 (0.0-5.7, median 1.1), meaning we spend disproportionately much time in the plume. We apply these
 as multiplicative correction factors to the in-plume and out-of-plume NO_2 values to improve the spatial representativeness of
 the vertical NO_2 profile for the TROPOMI pixel.

Plume NO_x -to- NO_2 conversion

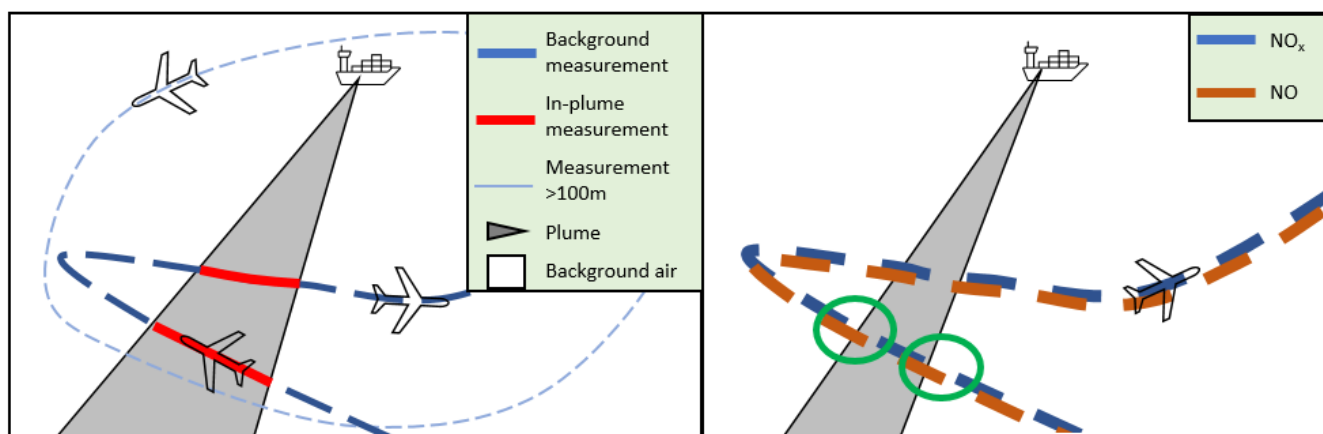

Figure 3. Sketches of profile flights visualizing the corrections. Left: The grey area indicates the part of the 2D-plane covered by a plume and the thick line the aircraft measurements in the polluted layer, with red showing in-plume measurements and blue indicating background sampling. The mismatch between the fraction of time spent in-plume and the fraction of the area covered by the plume is apparent. Right: The blue dashes indicate intervals of measuring NO_x , while the orange dashes indicate NO -intervals. For the situations highlighted by the green circles NO is measured partly in-plume while NO_x is measured fully in-plume (left circle) or out-of-plume (right). This will lead to negative or extremely high NO_2 values, respectively.

185 The NO_2 measurement values are taken from the differences between the Ecotech-sensor's NO_x and NO concentrations. How-
 ever, near the edges of plumes, we find unrealistically high or even negative NO_2 concentrations due to small time-delay
 between the NO_x and NO sampling in the Ecotech instrument, as mentioned in Sec. 2.2, and illustrated in Fig. 3. When the
 aircraft samples background air, the NO_2 values inferred from $\text{NO}_x - \text{NO}$ are still reliable in spite of the small delay. But when
 the aircraft samples the plume, we can not necessarily rely on $\text{NO}_x - \text{NO}$ and instead convert the NO_x concentration measure-
 190 ments into NO_2 concentrations via local $\text{NO}_2:\text{NO}_x$ ratios simulated with the PARANOX plume chemistry model which has
 been used before by Vinken et al. (2011) for ship plume modelling. PARANOX $\text{NO}_2:\text{NO}_x$ ratio's depend strongly on the age
 of the plume, as NO_x in the early stages after emissions is mostly present as NO , but the NO_2 portion typically increases to
 0.45 within some 15-30 minutes after emission following entrainment of O_3 , and subsequent NO_2 formation via the $\text{NO} + \text{O}_3$
 reaction in the plume. More details on PARANOX can be found in Supplement S2.

195 Zero-level offset calibration

The Ecotech sensor is capable of detecting clear in-plume NO_2 enhancements of several ppbs, but since near-zero, background

air NO₂ levels differed by a few ppb between flights on different days, we re-calibrated the aircraft NO₂ concentrations to ensure that the measured near-zero NO₂ levels at altitudes above 250 m are on average consistent with NO₂ values from the CAMS simulations. The calibration offset is applied as an additive correction to the entire profile, and its value is consistent for multiple profiles measured on the same day, as anticipated from the daily calibration routine executed prior to flight. The calibration offsets vary between 0 and 4 ppb between the different days, and we assume a uncertainty of the bias correction of 0.5 ppb. Using only values above 500 m for the offset calculation leads to slightly different offsets that fall within the assumed uncertainty range.

For a more detailed description of the three corrections, see supplement S3.

