6           **Abstract:** To improve computational efficiency while maintaining numerical accuracy,  
7           coupled hydrologic-hydrodynamic models based on non-uniform grids are used for  
8           flood inundation prediction. In those models, a hydrodynamic model using a fine grid  
9           can be applied for flood-prone areas, and a hydrologic model using a coarse grid can  
10          be used for the remaining areas. However, it is challenging to deal with the separation  
11          and interface between the two types of areas because the boundaries of the flood-prone  
12          areas are time-dependent. We present an improved Multigrid Dynamical Bidirectional  
13          Coupled hydrologic-hydrodynamic Model (IM-DBCM) with two major improvements:  
14          1) automated non-uniform mesh generation based on the  $D_\infty$  algorithm was  
15          implemented to identify the flood-prone areas where high-resolution inundation  
16          conditions are needed; 2) ghost cells and bilinear interpolation were implemented to  
17          improve numerical accuracy in interpolating variables between the coarse and fine grids.  
18          A hydrologic model, two-dimensional (2D) nonlinear reservoir model was  
19          bidirectionally coupled with a 2D hydrodynamic model that solves the shallow water  
20          equations. Three cases were considered to demonstrate the effectiveness of the  
21          improvements. In all cases, the mesh generation algorithm was shown to efficiently and  
22          successfully generate high-resolution grids in those flood-prone areas. Compared with  
23          the original M-DBCM (OM-DBCM), the new model had lower RMSEs and higher

24 NSEs, indicating that the proposed mesh generation and interpolation were reliable and  
25 stable. It can be adapted adequately to the real-life real flood evolution process in  
26 watersheds and provide practical and reliable solutions for rapid flood prediction.

27 **Key words:** Coupled hydrologic-hydrodynamic model; Multi-grid generation; Bilinear  
28 interpolation; Computational efficiency and accuracy; Flood simulation

## 29 **1 Introduction**

30 Floods are the most frequent natural disasters that seriously harm human health  
31 and economic growth. Numerical models are critical for predicting flooding processes  
32 to help prevent or mitigate the damaging effects of floods on people and communities  
33 (Bates, 2022). Coupled hydrologic-hydrodynamic models are widely used to translate  
34 the amount of rainfall obtained from weather forecasting models or rain gauge  
35 observations into surface inundation (Xia et al., 2019).

36 Coupled hydrologic-hydrodynamic models can be generally divided into external  
37 (one-way) and internal (two-way) coupling models (see Figure 1). The external  
38 coupling models utilize hydrographs obtained from hydrologic models as an input for  
39 hydrodynamic models in a fixed position, providing a one-way transition (Schumann  
40 et al., 2013; Feistl et al., 2014; Choi and Mantilla, 2015; Bhola, 2018; Wing et al., 2019).  
41 It is powerful tools for watershed flood simulation, in particular large spatial and  
42 temporal scale, due to its convenience in model construction. However, this one-way  
43 flow information cannot capture the mutual interaction between runoff production and  
44 flood inundation, and the fixed interface is inconsistent with the actual flood process  
45 where the inflow discharge positions, flow path, and discharge values change with  
46 accumulating rainfall.

The two-way coupling models are further divided into: the coupled hydrologic-1D hydrodynamic model (HH1D), indirect coupled hydrologic-2D hydrodynamic models (ICM2D), full 2D hydrodynamic models (HM2D), and dynamic bidirectional coupling model (DBCM or M-DBCM) proposed by author's team. In the HH1D, the discharges obtained from the hydrologic model is treated as mass source of the 1D hydrodynamic model, while the water depth calculated in 1D hydrodynamic model is fed back to hydrologic model, such as the coupled Mike SHE and Mike 11 (Thompson et al., 2004). The application of 1D modeling of overland flow is limited when developing precise and reliable flood maps in 2D inundation regions.

In order to overcome the lack of 2D hydrodynamic simulation in HH1D, the ICM2D is proposed, where the runoff first flows into 1D rivers, and then discharge into the 2D inundation regions (Seyoum et al., 2012; Chen et al., 2017 and 2018). For example, Mike SHE and Mike11 are coupled to form Mike Urban, and Mike11 and Mike21 are dynamically coupled to form Mike Flood. The indirect coupling between the hydrologic and the 2D hydrodynamic models can be developed by coupling Mike Urban and Mike Flood. The 1D hydrodynamic model is a connection channel between the hydrologic and the 2D hydrodynamic models. Compared with the HH1D, this coupling type has satisfactory and acceptable accuracy and is widely used. As the 2D

67 hydrodynamic model is only calculated in local inundation regions, its computational  
68 efficiency is greatly improved in comparison with the HM2D. However, the ICM2D  
69 assumed that the water first discharges into the 1D rivers, and then flows from 1D rivers  
70 to the 2D regions. The hydrologic model is not directly coupled with the 2D  
71 hydrodynamic model, which is inconsistent with the actual flood processes. In reality,  
72 water may be discharged into both 1D channel and 2D waterbodies simultaneously, and  
73 the hydrologic and 2D hydrodynamic models should be linked directly. Direct coupling  
74 of hydrologic and 2D hydrodynamic models can physically reflect the flood processes,  
75 which deserves more attention.

76 In HM2D, the 2D hydrodynamic model is used to simulate the overland flow  
77 (runoff routing and flood inundation), and the runoff generation serves as its mass  
78 source term (Singh et al., 2011; Garcia-Navarro et al., 2019; Hou et al., 2020; Costabile  
79 and Costanzo, 2021). It has satisfactory and acceptable numerical accuracy and has  
80 been widely used. But the development and simulation of HM2D require high-  
81 resolution topographic data at the catchment scale and extensive computational time,  
82 which hinder their application in large-scale flood forecasting (Kim et al., 2012). In  
83 HEC-RAS (US Army Corps of Engineers, 2023), for instance, the flooding process in  
84 1D rivers was simulated by a 1D hydrodynamic model, whereas the flooding process  
85 in 2D regions was simulated using 2D diffusion wave equations (DWEs) or shallow  
86 water equations (SWEs). If the 2D regions were discretized into finer grids and the 2D  
87 SWEs was applied, the 1D hydrodynamic model was coupled with the 2D SWEs. It has  
88 high numerical accuracy but is computationally prohibitive for large-scale applications.  
89 Conversely, if the 2D regions were discretized into coarse grids and the 2D DWEs was  
90 applied, the 1D hydrodynamic model was coupled with the 2D DWEs, which can  
91 expand the application scale at the cost of reducing the accuracy.

92 Jiang et al. (2021) proposed a DBCM based on uniform structured grids, where  
93 the hydrologic and 2D hydrodynamic models were coupled in a two-way manner and  
94 the coupling interface of these two models was time-dependent. The model can  
95 automatically evolve the surface flow and fully consider the flow states with both mass  
96 and momentum transfer. However, because uniform grids were adopted in DBCM, it  
97 inevitably increased the computational cost and time, especially in the large watershed.

98 An essential consideration to reduce computational time is mesh coarsening  
99 (Caviedes-Voullième et al., 2012). Adaptive mesh refinement (AMR) has been used to  
100 optimize the grid resolution during flood simulations (Donat et al., 2014; Hu et al., 2018;  
101 Ghazizadeh, 2020; Ding et al., 2021; Kesserwani and Sharifian, 2023). Aiming to  
102 increase computational efficiency by reducing computing nodes, it adjusts grid size for  
103 local grid refinement by domain features or flow conditions. Yu (2019) used quadtree  
104 grids to divide the computational domain and applied the DBCM to simulate the  
105 flooding process. It needs to segment and merge the grid elements repeatedly during  
106 the calculation, which can be time-consuming and offset the calculation time saved by  
107 the optimized grid. AMR is commonly employed in scenarios where flow  
108 characteristics exhibit abrupt variations, such as aerodynamic shock waves, hydraulic  
109 jumps, and seismic tsunami waves. Capturing discontinuous solutions necessitates local  
110 grid refinement, with the location of refinement dynamically adapting to the position  
111 of the discontinuities. AMR is indispensable for this purpose. Flow characteristic  
112 variations arising from abrupt geometric changes in the computational domain can be  
113 captured using static local refinement grids, provided that the extent of these changes  
114 is limited. This approach offers computational time savings.

