33 **Abstract.** The 21st June 2019 Raikoke eruption (48°N,153°E) generated one of the largest amounts of sulfur emission
34 to the stratosphere since the 1991 Mt Pinatubo eruption. Satellite measurements indicate a consensus best estimate of
35 1.5 Tg for the sulfur dioxide (SO₂) injected at an altitude of around 14-15 km. The peak northern hemisphere mean
36 525nm Stratospheric Aerosol Optical Depth (SAOD) increased to 0.025, a factor of three higher than background
37 levels. The Volcano Response (VolRes) initiative provided a platform for the community to share information about
38 this eruption, which significantly enhanced coordination efforts in the days after the eruption. A multi-platform
39 satellite observation sub-group formed to prepare an initial report to present eruption parameters including SO₂
40 emissions and their vertical distribution for the modelling community. It allowed to make the first estimate of what
41 would be the peak in SAOD one week after the eruption using a simple volcanic aerosol model. In this retrospective
42 analysis, we show that revised volcanic SO₂ injection profiles yield a higher peak injection of the SO₂ mass. This
43 highlights difficulties in accurately representing the vertical distribution for moderate SO₂ explosive eruptions in the
44 lowermost stratosphere due to limited vertical sensitivity of current satellite sensors (+/- 2 km accuracy) and low
45 horizontal resolution of lidar observations. We also show that the SO₂ lifetime initially assumed in the simple aerosol
46 model was overestimated by 66%, pointing to challenges for simple models to capture how the life cycle of volcanic
47 gases and aerosols depends on the SO₂ injection magnitude, latitude and height. Using revised injection profile,
48 modelling results indicate a peak northern hemisphere monthly mean SAOD at 525nm of 0.024, in excellent agreement
49 with observations, associated with a global monthly mean radiative forcing of -0.17 W/m² resulting in an annual global
50 mean surface temperature anomalies of -0.028 K. Given the relatively small magnitude of the forcing, it is unlikely
51 that the surface response can be dissociated from surface temperature variability.

52 **1. Introduction.**

53 After 95 years of dormancy, the Raikoke volcano in the Kuril Islands (North-West Pacific; 48.292°N, 153.25°E)
54 began a series of explosions at 18UTC on 21 June 2019 lasting around 24 hours. Raikoke forms a small uninhabited
55 Island of 2 km x 2.5 km which belongs to the Russian federation, 16 km from Matua Island in the Sea of Okhotsk.
56 Its name originates from the ancient Japanese Ainu language and translate to “hellmouth” referring to past volcanic
57 eruptions. The first eruption reports of Raikoke originated from the mid-18th century but it was during the 1788
58 eruption that one third of the Island was destroyed (Gorshkov, 1970). The last known eruption was reported in
59 February 1924. Since then, the volcano remained dormant. The volcano is monitored by the Sakhalin Volcanic
60 Eruption Response Team (SVERT) part of the Institute of marine geology and the Kamchatka Volcanic Eruption
61 Response Team (KVERT). During the latest 2019 eruption, the first explosion of a series of 8 was reported by
62 KVERT on 21 June at 17h50 UTC and quickly followed 1h later by a volcanic ash advisory produced by the Tokyo
63 Volcanic Ash Advisory Center (VAAC) responsible to provide ash warnings to the International Civil Aviation
64 Organization (ICAO) across the Pacific Northwest (Sennert, 2019). In addition, KVERT and SVERT issued red
65 warnings for aviation. As a result, nearly 40 flights were re-routed to avoid volcanic ash clouds.

66 Firstov et al., (2020) analyzed Infrasound Signal (IS) from ground stations in Kamchatka and found a total of 11
67 explosive episodes (see Fig.1a). The first 8 episodes were followed by a continuous episode (9) which lasted for 3.5
68 h. Based on IS analysis, episodes are separated into magma fragmentation/ non-stationary processes and vent

69 outflow (1,2,3,7,9 and 10) of ash-gas into the atmosphere. They were used to derive a minimal eruption tephra
70 volume of 0.1 km³ allowing to categorize the eruption as Volcanic Explosivity Index (VEI) 4 (Firstov et al., 2020).
71 Fig1b shows cloud top temperature (11µm) and associated cloud top heights derived from Himawari-8 geostationary
72 satellite compared with IS data shown in Fig. 1a. The eruption started at around 18:00 UTC on 21 June 2019
73 followed by at least 8 discrete “bursts” (eruptions) and continuous emissions. A further two discrete pulses occurred
74 later. The IS analysis coincides very well with the Himawari-8 observations where each IS corresponds to the
75 release of volcanic cloud into the atmosphere. Muser et al. (2020) used one-dimensional volcanic plume models
76 (Mastin, 2007; Folch et al., 2016) to invert the mass eruption rate of ash and initialize the ICON-ART (Zängl et al.,
77 2015) dispersion model to investigate the complex aerosol, dynamical and radiative processes governing the plume
78 evolution. More simplistic initialization approach with the dispersion model NAME (Beckett et al., 2020) and the
79 aerosol-chemistry-climate model WACCM (Mills et al., 2016) were performed during the VolRes activities shortly
80 after the eruption to assess the early dispersion of the plume.