205 3.2 Observed vertical NO₂ profiles

We now present the vertical NO₂ profiles obtained from the BN2 aircraft measurements over the North Sea following the procedure sketched in Sect. 3.1. Each of these vertical NO₂ profiles is spatially representative for the spatial scale of a TROPOMI pixel. For time and location of the profiles taken see Table 3. Aircraft NO₂ measurements were aggregated in 50 m altitude bins, where the reported altitude is the mean of the lower and upper boundary of each bin.

210 The aircraft data shows the highest NO₂ concentrations close to the sea surface, and a sharp drop above the lowest 100 m (Fig. 1), in agreement with the CO₂ profiles shown in S5. To better understand the emissions sources and physical transport processes leading to the observed profile shapes, we analyse simulations over the campaign period from the TM5-MP, CAMS, and LOTOS-EUROS models (see Sect. 2.3). The mean simulated NO₂ profiles coinciding with the aircraft flights show NO₂ pollution up to 200 m and above (Fig. 1). In the following, we will investigate the roles of model vertical mixing, emission strength, and transport of pollution from elsewhere as possible explanations for the mismatch between the simulations and observations. For that we need to study the NO₂ profiles according to their distinct meteorological circumstances. Fig. 4 shows the individual measured and modeled profiles with the numbering consistent to Table 3. For uncorrected profiles and the uncertainty estimates see Fig. S4. Meteorological conditions such as mean wind directions reveal that vertical profiles have been collected for two distinctly different types of situations over the North Sea: one with outflow of possibly polluted air from the Low Countries over the North Sea, and one under pristine conditions with wind from the North and low background NO₂ concentrations. Hereafter we classify these profiles as 'land outflow', and 'clean'. A more complete description of the general chemical and meteorological conditions during each flight can be found in Supplement S1.

NO₂ profiles during land outflow - profiles 1, 2, 7, 8, 9, 10

225 Fig. 5 shows the observed and simulated NO₂ in a situation of outflow from continental Europe. We see that the profile (indicated by the blue circle) was indeed sampled under conditions of pollution outflow from land. The corresponding profiles for all outflow cases in Fig. 4 show pollution close to the sea surface. While the aircraft measured NO₂ is enhanced only in the lowest 100 m (for the exception of profile 7 see below), the models - especially LOTOS-EUROS - show elevated NO₂ at 200 m and above, overestimating the total NO₂ in the column. The measured and modelled potential temperature profiles (Fig. S2) show a cold sea surface with a strong gradient in the lowest 400 m, hinting at a strong stratification. Together with moderate wind speeds this indicates stable conditions with limited vertical mixing.

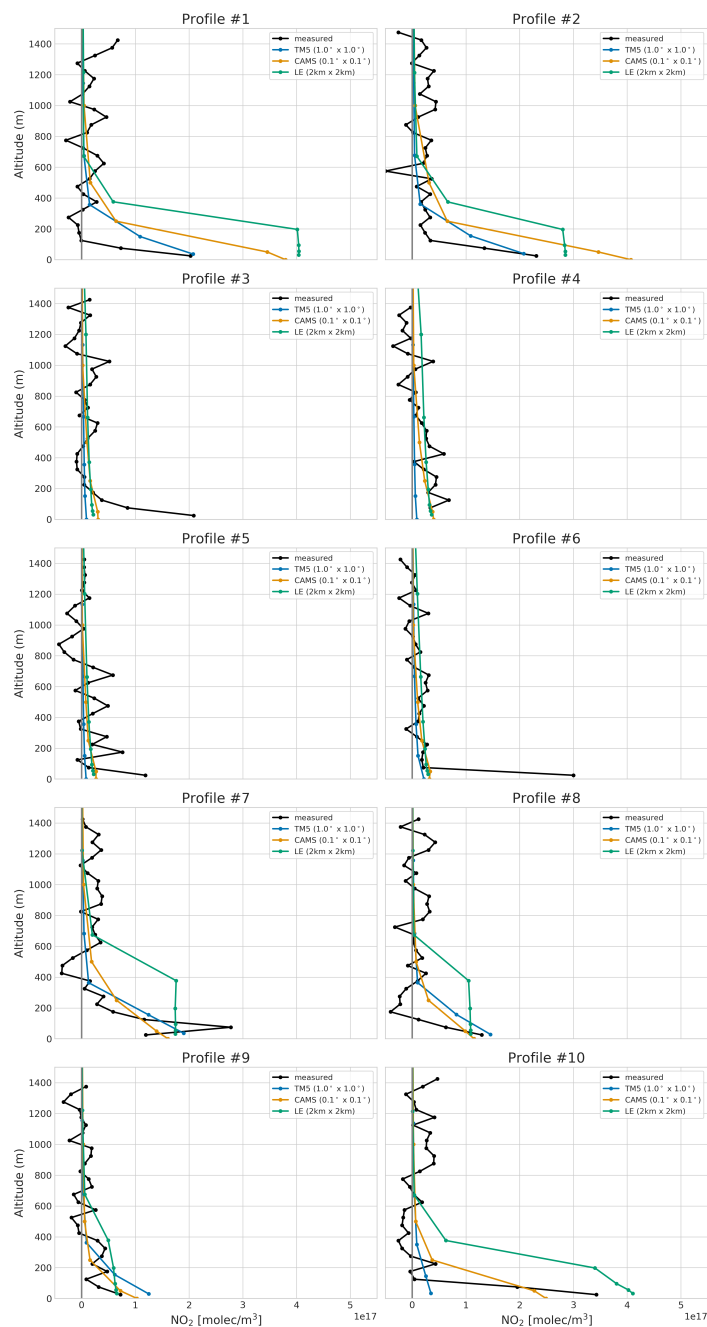

Figure 4. Profiles of all flights as well as coinciding TMS, CAMS ensemble mean and LOTOS-EUROS profiles.