115 Static non-uniform grids simplified grid generation procedure compared with  
116 AMR (Caviedes-Voullième et al., 2012; Hou et al., 2018; Bomers et al., 2019; Ozgen-

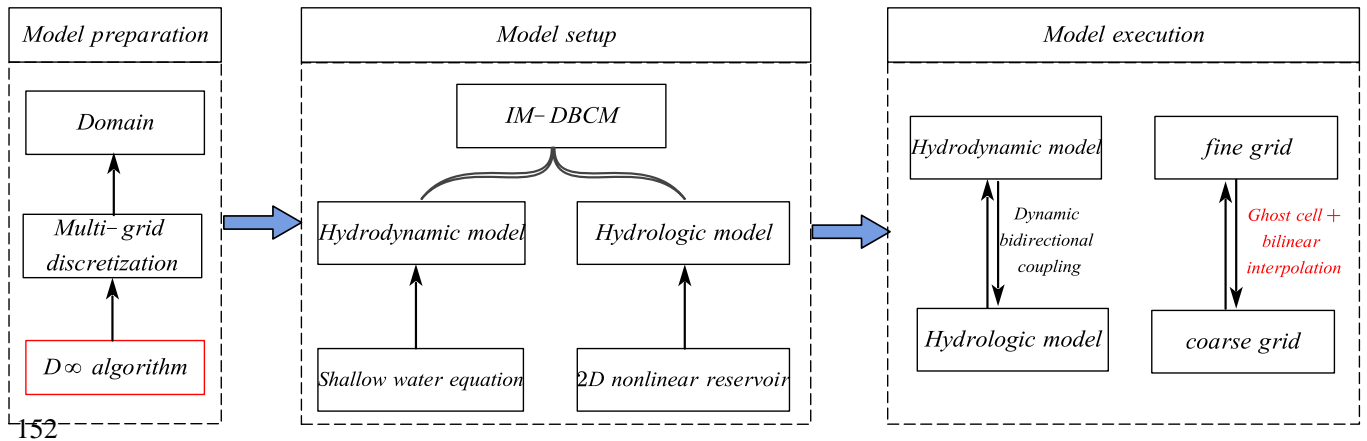

117 Xian et al., 2020). Compared with uniform grids and AMR, it can not only reduce  
118 computational nodes, but use different time steps in different grid sizes to further reduce  
119 computation time. Shen et al. (2021) and Shen and Jiang (2023) divided the  
120 computational domain based on static multi-grids, where the different grid size ratios  
121 of coarse to fine grids were designed. But there were two limitations to this scheme.  
122 One limitation is that the grids need to be generated manually, which can be subjective  
123 and uncertain. It also needs a heavy workload, especially for large watersheds. Besides  
124 the grid generation, the variable interpolation between the coarse and fine cells was also  
125 not reasonable. There are shared and hanging nodes at the interpolation interface. Shen  
126 et al. (2021) assumed the variables at the shared nodes were equal to that at the cell  
127 center, and the hanging nodes were calculated by the shared nodes. The results showed  
128 that this scheme has unsatisfactory accuracy and frequently fails to converge. Although  
129 the multi-grid-based model can reduce computational time, there are remarkable  
130 challenges such as the grid partition technique, determination of coarse and fine regions,  
131 and variables interpolation between coarse and fine grids.

132 The objective of this study is to develop an integrated system that fully couples  
133 the hydrologic and 2D hydrodynamic models, utilize an automated method for efficient  
134 multi-grid mesh generation, and resolve variable interpolation between coarse and fine  
135 grids more accurately. An improved dynamic bidirectional coupling model (IM-DBCM)  
136 was presented, where the 2D nonlinear reservoir (NLR) model was coupled with the  
137 2D hydrodynamic model through a CMI. The  $D_\infty$  algorithm was implemented to divide  
138 the computational domain into non-uniform grids automatically. Ghost cells (i.e., the  
139 virtual cells located on the boundaries of the computational domain) and bilinear  
140 interpolation were used to interpolate variables between the coarse and fine grids. Three  
141 case studies were conducted, and the simulation results were compared with the original

142 M-DBCM (OM-DBCM) to evaluate the effectiveness of the improvements.

## 143 **2 Methodology**

144 The Fortran programming language was adopted to apply the coupling model. The  
145 framework of IM-DBCM is illustrated in Figure 2. The model consists of two  
146 components: a hydrologic model (i.e., 2D NLR) that simulates the runoff generation  
147 and routing, and 2D hydrodynamic model simulating the flood inundation process.  
148 Before the model setup, it is required to first design the grids. Static multi-grids were  
149 applied to the model. For the model execution, the variables interpolation between  
150 coarse and fine grids and the coupling of hydrologic and hydrodynamic models are the  
151 two main issues that must be addressed.

152

153

Figure 2 Framework of IM-DBCM

### 154 **2.1 Automated multi-grid generation**

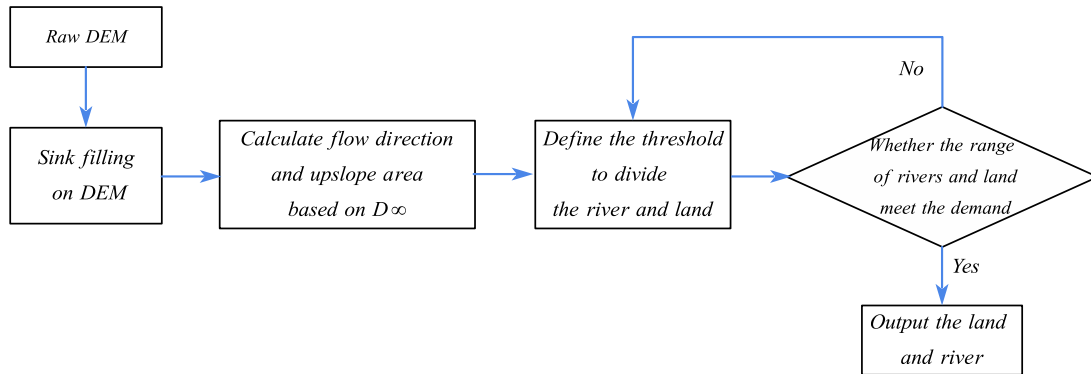

155 Associated with flood models, the design of computational grids that are scalable  
156 and suitable for all applications is challenging. The grid generation can be considered  
157 as a model preprocess, which is the foundation of flood simulation and can influence  
158 both computational accuracy and efficiency. In this study, a multi-grid generation  
159 method was proposed based on the  $D^\infty$  algorithm, to generate refined grid cells at flood-  
160 prone areas where high-resolution representation of topographic features is essential for  
161 flood simulation while discretizing the rest of the domain using coarse grids. The  $D^\infty$

162 algorithm is a method of representing flow directions based on triangular facets in grid  
163 DEM proposed by Tarboton (1997). It allocates the flow fractionally to each lower  
164 neighboring grid in proportion to the slope toward that grid. The flow direction is  
165 determined as the direction of the steepest downward slope on the eight triangular facets  
166 formed across a  $3 \times 3$ -pixel window centered on the pixel of interest, which was detailed  
167 by Tarboton (1997). Compared with the D8 algorithm, where the flow is discretized  
168 into only one of eight possible directions, separated by  $45^\circ$ , the  $D_\infty$  algorithm is more  
169 reasonable and accurate for delineating the actual river trend.

170 The process of discretizing computational domain based on the  $D_\infty$  algorithm is  
171 shown in Figure 3. First, a raw DEM was prepared, and sink filling was performed on  
172 the DEM. Second, the  $D_\infty$  algorithm was applied to determine the flow direction on  
173 grids. Subsequently, the upslope area, defined as the total catchment area that is  
174 upstream of a grid center or short length of contour (Moore et al., 1991), was calculated  
175 based on the flow direction. Finally, an area threshold was defined to identify the slope  
176 lands and derive the river drainage networks from accumulated drainage areas. In a grid  
177 cell, if the upslope area was larger than the predefined threshold, it was considered as a  
178 river drainage network; otherwise, it was defined as slope lands. The generated slope  
179 lands and river network were verified through field surveys or satellite images-based  
180 estimates. Generally, the river drainage networks present low slopes and hydraulic  
181 conveyance, which is subject to flooding. Areas prone to waterlogging, characterized  
182 by persistent water saturation, frequently occur adjacent to rivers. The dynamics of  
183 inundation in these low-lying zones constitute a central aspect of our investigation.  
184 Therefore, these areas should be discretized using fine grids to represent the flooding  
185 process in high resolution. However, in the slope lands, fine grids were not required  
186 and coarse grids were used to improve computational efficiency. Because the regions

187 of interest were of high resolution, the reliability of the prediction would not deteriorate,  
 188 although the number of grid cells was considerably reduced, which can increase model  
 189 efficiency and capability for flood simulations over large domains. Compared with  
 190 manual work, the grid generation based on the  $D^\infty$  algorithm can both reduce workload  
 191 and time.

192

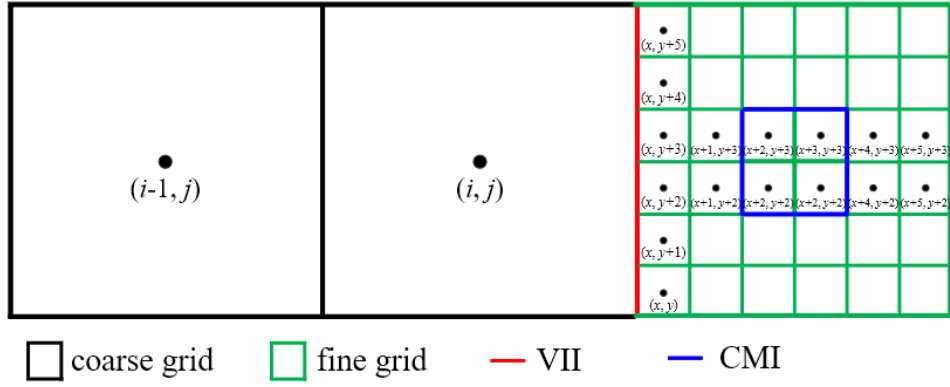

193 Figure 3 Grid generation based on the  $D^\infty$  algorithm

194 AMR dynamically adapts the grid resolution during the simulation, refining the  
 195 grid locally based on domain characteristics or flow conditions. AMR is commonly  
 196 employed in scenarios where flow characteristics exhibit abrupt variations, such as  
 197 aerodynamic shock waves, hydraulic jumps, and tsunami waves. Capturing  
 198 discontinuous solutions necessitates local grid refinement, with the location of  
 199 refinement dynamically adapting to the position of the discontinuities. Consequently,  
 200 AMR are indispensable. However, AMR needs to segment and merge the grid elements  
 201 repeatedly during the calculation, which can be time-consuming and offset the  
 202 calculation time saved by the optimized grid. Besides, the mesh generation and flood  
 203 simulation were compiled in the same code base, which increased the computation cost  
 204 and time.