81 As part of the scientific response to the eruption, the Volcano Response (Volres) initiative triggered an initial
82 dialogue among the science community. VolRes is an international working group, within the Stratospheric Sulfur
83 and its Role in Climate (SSiRC) to establish co-operation and community planning, for the next large-magnitude
84 eruption, aligned also to the NASA initiative for US-based volcano response plan (Carn et al., 2021). The SSiRC
85 initiative is itself an activity within the SPARC project of the World Climate Research Program (WCRP). Since its
86 inception in 2015, VolRes consist of more than 250 scientists worldwide, from a diverse range of both model and
87 observational experts, aiming to contribute from sharing and discussion of information related to the atmospheric
88 impacts of volcanoes. Discussion and sharing to the mailing list is maintained through an archive and Wiki page,
89 structured by eruption since 2018 (<https://wiki.earthdata.nasa.gov/display/volres²>).

90 The discussions on the VolRes forum have mostly been focused towards: i) establishing initial estimates of the
91 emitted SO₂ and ash, and injection heights estimates from multiple satellite observation platforms; ii) the expected
92 impacts on stratospheric aerosol loadings; iii) factors to consider in modelling the aerosol cloud, towards then
93 projecting radiative and climate effects; and iv) common related findings after other similar eruptions. Several cross-
94 institutional co-operations resulted from the VolRes activity, which also motivated the Raikoke ACP/AMT/GMD
95 inter-journal special issue “Satellite observations, in situ measurements and model simulations of the 2019 Raikoke
96 eruption “. The Raikoke special issue includes a series of publications (Muser et al., 2020; Kloss et al., 2021;
97 Vaughan et al., 2021; de Leeuw et al., 2021; Horváth et al., 2021a,b; Gorkavyi et al., 2021; Inness et al., 2022;
98 Mingari et al., 2022; Osborne et al., 2022; Bruckert et al., 2022; Capponi et al., 2022; Cai et al., 2022; Harvey et al.,
99 2022; Knepp et al., 2022; Prata et al., 2022; Petracca et al., 2022) focusing on the atmospheric impacts of this
100 eruption using satellite Low Earth Orbiting/Geostationary nadir and limb observations from UV-Visible to far IR,
101 model simulations, airborne measurements and ground-based lidar observations.

102 The goals of this paper is to:

- 103 • Describe the activities undertaken by the Volcano Response group (VolRes,
104 <https://wiki.earthdata.nasa.gov/display/volres/Volcano+Response>) at the time of the 2019 Raikoke eruption. A

- 105 chronology of these activities is provided in Table 2.
- 106 • Give an overview of the early estimates of the mass of SO₂ emitted as well as the associated radiative forcing
107 and temperature response inferred quickly after the eruption.
 - 108 • Discuss how revised estimates of SO₂ mass and plume heights as well as radiative forcing estimates differ from
109 the rapid assessment made a week after the eruption.
 - 110 • Summarize the findings of the Raikoke special issue and highlight the remaining science questions as well as
111 the challenges associated with rapid response to volcanic eruptions in the context of atmospheric impacts.

112 **2. Satellite Datasets**

113 **HIMAWARI-8**

114 Himwari-8 is a spacecraft developed and operated by the Japanese Meteorological Organization (JAXA). The
115 primary instrument aboard Himawari 8 is the Advanced Himawari Imager (AHI), a 16 multi-channel spectral
116 imager to capture visible light and infrared images of the Asia-Pacific region at 500m horizontal resolution and
117 every 10 minutes. AHI is used to derived the cloud-top temperature and associated cloud top height associated with
118 the Raikoke eruption.

119 **TROPOMI**

120 The TROPospheric Monitoring Instrument (TROPOMI), on board the Sentinel-5 Precursor satellite provides
121 atmospheric composition measurements (Veeffkind et al., 2012) at high spatial resolution of 3.5 x 5.5 km².
122 TROPOMI is a hyperspectral sounder with different spectral bands from the ultraviolet (UV) to the short-wave
123 infrared. TROPOMI provides nearly global coverage in one day at 1.30 pm local time. For a rapid assessment of the
124 total emitted SO₂ mass, the operational SO₂ product (Theys et al., 2017) was used. A refined analysis was then
125 performed with the scientific SO₂ layer height and vertical column joint retrieval of Theys et al.(2022)