TM5 grid cells are very large and contain a mixture of land and sea surface as can be seen in Fig. 5. This means that emissions within the cell are originating from land-based sources as well as ships. Likewise, boundary layer dynamics are a mix of

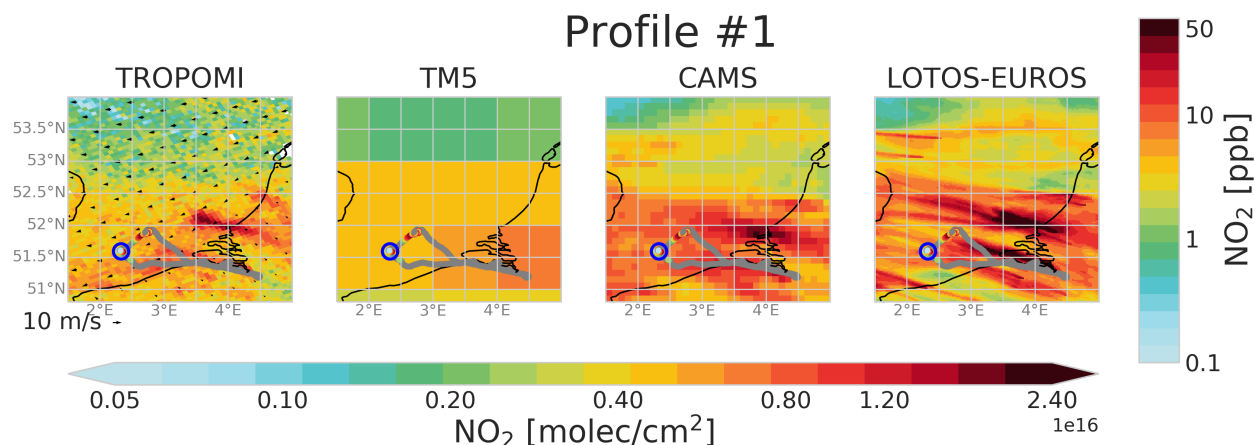

Figure 5. NO₂ columns as seen by TROPOMI and several model products for the time of the first profile measurement as indicated by the bottom colorbar. Overlaid are the aircraft measurements in grey for flights above 200 m and in colors below as indicated by the colorbar on the right as well as wind speed and direction by the arrows in the left panel.

sea and land characteristics. Overall, TM5 profiles show too little NO₂ in the lowest layer and overestimate the NO₂ above. Nonetheless, the coarse TM5 columns show reasonable agreement with TROPOMI retrieved columns with the exception of profile 10.

On the other hand, the higher horizontal resolution in CAMS and LOTOS-EUROS allows the separation of sea and land NO_x contributions. The resulting columns show massive outflow of NO₂ from land, we see plume-like structures from the region of Antwerp and Rotterdam in CAMS, LOTOS-EUROS and TROPOMI. The aircraft profile 1 shown in Fig. 5 was taken within the outflow of Antwerp pollution. LOTOS-EUROS, and to a lesser degree also CAMS, show overestimated NO₂ columns compared to TM5 and TROPOMI. This is in line with the observed profiles shown in Fig. 4: While surface NO₂ levels in LOTOS-EUROS and CAMS are in reasonable agreement with observations overall, the polluted layer is significantly deeper than in the observations, leading to a high bias in LOTOS-EUROS and CAMS NO₂ columns in these outflow cases. Additionally, CAMS and LOTOS-EUROS show two strong emission plumes in the North Sea (e.g. around 53.3°N, 2.5°E), which are not visible in TROPOMI or TM5. These likely originate from gas platforms, but the missing plumes in the TROPOMI observations point at large overestimations of the emission strength in the CAMS inventory (≈ 0.2 kg/s for these two sources). TROPOMI and modelled NO₂ columns during the other profile flights can be found in Supplement S4.