205 Flow characteristic variations arising from abrupt geometric changes in the  
 206 computational domain can be captured using static local refinement grids, provided that

207 the extent of these changes is limited. This approach offers computational time savings.  
208 In flood simulations, inundation regions are typically situated in low-lying 2D regions.  
209 The outer boundary of the inundation regions can be determined using DEM or  
210 calculating by hydrologic models. The  $D_\infty$  algorithm was employed to preemptively  
211 estimate the extent of these areas, providing enhanced computational efficiency relative  
212 to AMR and obviating the uncertainty and complexity associated with manual  
213 subdivision of the computational domain.

214 A schematic of grid generation is shown in Figure 4. Two types of connecting  
215 interfaces are presented, which divide the computing domain into three parts. The first  
216 type is the red line (Variable Interpolation Interface, VII) between the coarse and fine  
217 grids. The grid cell size changes suddenly on both sides of this line. The second type  
218 (Coupling Moving Interface, CMI) is marked in blue on fine grids, which is moving  
219 and time-dependent. The first part represents the coarse-grid areas, where the  
220 hydrologic model is used to simulate rainfall-runoff. The other two parts are located in  
221 the fine-grid areas. The regions between VII and CMI are defined as intermediate  
222 transition zones, where the hydrologic model is used to simulate the flooding process.  
223 These transition zones facilitate the application of different time steps in different grid  
224 cell sizes to improve computational efficiency. The hydrologic and hydrodynamic  
225 models are dynamically coupled to represent the flooding process on fine grids, and the  
226 CMI is a coupling boundary.

227

228 Figure 4. Schematic diagram of grid generation, where  $i$  and  $j$  are the coordinates of  
 229 coarse grid;  $x$  and  $y$  are the coordinates of fine grid; VII is the Variable Interpolation  
 230 Interface and CMI is the Coupling Moving Interface

231 **2.2 Variable interpolation between coarse and fine grids**

232 During a flow computation, if a cell has a neighbor of different size, interpolation  
 233 may be required to approximate variables in certain locations so that the governing  
 234 equation can be solved smoothly. An example is presented in Figure 5(a), where the  
 235 coarse grid has two eastern neighbors that are half its size. In this case, the variable  
 236 values of the smaller cells are obtained from those of larger cells. In the traditional  
 237 method, these variables are directly calculated using certain interpolation methods.  
 238 There are shared ( $P_1, P_2$ ) and hanging ( $Q$ ) nodes at the interface between the coarse and  
 239 fine grids. In Shen et al. (2021), the variable values on shared nodes can be transmitted  
 240 directly, while the values on hanging nodes were obtained by linear interpolation of the  
 241 shared nodes. This method is simple, feasible and easy to use. However, the variable  
 242 values are stored at the cell center, and there are no values at the interface nodes. Shen  
 243 et al. (2021) assumed that the values at the interface nodes were equal to that at the cell  
 244 center. It is inaccurate to make such an assumption, which can bring errors. And the  
 245 resulting error will increase as the cell size increases.

246 To overcome these drawbacks, ghost cells and bilinear interpolation method were

247 used to interpolate variables between coarse and fine grids. Figure 5(a) shows the  
 248 variable interpolation between the coarse and fine grids. Two ghost fine cells were  
 249 created, which were overlaid with partial coarse grids. The variables on the ghost fine  
 250 cells were interpolated through the coarse and fine grids between the interface, which  
 251 were then used as the boundary conditions for the calculation of the fine grids at the  
 252 next time step. The bilinear interpolation method was applied. The variable  
 253 interpolation may involve variables at locations  $c_1, c_2, c_3, f_{v1}', f_{v2}', f_1$  and  $f_2$ . As the  
 254 variables are stored at the cell center, the variables at  $c_1, c_2, c_3, f_1$  and  $f_2$  are available  
 255 directly. The values at  $f_{v1}'$  and  $f_{v2}'$  are obtained via natural neighbor interpolation, as  
 256 follows:

$$257 \quad U_{f_{v1}'} = U_{c_1} + \frac{U_{c_2} - U_{c_1}}{y_{c_2} - y_{c_1}} (y_{f_{v1}'} - y_{c_1}) \quad (1)$$

$$258 \quad U_{f_{v2}'} = U_{c_3} + \frac{U_{c_1} - U_{c_3}}{y_{c_1} - y_{c_3}} (y_{f_{v2}'} - y_{c_3}) \quad (2)$$

259 where  $U_{f_{v1}'}, U_{f_{v2}'}, U_{c_1}, U_{c_2}, U_{c_3}$  are the variables at locations  $f_{v1}', f_{v2}', c_1, c_2, c_3$  respectively;  
 260  $y_{f_{v1}'}, y_{f_{v2}'}, y_{c_1}, y_{c_2}, y_{c_3}$  are the coordinates in y directions at  $f_{v1}', f_{v2}', c_1, c_2, c_3$  respectively.

261 And then, the variables of ghost fine cells at  $f_{v1}'$  and  $f_{v2}'$  can be calculated based  
 262 on that at  $f_{v1}'$  and  $f_{v2}'$ , as follows:

$$263 \quad U_{f_{v1}'} = U_{f_{v1}'} + \frac{U_{f_1} - U_{f_{v1}'}}{x_{f_1} - x_{f_{v1}'}} (x_{f_{v1}'} - x_{f_{v1}'}) \quad (3)$$

$$264 \quad U_{f_{v2}'} = U_{f_{v2}'} + \frac{U_{f_2} - U_{f_{v2}'}}{x_{f_2} - x_{f_{v2}'}} (x_{f_{v2}'} - x_{f_{v2}'}) \quad (4)$$

265 where  $U_{f_{v1}'}, U_{f_{v2}'}$  are the variables of ghost fine cells;  $U_{f_1}, U_{f_2}$  are the variables at  $f_1, f_2$ ,  
 266 respectively, which were calculated in the last time step;  $x_{f_1}, x_{f_2}, x_{f_{v1}'}, x_{f_{v2}'}, x_{f_{v1}'}$  and  $x_{f_{v2}'}$

267 are the coordinates in  $x$  directions at  $f_1, f_2, f_{v1}, f_{v2}, f_{v1}', f_{v2}'$  respectively.

268 The values at  $f_{v1}, f_{v2}$  were used as the boundary conditions for the calculation of  
269 fine grids.

270 The variable interpolation from fine to coarse grids is presented in Figure 5(b),  
271 where one ghost coarse cell was established. The variables of ghost coarse cells were  
272 determined according to the fine and coarse grids between the interface. The variable  
273 interpolation may involve variables at locations  $c_v', c_1, f_1, f_2$ . As the variables are stored  
274 at the cell center, the variables at  $c_1, f_1, f_2$  are available directly. The values at  $c_v'$  are  
275 obtained via natural neighbor interpolation, as follows:

$$276 \quad U_{c_v'} = U_{f_2} + \frac{U_{f_1} - U_{f_2}}{y_{f_1} - y_{f_2}} (y_{c_v'} - y_{f_2}) \quad (5)$$

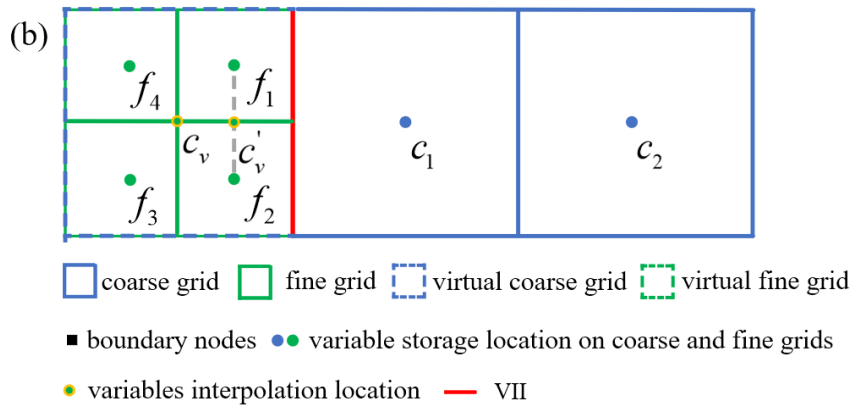

277 where  $U_{c_v'}, U_{f_1}, U_{f_2}$  are the variables at  $c_v', f_1, f_2$  respectively;  $y_{c_v'}, y_{f_1}, y_{f_2}$  are the  
278 coordinates in  $y$  direction at  $c_v', f_1, f_2$  respectively.