126 **IASI**

127 The Infrared Atmospheric Sounding Interferometer (IASI) is the high spectral resolution infrared sounder onboard
128 the operational Metop A-B-C platforms. With a morning and evening overpass (around 9:30 AM and PM),
129 combined with a large swath, the instrument samples the entire globe twice a day. Its footprint is a 12km diameter
130 circle at nadir viewing angles, gradually increasing to a 20 km x 39 km ellipse at the far end of its swath. The SO₂
131 product that was used for rapid assessment is the one detailed in Clarisse et al. (2014). The retrieval algorithm
132 consists of two steps. First a so-called Z function that is estimated for each observed spectrum, using a set of
133 derivatives (Jacobians) with respect to the SO₂ partial columns at varying altitudes. The altitude at which Z function
134 reaches is maximum is the retrieved SO₂ height. In a second step, the estimated SO₂ height is used to constrain the
135 IASI SO₂ column retrieval. Note that the entire retrieval uses the 7.3 μm absorption band of SO₂, which is less
136 affected by ash than the 8.6 μm band. While the altitude algorithm has a general accuracy better than 2 km, it is
137 known to underestimate the SO₂ altitude for high SO₂ columns. For the refined analysis discussed below, a new
138 experimental product was used that deals better with saturation issues.

139 **Aqua/AIRS**

140 The atmospheric Infrared Radiation Sounder (AIRS) instrument is on board the NASA polar-orbiting Aqua satellite
141 at an altitude of about 705 km above the Earth surface with an Equatorial crossing time at 1.30am/pm local time
142 (Chahine et al., 2005; Prata & Bernardo, 2007). AIRS provides nearly continuous measurement coverage during
143 14.5 orbits per day and a 95% global daily coverage with a swath of 1650 km and special resolution of 13.5 km x
144 13.5 km at nadir (Tournigand et al., 2020). We use the version 7.0 AIRS level 2 Support Retrieval product, and the
145 results are averaged into 1° x 1° grid cells in this analysis. The brightness temperature difference (less than -6 K) is
146 used as a proxy of SO₂ released from volcanoes.

147 **CALIPSO/CALIOP**

148 The Cloud-Aerosol Lidar with Orthogonal Polarization (CALIOP), on board the Cloud-Aerosol Lidar and Infrared
149 Pathfinder Satellite Observations (CALIPSO) platform, has been providing aerosol vertical profile measurements of
150 the Earth's atmosphere on a global scale since June 2006 (Winker et al., 2010). We use the version 4.21 CALIOP
151 level 2 Aerosol layer and Cloud layer products and only quality screened samples are used in the analysis. Aerosol
152 layers with Cloud Aerosol Discrimination (CAD) score less than -100 or greater than -20 are rejected to avoid low
153 confidence in cloud-air discrimination. Aerosol layers with the extinction Quality Control (QC) flag that are not
154 equal to 0, 1, 16, and 18 are rejected to remove low confidence extinction retrievals, and aerosol extinction samples
155 with the extinction uncertainty equal to 99.99 km⁻¹ and all samples at lower altitudes in the profile are rejected to
156 remove unreliable extinctions (Winker et al., 2013).

157 Firstov et al., (2020) analyzed Infrasound Signal (IS) from ground stations in Kamchatka and found a total of 11
158 explosive episodes (see Fig.1a). The first 8 episodes were followed by a continuous episode (9) which lasted for 3.5
159 h. Based on IS analysis, episodes are separated into magma fragmentation/ non-stationary processes and vent
160 outflow (1,2,3,7,9 and 10) of ash-gas into the atmosphere. They were used to derive a minimal eruption tephra
161 volume of 0.1 km³ allowing to categorize the eruption as Volcanic Explosivity Index (VEI) 4 (Firstov et al., 2020).
162 Fig1b shows cloud top temperature (11µm) and associated cloud top heights derived from Himawari-8 geostationary
163 satellite compared with IS data shown in Fig.1a. The eruption started at around 18:00 UTC on 21 June 2019
164 followed by at least 8 discrete “bursts” (eruptions) and continuous emissions. A further two discrete pulses occurred
165 later. The IS analysis coincides very well with the Himawari-8 observations where each IS corresponds to the
166 release of volcanic cloud into the atmosphere. Muser et al. (2020) used one-dimensional volcanic plume models
167 (Mastin, 2007; Folch et al., 2016) to invert the mass eruption rate of ash and initialize the ICON-ART dispersion
168 model to investigate the complex aerosol, dynamical and radiative processes governing the plume evolution. More
169 simplistic initialization approach with the dispersion model NAME and the aerosol-chemistry-climate model
170 WACCM were performed during the VolRes activities shortly after the eruption to assess the early dispersion of the
171 plume.