A special case is profile 7. This is the only profile with clearly enhanced NO₂ above 100 m (see also S5 for the CO₂ profile). In fact, the profile agrees reasonably well with TM5 and CAMS data, whereas LOTOS-EUROS again shows a too deep mixing layer and too much NO₂ in the column. This enhanced NO₂ observed between 100 and 300 m altitude might be caused by polluted air masses originating from the Netherlands and transported over Sea while rising above the stable surface layer. This hypothesis is supported by parts of the flight on June 2nd, when enhanced NO₂ was observed at an altitude of 300 m descending

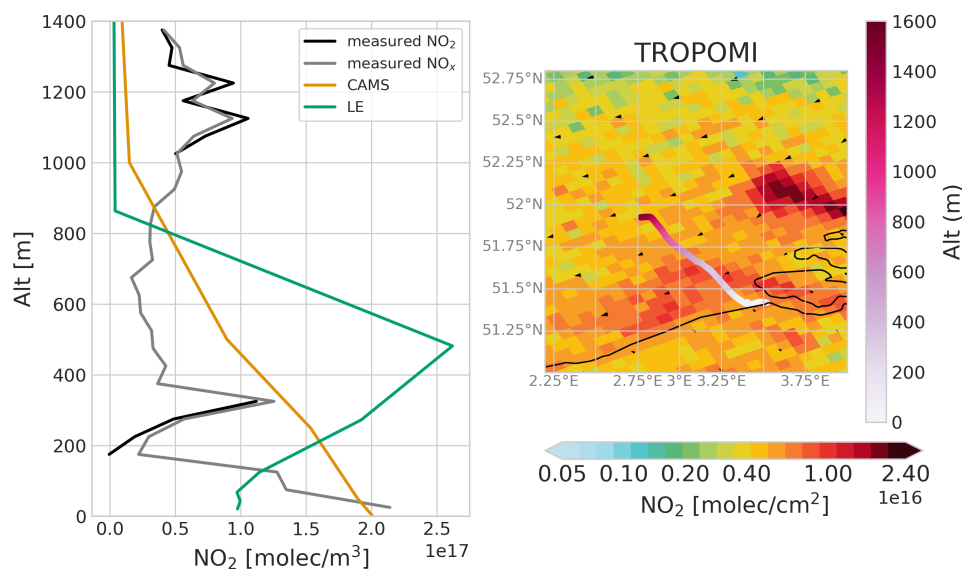

Figure 6. Left: Measured and modeled Vertical distribution of NO₂ along the flight path indicated on the right. This is not a vertical profile in the strict sense, as the sampling took place over ≈ 70 km horizontal extend. During part of the flight the airplane instrumentation was operating in a different mode so that no NO₂ data is available. However, NO_x (gray) was sampled throughout the whole flight and indicates a thin pollution layer between 300 and 400 m.

towards Antwerp airport into the land outflow after taking profile 2. A vertical profile for this part of the flight and the flight path can be seen in Fig. 6. The observed NO₂ layer at 300 m is also present in the co-sampled LOTOS-EUROS profile but not
 255 in CAMS. These findings also demonstrate that the aircraft instrumentation is able not only to detect high NO₂ values in fresh plumes but also to capture diluted NO₂ pollution from land. Additionally, this suggests that at least for profile 2 (which was sampled right before) enhanced NO₂ seen at 200 m in the models are unlikely to be caused by land emissions, as pollution originating from land would be expected higher in the atmosphere. Finally, this indicates that land outflow often observed by
 260 TROPOMI over the North Sea can be located in higher atmospheric layers, where TROPOMI has a higher sensitivity and thus possibly masking the low-level NO₂ from ships.

From our observations it remains unclear whether the high NO₂ in LOTOS-EUROS and CAMS is caused by overestimations in land-based emissions, timing of the emissions in the models, advection or vertical mixing. The low surface pollution of TM5 showcases the limitations of a coarse resolution whereas the too high NO₂ at 200 m hints at uncertainties in the vertical mixing. The very shallow pollution layer is also visible in the uncorrected and simultaneously measured CO₂ data (see S5) and
 265 therefore unlikely to result from the non-simultaneous measurement of NO_x species and our corrections.

NO₂ profiles during clean conditions - profiles 3, 4, 5, 6

Fig. 7 shows the observed and simulated NO₂ in a situation without outflow from continental Europe. Profiles 3 to 6 have all

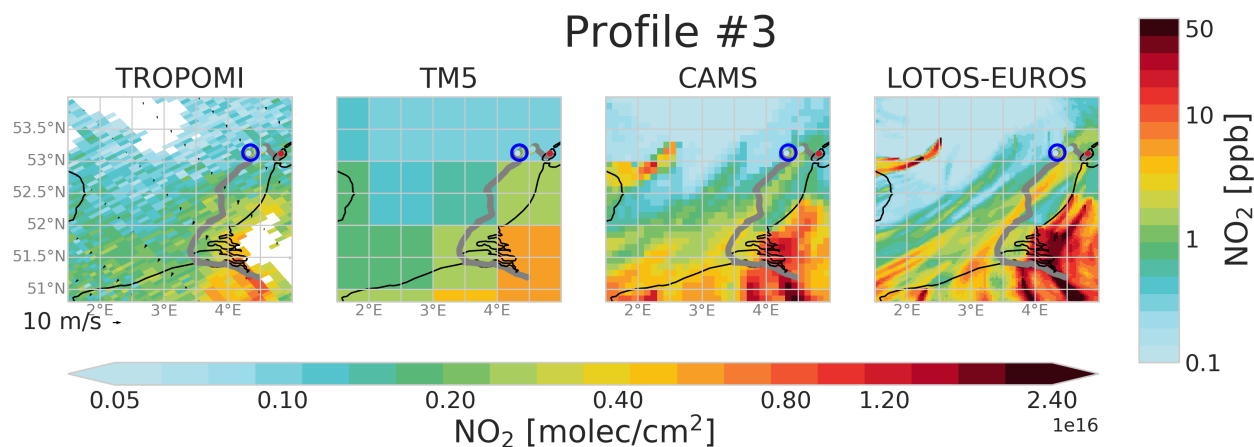

Figure 7. As Fig .5 but now for the third profile.