279 And then, the variables of ghost coarse cells at  $c_v$  can be calculated based on that  
280 at  $c_v', c_1$ , as follows:

$$281 \quad U_{c_v} = U_{c_v'} + \frac{U_{c_1} - U_{c_v'}}{x_{c_1} - x_{c_v'}} (x_{c_v} - x_{c_v'}) \quad (6)$$

282 where  $U_{c_v}$  are the variables of ghost fine cells;  $U_{c_1}$  are the variables at  $c_1$ , which were  
283 calculated in the last time step;  $x_{c_1}, x_{c_v'}, x_{c_v}$  are the coordinates in  $x$  direction at  $c_1, c_v', c_v$   
284 respectively.

285 The values at  $c_v$  were used as boundary conditions for the calculation of coarse  
286 grids at the next time step.

288

289 Figure 5. Variables interpolation between coarse and fine grids: (a) from coarse to  
290 fine grids and (b) from fine to coarse grids

291 On both sides of the interface between coarse and fine grids, the hydrologic model  
292 was used to simulate the flood process. In the hydrologic model applied to the IM-  
293 DBCM, the Manning equation is employed to simulate surface runoff processes. As a  
294 linear partial differential equation, the Manning equation lacks a nonlinear convection  
295 term. Consequently, the flow state undergoes relatively smooth changes without  
296 exhibiting discontinuous solutions. Linear interpolation is applied to interpolate  
297 variables between coarse and fine grids, with the interpolated values falling within the  
298 range defined by the maximum and minimum values of the interval. This interpolation

299 ensures that the result lies between these bounds, precluding the occurrence of increased  
 300 flow at the interface of coarse and fine grid transitions.

## 301 **2.3 Numerical models**

### 302 **2.3.1 Hydrologic model**

303 In this study, referring to the runoff calculation in the Storm Water Management  
 304 Model (SWMM), a 2D NLR model, including water balance and Manning equations,  
 305 was used to simulate rainfall-runoff. In SWMM, the watershed is divided into many  
 306 water tanks or reservoirs, where 1D NLR model including water balance and 1D  
 307 Manning equations is used to simulate the runoff (Rossman, 2015). It is a simple and  
 308 efficient method to calculate the runoff routing. In reality, however, the runoff routing  
 309 is a 2D way, so it is not accurate to calculate the 2D runoff routing using 1D NLR model.  
 310 Also, it is difficult to directly couple the 1D NLR model with 2D hydrodynamic model.  
 311 Therefore, the 2D NLR model was used to simulate the 2D surface runoff routing in  
 312 this study, as shown in Eqs. (7-11). The effects of subsurface runoff are assumed to be  
 313 negligible, which is reasonable for the intense rainfall-induced flood events considered  
 314 in this study (Hou et al., 2018; Li et al. 2021).

$$315 \quad \frac{V_i^{n+1} - V_i^n}{\Delta t} = (Q_x)_{in\ i} - (Q_x)_{out\ i} + (Q_y)_{in\ i} - (Q_y)_{out\ i} + A_i q_{r\ i}^n \quad (7)$$

$$316 \quad (Q_x)_{in\ i} - (Q_x)_{out\ i} = -\sum_{l=1}^L (q_{x\ \Gamma}^n \cdot n_x)_l \Delta L_l \quad (8)$$

$$317 \quad (Q_y)_{in\ i} - (Q_y)_{out\ i} = -\sum_{l=1}^L (q_{y\ \Gamma}^n \cdot n_y)_l \Delta L_l \quad (9)$$

$$318 \quad q_x = \frac{h^{5/3} S_x^{1/2}}{n_r} \quad (10)$$

$$319 \quad q_y = \frac{h^{5/3} S_y^{1/2}}{n_r} \quad (11)$$

320 where the superscript  $n$  and  $n+1$  is the time step;  $V$  is the water volume of grid ( $\text{m}^3$ );  
321  $(Q_x)_{in\ i}, (Q_x)_{out\ i}$  is the inflow and outflow of grid  $i$  in  $x$  direction ( $\text{m}^3/\text{s}$ );  
322  $(Q_y)_{in\ i}, (Q_y)_{out\ i}$  is the inflow and outflow of grid  $i$  in  $y$  direction ( $\text{m}^3/\text{s}$ );  $q_{r\ i}$  indicates  
323 runoff rate of grid  $i$  ( $\text{mm}/\text{h}$ ), which is rainfall intensity minus infiltration rate;  $A_i$  is the  
324 area of grid  $i$  ( $\text{m}^2$ );  $q_x, q_y$  are the unit discharge stored at cell-center along  $x$  and  $y$   
325 direction ( $\text{m}^2/\text{s}$ ), with  $h, u$  and  $v$  being water depth (m), flow velocity (m/s) in  $x$  and  $y$   
326 directions, respectively;  $q_{x\ \Gamma}, q_{y\ \Gamma}$  are the unit discharge at grid boundary in  $x$  and  $y$   
327 direction, respectively ( $\text{m}^2/\text{s}$ ), which are calculated based on  $q_x, q_y$ ;  $\Delta L_l$  is the side  
328 length of grid (m);  $l = 1, 2, 3, \dots, L$  is the number of edges of cell;  $n_r$  is the Manning  
329 roughness coefficient;  $S_x$  and  $S_y$  are water level gradients along  $x$  and  $y$  direction,  
330 respectively;  $S_x = -\partial(z_b + h)/\partial x$ ,  $S_y = -\partial(z_b + h)/\partial y$ , where  $z_b$  is the surface  
331 elevation.

### 332 2.3.2 Hydrodynamic model

333 The 2D SWEs, consisting of mass and momentum conservation equations (Toro  
334 2001), were used to represent the hydrodynamic model.

$$335 \quad \frac{\partial U}{\partial t} + \frac{\partial F}{\partial x} + \frac{\partial G}{\partial y} = S \quad (12)$$

$$336 \quad U = \begin{pmatrix} h \\ hu \\ hv \end{pmatrix}, F = \begin{pmatrix} hu \\ hu^2 + gh^2/2 \\ huv \end{pmatrix}, G = \begin{pmatrix} hv \\ huv \\ hv^2 + gh^2/2 \end{pmatrix}, S = \begin{pmatrix} q_r \\ -gh \frac{\partial z}{\partial x} - \frac{g}{C^2} u \sqrt{u^2 + v^2} \\ -gh \frac{\partial z}{\partial y} - \frac{g}{C^2} v \sqrt{u^2 + v^2} \end{pmatrix}$$

337 where  $U$  is the conserved variables;  $F, G$  are the convection term in the  $x$  and  $y$   
338 directions;  $S$  is the source term;  $C$  is Chezy's coefficient,  $C = \frac{1}{n_r} R^{1/6}$ , where  $n_r$  is the

339 Manning roughness coefficient and  $R$  is the hydraulic radius.

340 The Finite Volume Method for Conservative Scheme was used to solve the SWEs,  
341 which can ensure local mass and momentum conservation in each control volume cell.

342 The Eq. (12) can be discretized based on structured grids, as follows:

$$343 \quad U_{i,j}^{n+1} = U_{i,j}^n - \frac{\Delta t}{A_{i,j}} \sum_{l=1}^L \left[ F^l(U_{i,j}^n) dy - G^l(U_{i,j}^n) dx \right] + \frac{\Delta t}{A_{i,j}} S(U_{i,j}^n) \quad (13)$$

344 where the superscript  $n$  and  $n+1$  is the time step; the subscript  $i, j$  refers to the grid  $i, j$ ;  
345  $dx$  and  $dy$  are the grid edge length. The meaning of other symbols is the same as before.

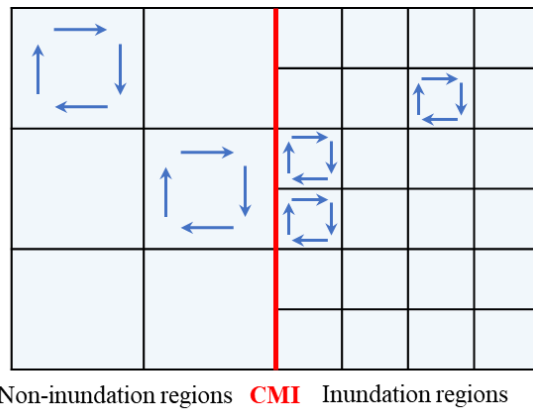

346 The Harten-Lax-van Leer contact (HLLC) approximate Riemann solver was used  
347 to solve the convection term. The second-order accuracy in temporal and spatial  
348 discretization was obtained based on the Runge-Kutta method and Monotone  
349 Upstream-centered Schemes for Conservation Laws (MUSCL) (Van Leer, 1979). The  
350 solution of SWEs was detailed in many references (Toro 2001).