172

173 **4. Early reports of injection parameters one week after the eruption**

174 One of the main activities of a satellite sub-group formed within the framework of VolRes was to derive eruption
175 parameters characterizing SO₂ emissions (e.g. mass, bulk height, injection profiles) so that modelers would run
176 numerical simulations to understand the potential hazards and climate impacts of this eruption. The basic approach
177 to estimate the total mass of SO₂ is similar for each satellite-based sensor. First, the process involves retrieving the
178 Vertical Column Density (VDC, measured in molecules cm⁻² or g m⁻² or Dobson units) in each pixel affected by
179 SO₂, followed by multiplying by the area of the pixels and integrating all the pixels to calculate the total SO₂
180 loadings. However, there are limitations to this method. Indeed, narrow swath width sensors, timing of the polar
181 orbit and, in the case of the geostationary sensors, extreme viewing geometry (high satellite zenith angles) and
182 movement out of the field of view will introduce errors (likely underestimations) of the total mass. There are also
183 many assumptions used by the various algorithms that if not valid will introduce errors, as will discussed hereunder.
184 When the Vertical Column Densities (VCDs) are large (>500 DU) most algorithms have difficulty estimating the
185 VCD correctly (Hyman and Pavolonis, 2020; Prata et al. 2021). Figure 2 shows the time evolution of the total SO₂
186 mass during and after the Raikoke eruption from multiple sensors. The measurements discussed here all assume SO₂
187 in the UTLS (7–12 km). The SO₂ retrieved from Himawari-8 peaks near 1.5 Tg nearly 48h after the beginning of the
188 eruption and follow similar temporal evolution than the one derived from LEO. Given the likelihood that most
189 satellites underestimated the SO₂ mass, we chose at that time the maximum value from Himawari and the upper
190 limits of the other sensors yielding a 1.5+/-0.2 Tg estimation. IASI, TROPOMI and CALIPSO data suggested that
191 SO₂ was injected within a large altitude range from the ground up to well in the stratosphere (at least 15 km). In
192 addition to a total mass of SO₂ (of 1.5 Tg), the VolRes team also issued a provisional vertical distribution of the
193 emitted SO₂ mass that could be used by dispersion and climate modelers. To do so, IASI SO₂ height measurements
194 on the 22nd June 2019 were used. The mass-altitude indicated that most SO₂ was released between 8-12 km with a
195 secondary peak around 14-15 km. Scaled to the proposed 1.5 Tg, the distribution is shown in Figure 3 and is referred
196 to as the ‘VolRes profile’ (blue line; also see Table 1). For TROPOMI, and other LEOs, the plume can be partly
197 covered by a given orbit but using the multiple orbits of one day and the fact that they generally overlap most of the
198 plume is covered. To avoid double counting, the data of one full day are usually averaged on a regular latitude-
199 longitude grid, before the actual emitted SO₂ mass is calculated. An important source of error is the vertical
200 distribution of SO₂. In Fig.2, the retrieved SO₂ mass from TROPOMI was calculated by assuming a bulk plume
201 height of 15 km (all plume heights given above sea level unless specified). This assumption can introduce errors
202 (underestimation) in particular for clear-sky scenes and if the SO₂ is in the (lower) troposphere, typically below
203 7km, see e.g., Fig 1 of Theys et al. (2013). TROPOMI has less limitations in retrieving very large SO₂ columns
204 (>500 DU) because in that case the spectral range used (360-390nm) is weakly affected by saturation due to non-
205 linear SO₂ absorption (Bobrowski et al., 2010). The main problem is the presence of aerosols which are not
206 explicitly treated in the retrievals (Theys et al., 2017). For ash, the photons cannot penetrate deep in the volcanic
207 cloud (only the cloud top layer is sensed) and this leads to a strong underestimation of the mass of SO₂ (by a factor
208 of 5 or so).

209 **5. Revision and improvements of injection parameters.**

210 While the accuracy of the IASI SO₂ height retrievals is typically better than 2km, it became clear however that the
211 VolRes profile was peaking too low in the atmosphere (e.g., de Leeuw et al., 2021). The main reason for this is related
212 to the SO₂ Jacobians used in the retrieval. These are precalculated for relatively low SO₂ VCDs and are not directly
213 applicable to saturated plumes, as encountered during the Raikoke eruption. Refinement of the IASI algorithm to
214 better account for this dependence on the SO₂ loadings has led to SO₂ injection profile with a maximum SO₂ peaking
215 at ~14-15 km (see Figure 3) and a slightly lower total mass of ~1.3 Tg SO₂ (even though total mass estimates for the
216 days after reach again 1.5 Tg and higher).