been taken on the same day, 22 July 2021. On this day northern winds were prevailing, transporting clean air into the North Sea, resulting in low NO_2 columns as observed by TROPOMI in Fig. S1. The potential temperature profile on 22 July 2021 indicates a well mixed marine boundary layer of 800 m depth. All modelled NO_2 profiles show little pollution at the surface and NO_2 concentrations are slightly decreasing towards higher altitudes. While the profiles were taken right above the shipping lane, in CAMS and LOTOES-EUROS the shipping pollution can be seen south of the profile, caused by the northerly winds. Again, TM5 shows less NO_2 compared to the other models.

The observed profiles 4 and 5 (see Fig. 4) agree reasonably well with the models, showing little NO_2 enhancement close to the sea surface. On the other hand, profiles 3 and 6 show strong NO_2 enhancements in the lowest 50 m, in contrast to the models. This is driven by exceptionally high NO_x concentration measured in ship plumes (>250 ppb NO_x for profile 3). In fact, a Monte Carlo approach (see Supplement S3 & Fig. S4, leading to a more multi-profile-average 'in plume' NO_2 concentration) shows very similar surface NO_2 values of $\approx 1.5 \cdot 10^{17}$ molec/ m^3 for all 4 flights on that day. This shows the presence of ship plumes in all 4 profiles, while in two cases the plume was either not captured well due to the temporal sampling of the Ecotech sensor or the ships in profiles 4 & 5 were emitting significantly less.

The ship NO_x emissions - while captured by the aircraft - are spatially diluted over the area of the model grid cell and throughout the well-mixed boundary layer and advected with the prevailing wind. Additionally, the models represent ships with averaged, constant emission fluxes in the model grid cells along the ship tracks, whereas in reality a ship might be in a given model grid cell for a short time with a higher emission flux. Therefore, in reality strongly localized emission levels are observed as sharply defined plumes, not resolved by the CTMs. These observations indicate the weakness of temporally and spatially averaged emissions in the models which fail to capture high pollution levels in the vicinity of strong and moving emitters. Overall, the models seem to underestimate the influence of ship emissions, likely due to temporal and spatial averaging of emissions and instant dilution thereof in the grid cell.

4 Validation of TROPOMI NO₂ over the North Sea

290 4.1 Recalculate AMFs

With the observed vertical NO₂ profiles we can calculate a more accurate TROPOMI NO₂ column, replacing the coarse TM5 a priori in the retrieval with aircraft-measurement based vertical profiles. The adjusted tropospheric AMF $M_{\text{trop,ADJ}}$ can be calculated using the AMF from the a priori $M_{\text{trop,TM5}}$, the averaging kernels of layer l $A_{\text{trop},l}$ provided in the TROPOMI files as well as the NO₂ column density $x_{l,\text{meas}}$ of layer 1 from the aircraft data as

$$M_{\text{trop,ADJ}} = M_{\text{trop,TM5}} * \frac{\sum_{l=1}^L A_{\text{trop},l} x_{l,\text{meas}}}{\sum_{l=1}^L x_{l,\text{meas}}}$$

where L is the highest TM5 layer below the tropopause. Replacing the a priori with the measured NO₂ profiles and recalculating the AMFs is explicitly advised in the TROPOMI NO₂ documentation (Eskes and van Geffen, 2021) and has been done to improve satellite observations and validations previously (Visser et al., 2019; Douros et al., 2023). The adjusted vertical, tropospheric column can then be calculated as $N_{v,\text{trop,ADJ}} = N_s / M_{\text{trop,ADJ}}$. As the measured NO₂ profiles only extend to 1400 m,

295 we use TM5 profiles to fill the gap to the tropopause.

Too low NO₂ concentrations in TM5 close to the surface are expected to lead to a negative bias in the TROPOMI NO₂ retrievals, since the sensitivity to NO₂ close to sea surface is generally small as indicated by the averaging kernel. The shallow boundary layer depth in combination with the low surface albedo values (≈ 0.04) emphasize the difficulty to detect air pollution over sea with satellite remote sensing, despite the high signal-to-noise ratio and resolution of TROPOMI NO₂.

300 4.2 Tropospheric columns

We compare total tropospheric columns of NO₂ retrieved by TROPOMI (operational, PAL & CAMS) as well as measured columns. Lastly, we add the new product TROPOMI_{ADJ} which includes a re-calculation of the AMFs using the measured profiles following Sect.4.1.