#### 351 **2.4 Dynamic bidirectional coupling of hydrologic and hydrodynamic models**

352 The hydrologic and hydrodynamic models were coupled dynamically and bi-  
353 directionally. A water depth threshold was defined in advance and used to determine  
354 the state of the cell. In a grid cell, if the water depth was lower than the predefined  
355 threshold, it was defined as a non-inundation region where the hydrologic model was  
356 applied. Conversely, if the water depth was higher than the threshold, it was considered  
357 an inundation region where the 2D hydrodynamic model was applied. When the rainfall  
358 intensity increased, the water depth increased because of the gradual accumulation of  
359 surface water volume. Once the water depth exceeds the predefined threshold, the non-  
360 inundation regions defined last time step may change to the inundation regions. The  
361 inflow discharge positions, flow path, and discharge values subsequently changed.  
362 Therefore, a CMI was formed between the inundation and non-inundation regions and

363 the hydrologic and 2D hydrodynamic models were coupled bi-directionally through this  
 364 CMI.

365 The hydrologic model is rational for the continuous non-inundation regions, and  
 366 the hydrodynamic model is rational for the continuous inundation regions. However,  
 367 since discontinuity existed at the CMI, the single hydrologic or hydrodynamic models  
 368 were not acceptable, which was a challenge for the model calculation, as shown in  
 369 Figure 6. The key issue with the coupled model was to establish a reasonable approach  
 370 for determining the fluxes passing through the coupling interface, which should  
 371 integrate the effect of the current flow state obtained from these two models on both  
 372 sides of the coupling interface.

373  
 374 Figure 6. Model calculation at inundation regions, non-inundation regions and CMI

375 A pair of characteristic waves was used to determine the fluxes calculation  
 376 methods through the CMI. The characteristic waves were calculated as follows:

377 
$$S_L = u_{i,j} - \sqrt{gh_{i,j}} \quad (1)$$

378 
$$S_R = u_{i+1,j} - \sqrt{gh_{i+1,j}} \quad (2)$$

379 where  $S_L$  and  $S_R$  are the characteristic waves;  $u$  is the flow velocity (m/s);  $h$  is the  
 380 water depth (m); subscript  $(i, j)$  and  $(i+1, j)$  refer to the cells in non-inundation and  
 381 inundation regions, respectively.

382 If  $S_R > 0$  and  $S_L > 0$ , the fluxes through the CMI were calculated by the  
 383 hydrologic model, and the CMI may move toward the non-inundation regions.  
 384 Therefore, the non-inundation regions shrunk, whereas the inundation regions  
 385 expanded. Only mass conservation through the CMI can be considered in this situation.

386 If  $S_L < 0 < S_R$ , the fluxes were calculated by both hydrologic and hydrodynamic  
 387 models, and the CMI remained unchanged.

388 If  $S_L < 0$  and  $S_R < 0$ , the fluxes are calculated by the hydrodynamic model, and  
 389 the CMI may move toward inundation regions. Therefore, the inundation regions  
 390 shrunk, whereas the non-inundation regions expanded. Both the mass and momentum  
 391 conservation through the coupling boundary were obtained in the latter two situations.  
 392 The couplings were detailed in Jiang et al. (2021) and Shen et al. (2021).

### 393 **2.5 Time step**

394 An explicit scheme was used to solve the hydrologic and hydrodynamic models  
 395 over time. The time step was constrained by the Courant-Friedrichs-Lewy condition  
 396 (Delis and Nikolos, 2013), where the time step was a dynamic adjustment based on the  
 397 velocity and water depth in the computational domain. Different time steps were  
 398 adopted for the coarse and fine grids, and the time step of the fine grids was determined  
 399 as follows:

$$400 \quad \Delta t_f = C \cdot \min \left( \frac{\min(\Delta x_f)}{\max(|u_f| + \sqrt{gh_f})}, \frac{\min(\Delta y_f)}{\max(|v_f| + \sqrt{gh_f})} \right) \quad (14)$$

401 where  $\Delta t_f$  is the time step of fine grids;  $C$  is a constant used to maintain format stability;

402  $\Delta x_f$  and  $\Delta y_f$  are the side lengths of fine grid in  $x$  and  $y$  directions;  $u_f$  and  $v_f$  are the

403 flow velocities on fine grids along  $x$  and  $y$  directions, respectively;  $h_f$  is the water depth

404 on fine grids.

405 The time step of the coarse grids ( $\Delta t_c$ ) was determined based on that of the fine  
 406 grids. If the size of the coarse grid was  $k$  times that of the fine grid, the time step of the  
 407 coarse grid was determined to be  $\Delta t_c = k\Delta t_f$ .

### 408 **3 Results**

409 The performance of the IM-DBCM was analyzed by applying it to two 2D rainfall-  
 410 runoff experiments and one real-world flooding process. And the OM-DBCM  
 411 developed by Shen et al. (2021) was applied to the same cases for comparison with the  
 412 IM-DBCM.

#### 413 **3.1 Rainfall over a plane with varying slope and roughness**

414 In this case, a sloping plan measuring  $500m \times 400m$  was designed, with slopes  
 415  $S_{ox} = 0.02 + 0.0000149x$  and  $S_{oy} = 0.05 + 0.0000116y$  along the  $x$  and  $y$  directions,  
 416 respectively (Jaber and Mohtar, 2003). The Manning coefficient is equal to  
 417  $n = \sqrt{n_x^2 + n_y^2}$ , where  $n_x = 0.1 - 0.0000168x$  and  $n_y = 0.1 - 0.0000168y$ . The rainfall  
 418 intensity is given by a symmetric triangular hyetograph  $r = r(t)$ , with  
 419  $r(0) = r(200 \text{ min}) = 0$  and  $r(100 \text{ min}) = 0.8 \times 10^{-5} \text{ m/s}$ . The total simulation time was  
 420 14,400 s.

421 Different cases with various grid resolutions were developed to divide the  
 422 computational domain based on the  $D_\infty$  algorithm, as listed in Table 1. In these cases,  
 423 the size of all the fine grids was  $1m \times 1m$ . The grid discretization of different cases is  
 424 shown in Figure S1 in Supplement.

425 Table 1 Different cases designed to simulate

Cases	The ratio of coarse to fine grids	Number of grids
case12	1:2	112,100
case15	1:5	86,840
case10	1:10	83,220

426 The hydrographs at the outlet node of coordinates of (500m, 400m) obtained from  
427 different models are shown in Figure 7. A model proposed by Jaber and Mohtar (2003)  
428 was also used to simulate the overland runoff. Because finer grids and small time step  
429 were used to divide the computational domain to obtain more accurate results in the  
430 model developed by Jaber and Mohtar (2003), the results calculated by Jaber and  
431 Mohtar (2003) can be used as a reference solution.

432 From Figure 7, the IM-DBCM held a shape close to the results simulated by Jaber  
433 and Mohtar (2003) in all cases, as well as the peak discharge. But the peak discharge  
434 of the hydrograph is slightly overestimated by the OM-DBCM, which may be attributed  
435 to the difference in the variable interpolation between the coarse and fine grids. In the  
436 OM-DBCM, variables at the interpolation interface were equal to that at the cell center,  
437 which was then used to interpolate variables between the coarse and fine grids through  
438 shared and hanging nodes. This interpolation method had two drawbacks. Firstly, it is  
439 not reasonable to assume the variables at the interpolation interface are equal to that at  
440 the cell center, and the resulting error could increase as the grid size increases. Besides,  
441 compared with bilinear interpolation, the values at the hanging nodes are calculated by  
442 linear interpolation through shared nodes, which may result in relatively large errors.  
443 The results show that the methods to interpolate variable between the coarse and fine  
444 grids by developing ghost cells proposed in this study has acceptable accuracy.

445 To quantitatively assess the performance of IM-DBCM, the Root Mean Square  
446 Error (RMSE) of different cases was computed. The RMSEs of case12, case15 and  
447 case10 were  $4.01E-04$ ,  $7.85E-03$  and  $3.25E-02$ , respectively. It is showed that the error  
448 gradually increased with the increasing of the ratio of coarse to fine grids. The IM-  
449 DBCM may capture the shape of the hydrograph in case12 and case15, both in limbs  
450 and peak discharge, but the peak discharge is slightly underestimated in case10. A

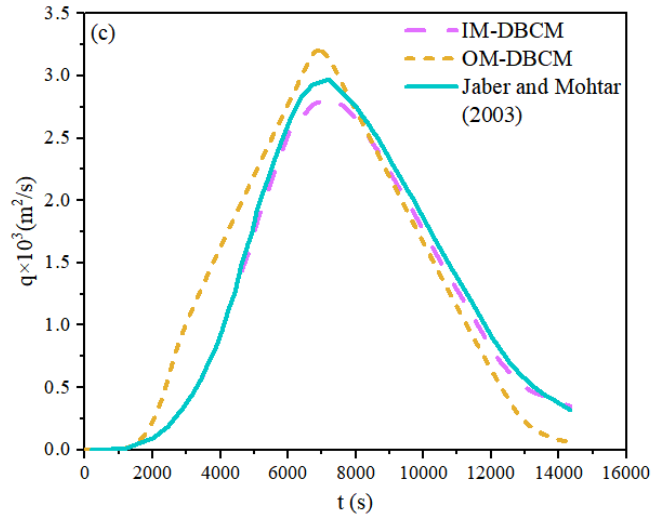

451 possible explanation is that, compared to the coarse grids, the fine grids could better  
452 capture the geometry of the channel cross-sections. High-resolution grids can better  
453 represent small-scale topographic features and flow passages (Hou et al., 2018);  
454 consequently, the simulation results on case12 and case15 are more satisfactory than  
455 those on case10. Similarly, the simulation accuracy of the OM-DBCM also gradually  
456 decreased with the increasing of the ratio of coarse to fine grids. Overall, the benefit of  
457 using the IM-DBCM for the flood simulations is evident.