217 As an alternative to IASI, ultraviolet observations from the TROPOMI nadir sensor have been used to estimate the
218 SO₂ injection profile (Table 1). Conceptually, the retrieval algorithm is like the IASI scheme. It relies on an iterative
219 approach making use of a SO₂ optical depth look-up-table, where both SO₂ height and vertical column are retrieved
220 jointly (Theys et al., 2021). The accuracy of the retrieved SO₂ heights is of 1-2 km, except when coincident with fresh
221 and optically thick ash plumes for which the estimated heights can be strongly biased low. Because of this, the first
222 reliable profile from TROPOMI which covers the full plume, is for the 24 June 2019. The maximum SO₂ height is
223 found at ~11-12 km (Figure 3) and the total mass derived is of ~1.2 Tg SO₂. However, the total mass is likely
224 underestimated because only the pixels with confident SO₂ height retrievals are considered (typically for SO₂ columns
225 > 5DU). Selected examples of retrieved SO₂ heights from the two instruments are illustrated in Figure 4.

226 Although the estimated SO₂ mass from IASI and TROPOMI agree well, the estimated SO₂ profiles show rather
227 inconsistent results with a discrepancy of about 3km for the SO₂ bulk height. It should be emphasized that SO₂ height
228 retrieval from nadir sensors is challenging in general but for Raikoke in particular. The retrievals and their
229 interpretation might also suffer from different aspects. For instance, the UTLS was characterized by isothermal
230 temperature profiles, which can lead to errors on the IASI height estimates. In addition, the measurement sensitivity
231 is different in the ultraviolet than in the thermal infrared and depends on the way the photons interact with the volcanic
232 cloud (and the constituents other than SO₂). In this respect, the retrieved SO₂ heights must be considered as effective
233 heights. Moreover, few CALIOP observations were available (see Section 6) for evaluating the results for the early
234 stage of the eruption.

235 Despite these challenges, our injection profiles estimates are not in contradiction with results found in the literature:

- 236 • Kloss et al. (2021) reported a 14 km altitude plume height based on an early OMPS aerosol extinction profile,
237 on 22 June 2019.
- 238 • Muser et al. (2020) derived typical altitudes of 8-14 km from MODIS and VIIRS cloud top height retrievals.
- 239 • By slightly adapting (assuming higher injection heights) the VolRes profile, de Leeuw et al. (2021) found
240 the best match between modeled and TROPOMI SO₂ columns for an injection profile with most of SO₂
241 between 11 and 14 km.
- 242 • Hedelt et al. (2019) reported SO₂ heights similar to the TROPOMI results shown here, i.e., with the bulk
243 height below 13km.

- 244 • SO₂ height retrievals from the Cross-track Infrared Sounder (CrIS) instrument (Hyman & Pavolonis, 2020)
245 are consistent with plume heights as high as 14-17 km in the plume center, but also show that most of the
246 SO₂ mass was emitted under 13 km.
- 247 • Geometric estimation of Raikoke ash column height suggests injection mainly between 5 and 14 km and an
248 overshooting cloud up to 17 km (Horváth et al., 2021b).
- 249 • MLS data for 23-27 June indicates SO₂ plumes at 11 to 18 km with maximum columns observed around 14
250 km (Gorkavyi et al., 2021).
- 251 • Using a Lagrangian transport model combined with TROPOMI and AIRS, Cai et al. (2022) reconstruct an
252 emission profile with a peak at 11 km with a large spread from 6 to 14 km.
- 253 • Prata et al. (2022) found ash clouds at a maximum height of 14.2 km (median height of 10.7 ± 1.2 km) during
254 the main explosive phase.

255 **6. New plume injection analysis derived from CALIPSO and AIRS**

256 CALIPSO observations were made publicly available within 24-48 h after the beginning of the eruption allowing
257 accurate early estimates of the height of downwind plume sections. However, due to the narrow swath of the lidar (a
258 few hundred meters) and consequently low horizontal resolution, they may not completely represent the entire
259 plume vertical distribution. Nevertheless, an overpass of the CALIPSO lidar across the plume on 22 June 2019 at
260 2.15 am, ~600 km east from the volcano within an SO₂ cloud observed by OMPS show volcanic layers between 9-
261 13.5 km (Prata et al., 2021). A second overpass the next day depicts another volcanic layer between 15-16 km.
262 Those observations were used to validate SO₂ emission profiles provided to the community a week after the
263 eruption. Here, we give a more comprehensive analysis of the plume injection height using a combination of quasi-
264 collocated (less than 1h apart) SO₂ observations from AIRS and detected volcanic layers from CALIOP during the
265 first two weeks after the eruption. The brightness temperature difference ($1361.44-1433.06$ cm⁻¹) is used as a proxy
266 of SO₂ released from volcanoes to identify CALIOP data within the SO₂ plume.