Table 4 shows the mean columns densities of all datasets mentioned above as well as their Pearson R and Root Mean Squared Error (RMSE) against the aircraft data. The ten aircraft measured NO₂ column densities averaged at $3.37 \cdot 10^{15}$ molec/cm². This is significantly higher than the coinciding operational TROPOMI ($2.42 \cdot 10^{15}$ molec/cm²) and TROPOMI_{PAL} ($2.47 \cdot 10^{15}$ molec/cm²) data. Using the re-calculated AMFs an average column density $N_{v,\text{trop,adj}}$ of 2.89 (2.71 - 3.23) $\cdot 10^{15}$ molec/cm² is determined. This is ≈ 20 (12 - 33)% higher than the TROPOMI products and brings the satellite retrievals closer to the aircraft-measured columns, showing a significant negative bias in operational TROPOMI NO₂ columns. The TROPOMI_{CAMS} dataset (see Sect. 2.1) is closer to the measured columns at mean columns of $3.03 \cdot 10^{15}$ molec/cm². It should be noted that CAMS shows systematically higher NO₂ columns compared to measurements and TM5. TROPOMI_{CAMS} and TROPOMI_{ADJ} also show an increased Pearson correlation coefficient to the aircraft columns of 0.87 and 0.91, respectively, compared to 0.82 of the operational product. Lastly, the root mean square error (RMSE) of the TROPOMI columns towards the aircraft columns is reducing going from the operational ($1.26 \cdot 10^{15}$) to TROPOMI_{CAMS} ($0.99 \cdot 10^{15}$) data and smallest for the aircraft-adjusted

310

315 columns at $0.77 \cdot 10^{15}$ molec/cm².

Given the large uncertainty and corrections involved at the lowest level NO₂ concentration, the sensitivity of the recalculated AMFs to that value was tested. A 20% change in the NO₂ number density leads to a change in AMF of less than 5%, and even a change of 50% in surface level NO₂ changes the AMF only by 10%. This supports the finding of a negative bias caused by the a priori profile as the differences in AMFs can not be explained by the surface level NO₂ alone.

Table 4. Tropospheric NO₂ columns measured by the aircraft and different TROPOMI products. For TROPOMI_{ADJ}, the values in the bracket give the average of the lower and upper estimates based on the uncertainties shown in Fig. S3

Product	Mean tropospheric NO ₂ column [10 ¹⁵ molec/cm ²]	Correlation to aircraft column	RMSE to aircraft column [10 ¹⁵ molec/cm ²]
aircraft	3.37	-	-
TROPOMI	2.42	0.82	1.26
TROPOMI _{PAL}	2.47	0.83	1.24
TROPOMI _{CAMS}	3.03	0.87	0.99
TROPOMI _{ADJ}	2.89 (2.71-3.23)	0.91	0.77

320 4.3 The land-sea contrast in TROPOMI NO₂ retrieval

As a contrasting case, Fig. 8 compares the sea NO₂ profiles to NO₂ profiles during the TROPomi vaLidation eXperiment (TROLIX) in 2019 (Sullivan et al., 2022) over the Netherlands (51.97°N, 4.93°E). The left panel shows mean TM5 NO₂ and averaging kernel profiles over land and sea as well as the mean aircraft-measured profiles. While modeled surface pollution levels over land are on average close to those over sea, the boundary layer is significantly more evolved with elevated pollution levels in the models reaching 400 m and above. At the same time, the averaging kernel over sea is smaller compared to land throughout the entire boundary layer. The right part of the same figure shows midday NO₂ concentrations measured during TROLIX as well as coinciding TM5 and CAMS profiles. No measured profile data are available at Cabauw for the days of the aircraft campaign. The measurements confirm a well mixed lowest 200 m, in contrast to the presented profiles over sea. Even if the models would overestimate vertical mixing over land, the higher mixed layer over land would lead to a smaller relative difference between modeled NO₂ concentration and observations compared to over Sea. This - together with the lower surface albedo (<0.04 for the North Sea vs 0.05 for land) causing a lower sensitivity to NO₂ close to the surface - emphasizes the challenge of accurate satellite retrieval of NO₂ over sea compared to over land. For more details, see Supplement S6. Overall, we find on average 20% lower tropospheric AMFs over the North Sea compared to land given similar overall retrieval conditions.