### 463 3.2 V-shaped catchment

464

A 2D surface flow simulation was conducted over a V-shaped catchment to  
 465 evaluate the performance of the IM-DBCM. The computational domain is  
 466 symmetrically V-shaped, with two symmetrical hillslopes converging to form a channel  
 467 in the central region. The river bed slopes -0.05 on the left side and 0.05 on the right  
 468 side. The channel bed has zero slope in the  $x$  direction and a slope of 0.02 in the  $y$   
 469 direction. The Manning coefficient is 0.015 on the hillslope and 0.15 on the main  
 470 channel. The detailed dimensions and associated information pertaining to the V-  
 471 shaped catchment are presented in Figure 8. The total simulation time was 10,800 s,  
 472 with a constant rainfall intensity of 10.8 mm/h applied for 5,400 s.

473

Figure 8. Geometry and size of the V-shaped catchment

474

475 The IM-DBCM was used to simulate the 2D surface flow over the V-shaped  
 476 domain. The computational basin was divided into coarse and fine grids based on the  
 477  $D_{\infty}$  algorithm. The size of the fine grids was  $10\text{m} \times 10\text{m}$ , whereas that of the coarse  
 478 grids was  $20\text{m} \times 20\text{m}$ . The grid partition is presented in Figure S2 in Supplement, where  
 479 a V-shaped zones near the watershed outlet was discretized using fine grids, while the  
 480 remaining areas were discretized using coarse grids.

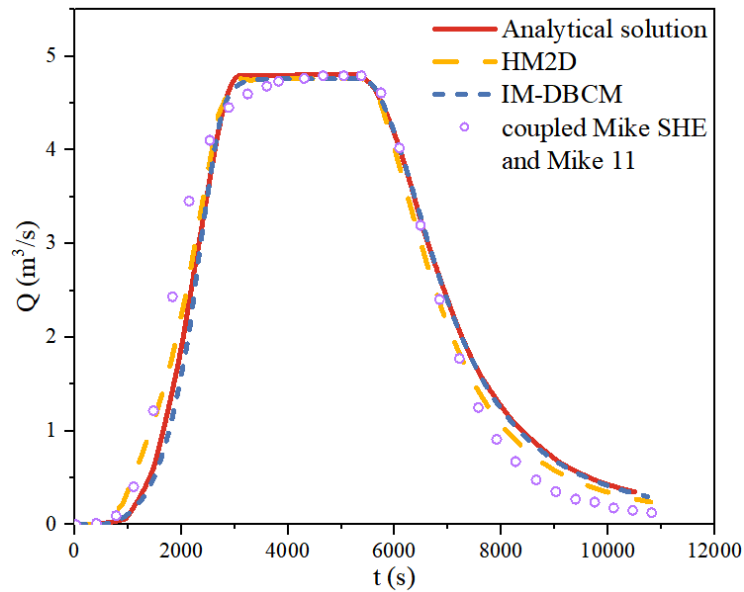

481 Besides, the HM2D and the coupled Mike SHE and Mike 11 was also developed  
 482 to simulate the surface flow under the same conditions. In the HM2D, the grid size was  
 483 set as  $10\text{m} \times 10\text{m}$ . In the coupled Mike SHE and Mike 11, the Mike SHE was used to  
 484 simulate the rainfall-runoff on the hillslopes and the grid sizes was also  $10\text{m} \times 10\text{m}$ ,  
 485 while the Mike 11 was used to simulate the runoff in the channel. Results were all  
 486 compared with measured data.

487 The discharge hydrographs obtained from different models are shown in Figure 9.  
 488 This figure showed a close match between the measured data and the computed results  
 489 obtained using the IM-DBCM. This indicated that the results were encouraging and the  
 490 overall trend was well captured. The hydrographs obtained from the IM-DBCM was  
 491 closer to the analytical solution compared with the coupled Mike SHE and Mike 11.

492 The weir flow equation was utilized to couple the Mike SHE and Mike 11. Notably,  
493 only mass was transferred between the models, excluding momentum. However, mass  
494 and momentum were exchanged between the hillslopes and river channels. The IM-  
495 DBCM model ensured the conservation of both mass and momentum, resulting in  
496 simulated hydrographs that closely match analytical solutions.

497 Comparing the hydrographs generated by the 2D hydrodynamic model and IM-  
498 DBCM, the discharge hydrographs exhibited congruence for the discharge receding  
499 limb and peak discharge. However, the consistency of the hydrographs simulated by  
500 these two models was less pronounced for the rising limb. In the rising limb, the flow  
501 calculated using IM-DBCM was lower than that simulated using HM2D. The disparity  
502 in hydraulic behavior between the hydrodynamic and hydrologic models explains the  
503 observed phenomenon. The HM2D consistently simulate the surface flow using the 2D  
504 hydrodynamic model; conversely, the hydrologic model was employed solely to  
505 simulate the flood processes when the upstream water level recedes below the threshold  
506 established in IM-DBCM. In the hydrologic models that lack time-partial derivative  
507 terms, the current velocity was solely determined by the instantaneous water level  
508 gradient. This differs from the previous calculation method, which added the flux term  
509 to the velocity at the previous time step. Consequently, the velocity calculation in 2D  
510 hydrodynamic models deviated from the IM-DBCM.

511

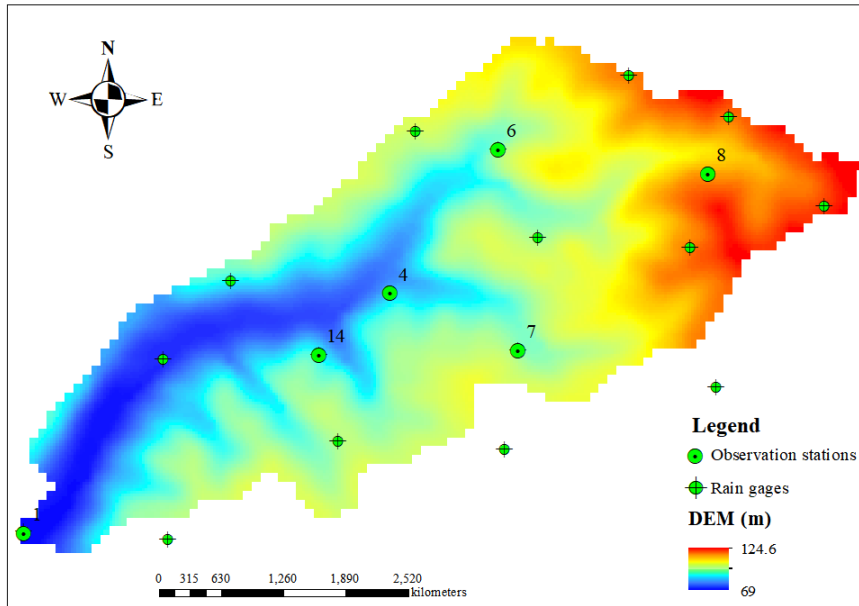

512 Figure 9. Measured and simulated results obtained from different models

513 **3.3 Flood simulation in a natural watershed**

514 The Goodwin Creek watershed, located in Panola County, Mississippi, USA, is  
 515 often selected as a benchmark to assess the capability of flood models because of  
 516 sufficient available observed data. Drainage is westerly to Long Creek which flows into  
 517 the Yocona River, one of the main rivers of the Yazoo River, a tributary of the  
 518 Mississippi River. The Goodwin Creek watershed covers an area of 21.3 km<sup>2</sup>. The  
 519 overall terrain gradually decreased from northeast to southwest, which is consistent  
 520 with the trend of the main channel, and the elevation ranged from 71 to 128 m. The  
 521 computational basin and bed elevations are shown in Figure 10.

522 Land use in this watershed was divided into four classes including forest, water,  
 523 cultivated, and pasture, and their Manning coefficients were 0.05, 0.01, 0.03, and 0.04,  
 524 respectively (Sánchez, 2002). The infiltration coefficients of different soil types were  
 525 determined according to Blackmarr (1995). The rainfall event in sixteen rain gages (see  
 526 Figure 10) of October 17, 1981 was chosen for simulation (Sánchez, 2002), and the  
 527 inverse distance interpolation method (Barbulescu, 2016) was used to calculate the  
 528 precipitation over the entire watershed. The rainfall duration was 4.8 h. Rainfall was

529 spatially distributed at different times, as shown in Figure S3 in Supplement. There  
 530 were measured data in six observation stations (i.e., 1, 4, 6, 7, 8 and 14) (Blackmarr,  
 531 1995), whose locations were shown in Table S1 in Supplement, and the simulated  
 532 results were compared with the measured data in these stations.