267 We combined SO₂ information from AIRS quasi-collocated observations from CALIOP to further investigate plume
268 injection heights after the Raikoke eruption assuming that SO₂ and volcanic aerosols remained collocated in space
269 and time during the first 10 days after the eruption. Figure 5 shows a map of SO₂ derived from AIRS together with
270 CALIOP orbit tracks (red). The corresponding cloud and aerosol level 2 V4.2 products are plotted along with BT
271 extracted along the orbit. All corresponding layers (clouds and aerosols) associated with negative BT (<6 K),
272 indicating the presence of SO₂ in the atmospheric column, have been further analyzed to distinguish the volcanic
273 plume. The distinction is based on the diagram of depolarization and color ratio shown in panel d. Figure 5 shows
274 that CALIOP intersected the plume along two orbit tracks on 25 June. The first being along the 17h53 UTC orbit
275 near 60°N and at two occasions between 55°N-65°N along the second orbit near 14h36 UTC. The first intersection
276 shows the plume near 9-11 km with weak particulate DePolarization Ratio (DPR) ($DPR < 0.2$) and particulate
277 CoLor Ratio (CLR) near 0.5. DPR values suggest a mixture of ash and sulfate aerosols. However, the second
278 intersection of the plume shows higher DPR near 0.3 and the same CLR than the first indicating a higher fraction of
279 ash particles resulting in increased DPR values. During those observations, two distinct plumes are visible between

280 the northern intersection near 11-13 km (green color on diagrams) and a piece at higher altitude (13-15 km) further
281 south (<60°N). We visually inspected all CALIOP observations (day and night) between 06/22 and 07/06 following
282 the same approach and used plume identification criterion when DPR < 0.4 and CLR < 0.7 and altitude > 5 km to
283 remove tropospheric aerosols and ice clouds. Because of the enhanced noise of the daytime observations, we chose
284 to focus this analysis on nighttime data only. Figure 6 shows the daily observations of the Raikoke plume since the
285 eruption and during the following two weeks. We note that the plume was observed by CALIOP from 8 km to 17
286 km. The cumulative Probability Density Function (pdf) suggests two main peaks, one near 10-11km km and another
287 smoother peak near 13-15 km. The overall aerosol vertical distribution is consistent with the distribution of SO₂
288 profiles derived with different approaches and instruments just after the eruption (Fig.3). However, the pdf does not
289 suggest a pronounced peak at a given altitude but rather a flatter distribution as opposed to what is shown in Figure
290 3. The pdf does not account for or is not weighted by the aerosol loading which may explain why we do not see a
291 pronounced peak as for the SO₂ profiles derived from IASI and TROPOMI. In addition, SO₂ and volcanic aerosol
292 layers are assumed to be collocated but it may not always be the case.

293 **7. Rapid projections of the aerosol forcing and the global mean surface temperature response.**

294 In the previous sections, we discussed in detail the methods used to derive injection parameters (SO₂ total mass,
295 plume heights and SO₂ distribution) which served as input to estimate the radiative and surface temperature
296 responses from the eruption in this section. Key metrics characterizing the climate effects of volcanic eruptions are
297 the peak global mean mid-visible SAOD, the global mean net radiative forcing and the global mean surface
298 temperature change. One motivation of the VolRes initiative is to provide an estimated magnitude for each of these
299 metrics. In the case of a large-magnitude eruption, these initial indicators of the scale of the climate response would
300 then help to determine whether resources should be directed towards additional measurement campaign and the
301 forcing datasets enable the community to run seasonal and decadal forecasts (Müller and Smith, 2018).

302 The first estimates of the injected SO₂ mass and height became available 24-48 hours after the 2019 Raikoke
303 eruption, followed one week later by an estimate of global mean peak SAOD (7.1), radiative forcing (7.2) and
304 surface temperature (7. 3). This section discusses: i) how these estimates were made; ii) how they compared to
305 observations; and iii) ongoing improvements to the protocol for rapid projection of volcanic forcing and climate
306 impact.

307 **7.1 Model simulations of aerosol optical properties**

308 We first made projections for SAOD on 25 June 2019 using EVA_H (Aubry et al., 2020), a simple volcanic aerosol
309 model based on inputs of the mass of volcanic SO₂ injected, its injection height, and the latitude of an eruption. The
310 first estimates made following Raikoke used a range of injection heights between 10-20 km, and a range of the mass
311 of SO₂ of 1-2 Tg of SO₂, on the basis of first estimates of 14 km and 1.5 Tg of SO₂ that initially circulated on the
312 VolRes mailing list (personal communication from Taha Ghassan and Lieven Clarisse). The corresponding
313 simulated range in peak Northern Hemisphere (25°N-90°N, NH) monthly-mean SAOD at 525nm (SAOD₅₂₅) was
314 0.015-0.023 (Figure 7). This range was obtained using Monte Carlo methods, i.e. EVA_H was run thousands of

315 times randomly resampling the range of injection height and mass. The negligible computational cost of simple
316 models like EVA_H is a key advantage for providing estimate of the volcanic SAOD perturbation and its
317 uncertainties as soon as measurements of the SO₂ mass and its injection height become available. The SAOD
318 perturbation was projected to be largely confined to 25-90°N (Figure 8). SAOD perturbations observed in the tropics
319 and Southern Hemisphere over 2019-2020 (Figure 8) are primarily driven by stratospheric emissions from the
320 Ulawun 2019 eruptions and the Australian 2019-2020 wildfires (Kloss et al., 2021).