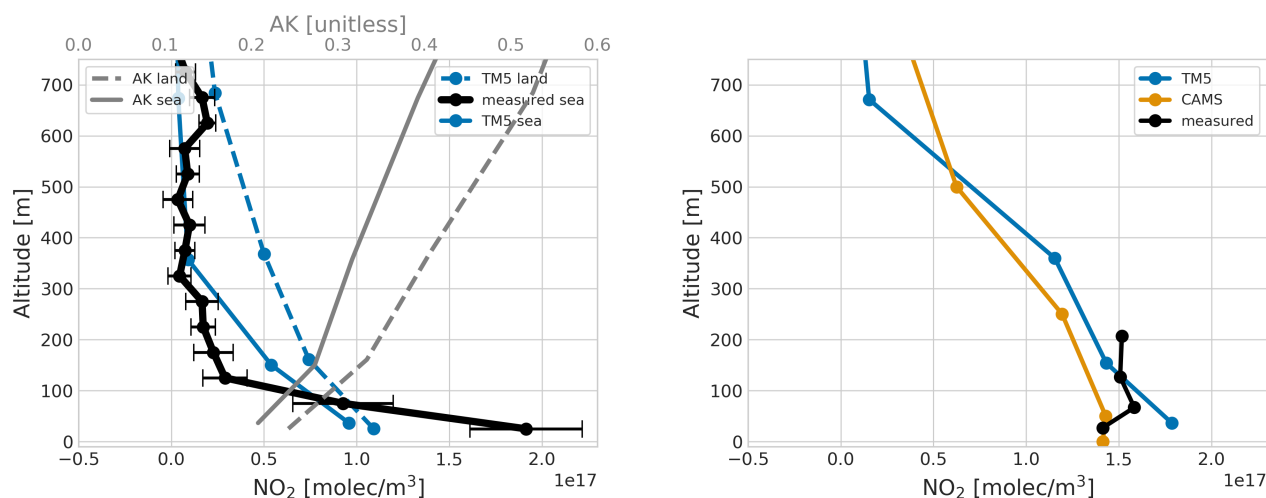

Figure 8. Left: The solid blue line shows mean TM5 profiles coinciding with the aircraft profiles (black). The dashed blue line shows simultaneous TM5 NO_2 profiles at the Cabauw tower in the Netherlands. Additionally, the mean TROPOMI averaging kernel profiles for land and sea are shown. The figure on the right shows mean measured (black) and modeled (TM5 in blue and CAMS in yellow) profiles at the Cabauw tower in the Netherlands for 6 cloud free days in September/October 2019 during the TROLIX-19 campaign (Sullivan et al., 2022).

335 5 Discussion

We evaluated the TROPOMI tropospheric vertical NO_2 column retrieval over the North Sea. For this, we measured ten vertical NO_2 profiles in the immediate vicinity of ships emitting air pollutants coinciding with the TROPOMI overpass, compared them to modeled profiles and studied the impact of a priori profiles on the retrieved NO_2 columns.

Flying down to below 30 m above the sea surface allowed us to fully capture ship plumes and NO_2 pollution over the North
 340 Sea. While our measurements suffer from the indirect measurement of NO_2 , the horizontal zig-zag patterns and applied corrections lead to profiles that are truly representative at the time and scale of a TROPOMI pixel.

Our measurements strongly hint at systematic negative bias in TROPOMI NO_2 columns over the polluted North Sea. Using the aircraft profiles to recalculate the AMFs, the TROPOMI columns are $\approx 20(12 - 33)\%$ larger on average compared to TROPOMI_{PAL} data using TM5 for a priori profiles. This is in agreement with earlier studies (Douros et al., 2023) for
 345 point sources. The vertical profile measurements over the North Sea reveal a very shallow boundary layer of 100-150 m above sea level, where the averaging kernel is the smallest. With one exception our measurements show no significant pollution above 150 m. This finding is supported by co-sampled CO_2 profiles presented in S5. The low pollution layer is in contrast to model profiles and could be attributed to an overestimated vertical mixing in the models compared to observations. The mixing schemes for vertical transport in the boundary layer used in TM5 (Williams et al., 2017; Holtslag and Boville, 1993) are known
 350 to overestimate vertical mixing for stable conditions (Köhler et al., 2011) which prevailed during several of the campaign

days (see Sect. 3.2). The updated K-diffusion based on Monin-Obukhov length used in LOTOS-EUROS (ECMWF, 2015) is expected to result in more shallow stable boundary layers. However, we still find a high bias in LOTOS-EUROS in the mixed layer height. Hints towards uncertainties in the vertical mixing of the LOTOS-EUROS can also be found in Escudero et al. (2019), who show a positive bias in boundary layer height (BLH) over Madrid in summer as well as overestimated vertical mixing in the boundary layer using the LOTOS-EUROS mixed-layer scheme. Additionally, they find more gradual vertical mixing and a better correlation of ozone surface measurements when increasing the number of vertical layers. Likewise, Skoulidou et al. (2021) connect underestimated surface NO_2 levels in Athens to problems in the temporal evolution of the BLH in LOTOS-EUROS, which is taken from the ECMWF operational weather analysis.

The very shallow mixed layer observed during the flights is in agreement with the observed strong gradient in potential temperature and indicates stable conditions. The reasons the models fail to reproduce the shallow mixed layer over the North Sea remain unclear and need further studies.

Next to the overestimated mixing, the TM5 profiles show less pollution close to the surface than the aircraft data and the other model simulations. This is likely an effect of the coarse TM5 resolution of $1^\circ \times 1^\circ$ where ship emissions are smeared out over a larger area and time. The exaggerated vertical mixing and underestimation of the lowest part of the profile in TM5 leads to high-biased AMFs which in turn decreases the vertical column density via $N_v = N_s/M$. While the higher spatial resolutions of CAMS and LOTOS-EUROS improve the surface level NO_2 (in fact, for 8 out of 10 profiles, the surface pollution in these model product agrees reasonably well with observations), the overestimated pollution layer height, giving a substantial overestimation of the total NO_2 in the columns. This may be caused by overestimated NO_x emissions, their timing in the models, exaggerated advection or too long NO_x lifetimes, and shows that increased horizontal resolution does not necessarily give more accurate profile shapes. While TROPOMI columns using CAMS profiles as a priori are higher and show better correlation and lower RMSE to the aircraft columns than using TM5, this is caused rather by the higher NO_2 column than by a correct profile shape. The TROPOMI_{CAMS} product, essentially, demonstrates improved agreement with the aircraft column compared to the operational product. However, using the aircraft profiles in the AMF calculation exhibit the highest correlation and lowest RMSE.