533  
 534 Figure 10. Overview of the Goodwin Creek watershed

535 The simulations were performed for 12 h. Different cases with various grid  
 536 resolutions were developed to verify the computational efficiency and numerical  
 537 accuracy of IM-DBCM, as listed in Table 2. In M-DBCM, the rivers were covered by  
 538 fine-grid cells with dimensions of  $10\text{ m} \times 10\text{ m}$ , whereas the coarseness in the rest of  
 539 the domain was increased to higher levels, as presented in Figure S4 in Supplement.

540 Table 2. Different cases designed to simulate the Goodwin Creek watershed

Cases	The ratio of coarse to fine grids	Number of grids
case12	1:2	104,555
case15	1:5	65,240
case10	1:10	59,431

541 The OM-DBCM was also used to simulate the rainfall runoff with the same  
 542 resolutions. The Nash-Sutcliffe efficiency (NSE) was used to quantify errors in each

543 model. The NSEs of IM-DBCM and OM-DBCM are shown in Table 3. From this table,  
 544 the NSEs of IM-DBCM were higher than that of OM-DBCM at most stations, which  
 545 was probably caused by the different interpolation method at the interface between  
 546 coarse and fine grids. It is verified that the IM-DBCM has relatively high accuracy in  
 547 simulating rainfall-runoff. In OM-DBCM, it is unreasonable to make the variables at  
 548 the interface between coarse and fine grids equal to that at the cell center, which can  
 549 bring errors. The induced error will increase as the ratio of coarse and fine grids increase.  
 550 Therefore, it is also observed that the NSEs of OM-DBCM decreased with the increased  
 551 ratio of coarse and fine grids. It is indicated that the ghost cells and bilinear interpolation  
 552 used in the IM-DBCM to interpolate variables between coarse and fine grids can make  
 553 the simulation more reasonable.

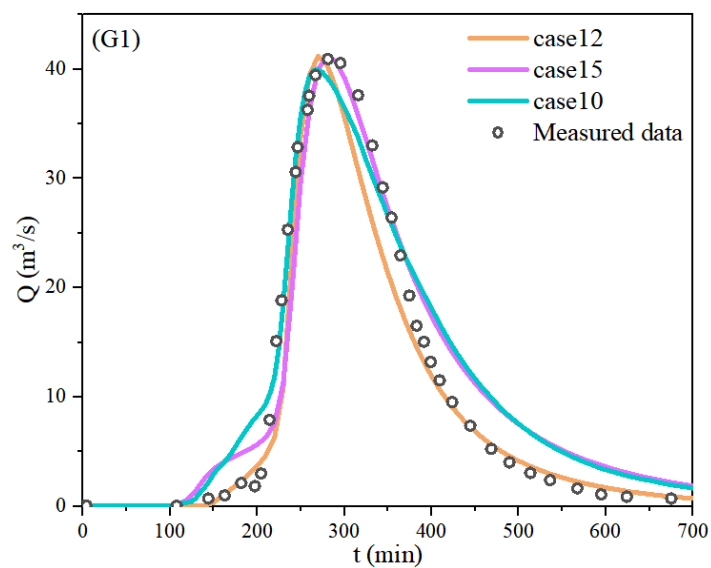

554 Table 3 NSEs of different models (“IM” and “OM” refer to IM-DBCM and OM-  
 555 DBCM, respectively)

Station	G1		G4		G6		G7		G8		G14	
	IM	OM	IM	OM	IM	OM	IM	OM	IM	OM	IM	OM
case12	0.9496	0.9108	0.9611	0.9011	0.9904	0.8982	0.9658	0.9004	0.9435	0.9104	0.9311	0.8804
case15	0.9399	0.8766	0.9404	0.8800	0.9426	0.8819	0.9258	0.8931	0.9341	0.8942	0.9001	0.7942
case10	0.9207	0.8261	0.8907	0.8435	0.9513	0.7977	0.9358	0.8525	0.9358	0.8678	0.9135	0.8078

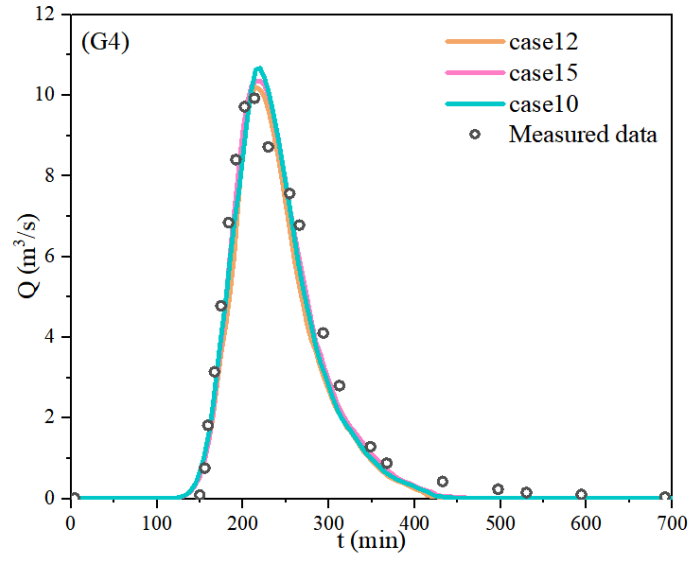

556 Figure 11 shows a comparison of the measured and simulated hydrographs by IM-  
 557 DBCM at the monitoring gauges, whose locations are presented in Figure 10. At all  
 558 gauges, the hydrographs obtained from different cases were well aligned with the  
 559 measured data, which indicates that the IM-DBCM could reliably reproduce the flood  
 560 wave propagation in the complex topography. The results of case12, in general, were

561 better than those of case15 and case10, especially at station G1. A possible explanation  
562 is that a finer grid is needed to better capture the watershed geometry and obtain more  
563 satisfactory simulation accuracy. The cell size of case15 and case10 is larger than that  
564 of case12.

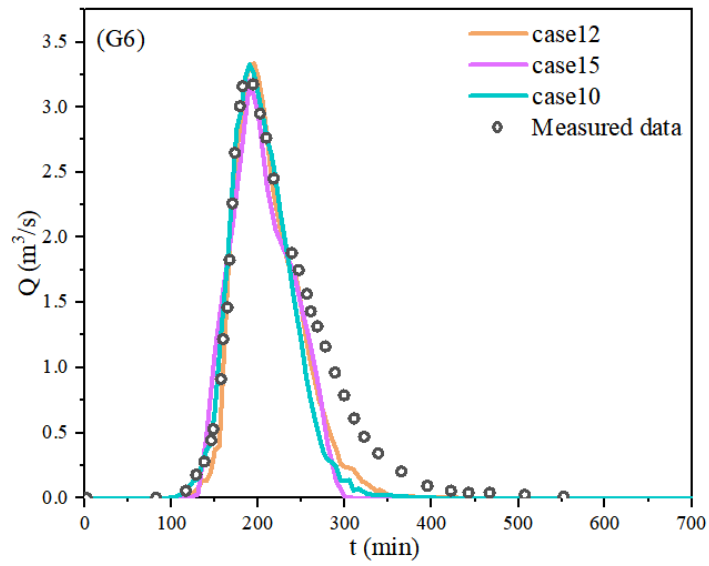

565 Compared with other stations, at station G1, the simulation results obtained from  
566 case15 and case10 deviated substantially from the measured data, especially at receding  
567 limb of the hydrographs. We deduced that the reason for this discrepancy is not the  
568 mesh partitioning, but the location of the G1. G1 is located at the watershed outlet,  
569 where water flows out of the watershed from here. The errors generated upstream may  
570 be accumulated at this station. Despite the deviation, the overall trend of the  
571 hydrographs indicated that the IM-DBCM is satisfactory and can reliably reproduce  
572 flood wave propagation in complex topography.