321 Following the communication of the initial VolRes SO₂ profile (Figure 3) through the VolRes mailing list, EVA_H
322 peak NH monthly-mean SAOD₅₂₅ estimate for Raikoke were revised to an even smaller value of 0.014. Compared to
323 observations from GloSSAC (v2.1) (Kovilakam et al., 2020), this value was largely underestimated as GloSSAC NH
324 monthly-mean SAOD₅₂₅ peaks at 0.025 (Figure 7, with GloSSAC in excellent agreement with observational values
325 from Kloss et al., 2021) using OMPS-limb data. The new IASI June 22 profile presented in Figure 3 results in a
326 higher peak NH monthly-mean SAOD₅₂₅ of 0.0175, with the higher proportion of stratospheric SO₂ in the new
327 profile more than compensating for the total mass decreasing from 1.5 to 1.29 (average of the two IASI profiles) Tg
328 of SO₂. Although the new SO₂ emission profile improves agreement with observations, the estimated SAOD₅₂₅
329 value is still a substantial underestimate. Furthermore, the characteristic rise and decay timescales of the SAOD₅₂₅
330 perturbation are also overestimated by EVA_H (Figure 7). These mismatches are caused by the constant timescale
331 EVA_H uses for SO₂ to sulfate aerosol conversion, which is biased towards an 8-month value adequate for the
332 Pinatubo 1991 eruption (Aubry et al, 2020). If we decrease the value of this timescale by 66% to 2.8 month in
333 EVA_H, the NH peak SAOD value as well as the characteristic rise and decay timescale of the SAOD perturbation
334 are in excellent agreement with observations for the 2019 Raikoke eruption (Figure 7). The fact that this model
335 timescale is independent of the eruption characteristic is an already identified weakness of EVA_H that will be
336 addressed in future developments (Aubry et al., 2020). This timescale has indeed been shown to depend on the
337 volcanic SO₂ mass (e.g. McKeen et al., 1984; Carn et al, 2016), injection altitude and latitude (e.g. Carn et al, 2016,
338 Marshall et al. 2019) as well as co-emission of water vapor (Legrande et al., 2016) and volcanic ash (Zhu et al.,
339 2022).

340 **7.2 Projection for global mean volcanic forcing**

341 On the same day that SAOD projections were initially provided, Piers Forster independently suggested via the
342 VolRes mailing list (Forster, personal communication) that the global annual-mean net radiative forcing would be at
343 most -0.2 W m⁻² based on a scaling between the estimated SO₂ mass of 1.5 Tg SO₂ for 2019 Raikoke and the
344 estimated 15-20 Tg SO₂ for the 1991 Mt. Pinatubo eruption, which resulted in a global annual-mean forcing of -3.2
345 W/m² in 1992. This projection was a back-of-the-envelope calculation using simple proportionality arguments and it
346 did not rely on any SAOD estimates. A monthly global mean peak shortwave forcing with a range from -0.16 to
347 -0.11W/m² was derived from SAGE III observations (Kloss et al., 2021). The corresponding annual mean net
348 forcing is expected to be much smaller because of the difference between the peak monthly NH mean SAOD and its
349 average value over the first post-eruption year (Figure 7), as well as the fact that longwave stratospheric volcanic

350 aerosol forcing can offset as much as half of the shortwave forcing (Schmidt et al. 2018). Altogether, the educated
351 guess made for global annual mean radiative forcing was thus likely overestimated.

352 **7.3 Projection of the global mean surface temperature response**

353 Last, as part of the eruption response, one day after the first global annual-mean radiative forcing estimate of 0.2 W
354 m⁻² was made, we estimated that the peak global annual-mean surface temperature change would be -0.02 K (Figure
355 9). We obtained this estimate using FaIR, a simple climate model (Smith et al., 2018). Like EVA_H, FaIR has a
356 negligible computational cost enabling rapid estimates of global-mean surface temperature change following an
357 eruption and facilitating uncertainty estimation, although the latter was not done for the 2019 Raikoke eruption. The
358 model-projected surface temperature response cannot be compared to measurements owing to difficulties in
359 disentangling such a small forced temperature response from temperature variations related to natural variability.