Furthermore, we conclude that TM5, CAMS and LOTOS-EUROS are unable to fully capturing the spatially and temporally confined ship emissions over sea and that the pollution levels as a result of land outflow dominate the model results. This is supported by profiles 3-6, which were measured in clean conditions without land outflow. Observed and modeled temperature profiles indicate a well mixed atmosphere up to ≈ 800 m and show little NO_2 enhancement in all model products while we observe strong enhancements in profiles 3 & 6 as discussed before. The observed enhancements can be directly linked to fresh ship plumes that show to be vertically confined to the lowest 50 m and are not present in the models. Better results can be expected with plume resolving models, incorporating ship plumes using AIS and ship specific data for their location and emission strength (e.g. from Jalkanen et al. (2016), or from a climatology of representative NO_2 profiles observed over shipping routes. The presented profiles can be the starting point for such a climatology.

More validation flights over polluted sea are desirable, especially spanning different locations, seasons and meteorological conditions. While this study presents a cost-efficient way of measuring NO_2 profiles utilizing an aircraft already equipped

for emissions monitoring, direct NO₂ measurements with a temporal resolution of 1 Hz or higher and higher accuracy could have reduced post-processing and uncertainties. Better calibration, a more sensitive sensor and expanding the flights to higher altitudes can further reduce the dependence on model simulations.

Overall, this study shows the bias arising from using modelled and uncertain a priori profiles. This is true especially over sea
390 where the boundary layer is less developed than over land and the surface is darker. The observed negative bias in TROPOMI has important implications for the application of TROPOMI NO₂ columns for ship emission monitoring. As advised in Eskes and van Geffen (2021) the recalculation of AMFs using more realistic a priori profiles is beneficial.

6 Conclusion

This study clearly shows the need for additional evaluation of vertical NO₂ profiles over sea for both model and TROPOMI
395 validation while providing a recipe for such an analysis. We present ten vertical profiles of NO₂ over the North Sea in Summer, which - due to the low-altitude sampling (<30 m) and the location over busy shipping routes - present a unique opportunity to evaluate TROPOMI vertical NO₂ columns and model profiles (TM5, CAMS & LOTOS-EUROS) that was previously missing from literature.

We find that the coarse resolution of TM5 leads to too low NO₂ concentrations near the surface while overestimating NO₂
400 above 100 m. The higher model resolution of CAMS and LOTOS-EUROS results in more accurate surface NO₂ values, while at the same time vertical mixing is exaggerated compared to our observations. Additionally, CAMS and LOTOS-EUROS vertical NO₂ columns are too high compared to aircraft and TROPOMI data.

Furthermore, the comparison between observed and modeled vertical NO₂ profiles, along with the examination of TROPOMI averaging kernels over land and sea, stresses the significant challenges involved in accurately retrieving satellite NO₂ columns
405 over sea, where vertical sensitivity to NO₂ is 20% lower than over land, because of lower surface albedo and confinement of NO₂ pollution in a thin marine boundary layer.

When replacing the TM5 a priori profiles with the aircraft-measured NO₂ profiles in the TROPOMI AMF calculation, we find a significant increase of the retrieved vertical NO₂ columns of ≈ 20 (12 – 33)%, showing substantially improved agreement with aircraft-measured columns. Our findings align with previous studies (e.g. by Douros et al. (2023); Pseftogkas et al. (2022);
410 Lorente et al. (2017)), highlighting the importance of precise vertical a priori profiles for satellite-based trace gas retrieval.

Data availability. The corrected aircraft NO₂ profiles and co-sampled TM5 profiles are available at <https://zenodo.org/record/7928291>. TROPOMI L2 NO₂ and TM5 data are publicly available via the copernicus open access hub (<https://scihub.copernicus.eu>). The TROPOMI_{CAMS} data set is available on the temis portal (https://www.temis.nl/airpollution/no2col/no2_euro_tropomi_cams.php). CAMS data is
415 available at the Copernicus Atmospheric Data Store (<https://ads.atmosphere.copernicus.eu>). LOTOS-EUROS data can be made available upon reasonable request by contacting the author (christoph.riess@wur.nl).

Author contributions. TCVWR, KFB and JvV designed the study in consultation with WvR and JdL. JdL choose flight dates with forecasted favorable conditions. WvR was the operator of the flights and performed the measurements. TCVWR and KFB led the writing of the manuscript with contributions from all other co-authors. ED ran the LOTOS-EUROS simulations and assisted in their interpretation.