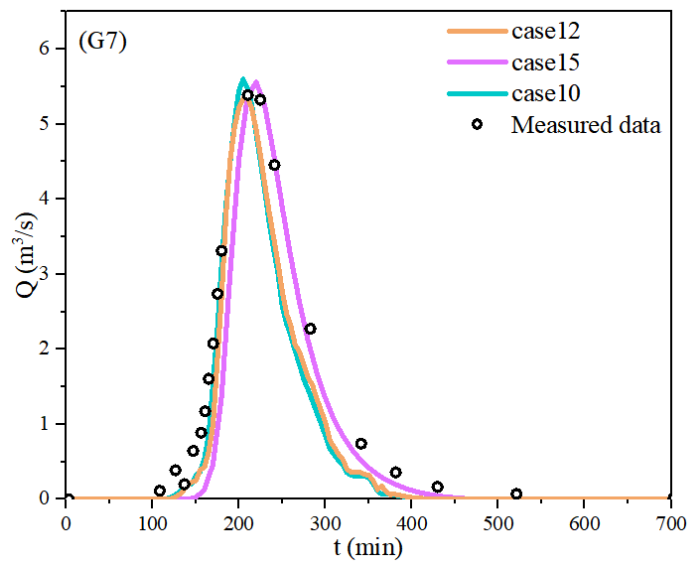

573

574

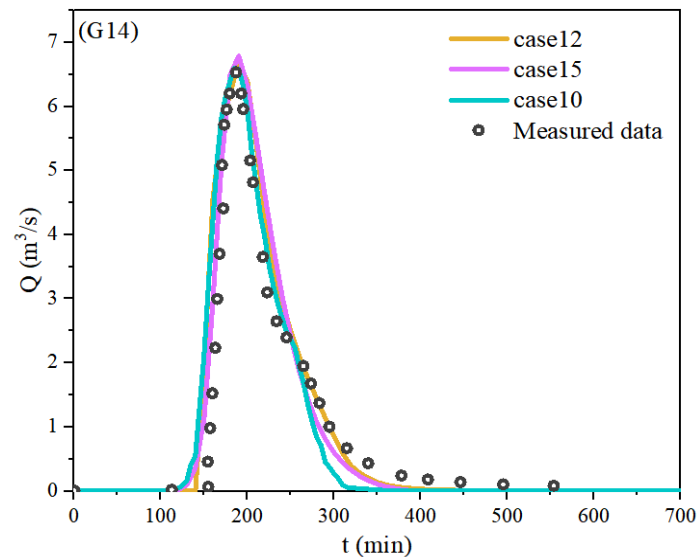

575

576

577

578

579

Figure 11. Hydrographs obtained from different cases

580

The water depth distribution at different times is shown in Figure 12. The

581

probability of flooding and inundation increases with increasing water depth. From 0

582

to 100 min, the water depth in the computational domain increased with the rainfall.

583

The water depth across the computational domain is predominantly shallow, as shown

584

in Figure 12(a). The discharge hydrographs within the watershed reached their peak at

585

200 minutes. Concurrently, the water depth in the watershed attained its maximum level,

586

as shown in Figure 12(b). After 200 min, when rainfall stopped, the water depth in the

587

computational watershed decreased (Figure 12(c)).

594

595 In terms of efficiency, the total execution time of IM-DBCM was compared with  
 596 the uniform grid-based model (HM2D), as shown in Figure 13. The total execution time  
 597 of the different cases ranked from highest to lowest is as follows: HM2D> case12>  
 598 case15> case10. Compared to HM2D, the multi-grid discrete computing domain  
 599 improves computational efficiency by 60%. Uniform fine grids were used to divide the  
 600 computing zones in HM2D, and 207,198 computational grids were generated.  
 601 Compared with HM2D, most of the areas were discretized with coarse grids, and only  
 602 a small part of the regions was calculated based on fine grids in IM-DBCM; the  
 603 computational grids of the multi-grid-based model (Table 2) were considerably lower  
 604 than that of HM2D. Furthermore, case12 required more computational time than case15  
 605 and case10. Fewer computational grid nodes were presented in case15 and case10,  
 606 which required less time for calculation, and the computational efficiency could be  
 607 further improved. The advantages of using IM-DBCM based on multi-grids for flood  
 608 simulations are evident. The difference in total runtime between the IM-DBCM and  
 609 OM-DBCM is the time spent on mesh generation. In the OM-DBCM, the

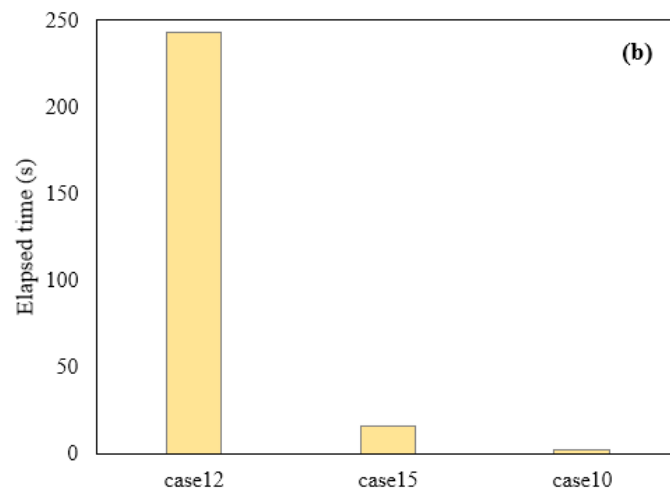

610 computational domain is divided manually, which is highly subjective, and the  
611 computational time varied from person to person.

612 However, there was not a significant difference in the computation time among  
613 case12, 15 and 10. The calculation time for coarse grids is shown in Figure 13(b). It is  
614 observed that the runtime for coarse grids decreases rapidly in different cases. In case12,  
615 case15 and case10, the number of coarse grids is 42517, 7425, and 2153, respectively.  
616 As the number of coarse grids decreased significantly, the runtime for these grids also  
617 decreased rapidly. The number of fine grids is consistent in case12, case15, and case10,  
618 with a calculation time of 4800s. The fine grids number is much greater than that of the  
619 coarse grids, especially in case15 and case10. The 2D hydrodynamic model was solved  
620 in the fine-grid regions, which cost more computation time compared with the coarse  
621 grids where the hydrologic model was applied. The calculation time for fine grids is  
622 significantly longer than that for coarse grids, comprising a substantial portion of the  
623 overall execution time.

624 In many watersheds, the 2D inundation regions account for a minor proportion of  
625 the total watershed area. The fine grids were employed to partition the small inundation  
626 regions, while the coarse grids were utilized to discretize the majority of the non-  
627 inundation regions. The computational efficiency can be significantly enhanced due to  
628 the smaller proportion of fine grids and larger proportion of coarse grids. In the IM-  
629 DBCM, the 1D rivers and 2D inundation regions were not distinguished, resulting in  
630 their division using fine grids. Consequently, the 2D hydrodynamic model was applied  
631 to both regions, leading to an increased computational time. In future studies, the 1D  
632 hydrodynamic model will be used to compute the flood evolution specifically in the 1D  
633 rivers, leading to a reduction in computational time. Hence, the computational  
634 efficiency advantages of the proposed IM-DBCM are more pronounced.

 638 and IM-DBCM; (b) the runtime for coarse grids

639 **4 Conclusions**

640 An improved dynamic bidirectional coupled hydrologic-hydrodynamic model  
 641 based on multi-grid (IM-DBCM) was presented in this study. A multi-grid system was  
 642 generated based on the  $D_\infty$  algorithm, dividing regions that required high-resolution  
 643 representation using fine grids and the rest using coarse grids to reduce computational  
 644 load. A two-dimensional non-linear reservoir was adopted in the hydrologic model,  
 645 while two-dimensional shallow water equations were applied in the hydrodynamic  
 646 model. The hydrologic model was applied to the coarse-grid regions, whereas the  
 647 hydrologic and hydrodynamic models were coupled in a bidirectional manner for the

648 fine-grid areas. Different time steps were adopted in coarse and fine grids. Ghost cells  
649 and bilinear interpolation were used to interpolate variables between coarse and fine  
650 grids. The hydrologic and hydrodynamic models were dynamically and bidirectionally  
651 coupled with a time-dependent and moving coupling interface.

652 The performance of IM-DBCM was verified using three cases. The IM-DBCM  
653 was demonstrated to effectively simulate flow processes and ensure reliable simulation.  
654 Compared with the OM-DBCM, the results obtained from the IM-DBCM were well  
655 aligned with the measured data, and it could reliably reproduce the flood wave  
656 propagation in complex topography. In addition to producing numerical results with  
657 similar accuracy, the IM-DBCM saved computational time compared with the model  
658 on fine grids. Furthermore, a moving coupling interface between the hydrologic and  
659 hydrodynamic models was observed in the IM-DBCM. The IM-DBCM has both high  
660 computational efficiency and numerical accuracy, which was adapted adequately to the  
661 real-life flooding process and provided practical and reliable solutions for rapid flood  
662 prediction and management, especially in large watersheds.

663 The IM-DBCM accurately and efficiently reproduces the flooding process and has  
664 the potential for a wide range of practical applications. The hydrologic model considers  
665 only surface runoff, which is appropriate for the intense rainfall-induced flood events  
666 examined in this study. However, a complete hydrologic model should include surface  
667 flow, interflow, and underground runoff. In future works, the interflow and  
668 underground runoff could be calculated in the hydrologic model.

#### 669 **Data availability**

670 Model simulation and calibration data are available upon request from the  
671 corresponding author. Digital elevation model data are provided by the Geospatial Data  
672 Cloud at <http://www.gscloud.cn>. The data sets of Soil Properties and Land cover are

673 provided by Sánchez (2002) and Blackmarr (1995). The rainfall and measured data  
674 were Blackmarr (1995).

#### 675 **Author contributions**

676 Yanxia Shen designed the methodology and carried out the investigation. Qi Zhou  
677 provided the original model input data. The study was supervised by Chunbo Jiang.  
678 Yanxia Shen prepared the first draft of the manuscript and Zhenduo Zhu revised and  
679 improved the original manuscript.

#### 680 **Competing interests**

681 The authors declare that they have no conflict of interest.

#### 682 **Acknowledgements**

683 This study was supported by the National Natural Science Foundation of China  
684 (Grant No. 52179068) and the Key Laboratory of Hydrosience and Engineering (Grant  
685 No. 2021-KY-04). The authors thank the anonymous reviewers for their valuable  
686 comments.