360 **8. Discussions**

361 The Raikoke eruption ended a period without moderate volcanic eruptions in the Northern Hemisphere since Nabro
362 in 2011 (Bourassa et al., 2013, Fairlie et al., 2014; Sawamura et al., 2012) which injected 1.5-2 Tg of SO₂ partially
363 distributed between the troposphere and stratosphere. Following the Nabro eruption, the role deep convection during
364 the Summer Asian Monsoon was evoked to explain an apparent ascent of the plume (Bourassa et al., 2013) debated
365 by others (Fromm et al., 2013, Vernier et al., 2013) based on initial observations of injection heights. The substantial
366 debate provoked by this eruption clearly demonstrated the complexity of assessing accurately SO₂ injection heights
367 and their partition relative to the tropopause. The VolRes initiative substantially helps fill those gaps by providing a
368 coordinated structure to derive injection parameters after the Raikoke eruption. Multiple sensors were used to assess
369 the total SO₂ mass and its distribution just one week after the eruption (Fig.3). However, the lack of vertically
370 resolved SO₂ information remains a limitation to accurately assess SO₂ plume distribution and the revised estimates
371 proposed here remain with a 2 km uncertainty regarding the exact position of the plume peak while the initial 1.5 Tg
372 SO₂ mass estimate might be slightly overestimated. Advances in measuring SO₂ with lidar observations may fill
373 those gaps in the future.

374 The VolRes team provided eruptive parameters within a week after the eruption that strongly helped modelers to
375 estimate climate response of the Raikoke eruption. The use of simple models like EVA_H and FaIR to project the
376 climate response to an eruption in almost near real-time is a powerful way to generate first-order estimates of the
377 perturbations to SAOD, and surface temperatures. Unlike simple proportionality arguments based on the Pinatubo
378 1991 eruption, these models can estimate the time (and spatial, for EVA_H) evolution of the response variable, and
379 they account for complexities such as the dependency of SAOD on the SO₂ injection latitude and height. Their
380 computationally inexpensive nature also enables a comprehensive quantification of uncertainties related to eruption
381 source parameters, which are often poorly constrained in the days-months following an eruption as highlighted by
382 this special issue, as well as uncertainties on parameters of these empirical models, such as the SO₂-aerosol
383 conversion timescale in EVA_H (Figure 7).

384 One limitation of the application of these models following the Raikoke 2019 event is that they were not applied in
385 concordance, i.e. FaIR was run using an expert guess for the radiative forcing instead of values derived from
386 EVA_H's SAOD estimates (see section 7.2 and 7.3). Following the Raikoke 2019 VolRes response, we combined
387 the simple models EVA_H (for aerosol forcing) and FaIR (for surface temperature response). To do so, we apply
388 simple linear (Schmidt et al., 2018) or exponential (Marshall et al., 2020) relationships to derive the global mean
389 radiative forcing (FaIR's key input) from the global mean SAOD (one of EVA_H's outputs). EVA_H, SAOD-
390 radiative forcing scalings, and FaIR were for example applied in concordance to estimate the climate impacts from
391 the sulfate aerosols of the January 2022 Hunga Tonga-Hunga Ha'apai eruption. These models have been combined
392 into a single dedicated webtool called Volc2Clim (Schmidt et al., 2023), publicly available at
393 <https://volc2clim.bgs.ac.uk/>. Applied to Raikoke 2019 using the new injection profile (Figure 3) and revised SO₂ to
394 sulfate aerosol conversion timescale, the beta version of Volc2Clim projected peak global mean of 0.008, -0.17
395 W/m² and -0.028 K for monthly mean SAOD, monthly mean radiative forcing and annual mean temperature
396 anomaly. In addition to key metrics discussed in this section such as global mean SAOD, radiative forcing and
397 surface temperature, aerosol optical properties field (dependent on latitude, altitude and wavelength) are outputted
398 by Volc2Clim for use in climate models that do not have an interactive stratospheric aerosol scheme. With a webtool
399 for rapid estimation of the global climate response during an eruptive crisis, we hope to support communication
400 amongst the scientific community (including VolRes), with authorities and with the public, which in turn will help
401 to mitigate potential consequences arising from the climate effects of an eruption.

402 Although Volc2Clim offers new perspectives for rapid response and communication following volcanic eruptions,
403 the simplified nature of the models at its core currently do not allow projections of effects related to co-emission of
404 species such as water vapor or halogen in volcanic plumes, or PyroCumulonimbus (PyroCbs) plumes. Before and
405 after the Raikoke eruption, three significant events affected stratospheric aerosols. Indeed, SO₂ injected from the
406 June an August 2019 Ulawun eruptions and smoke from PyroCbs in Canada made the Raikoke eruption even more
407 challenging to understand. The PyroCbs in Canada produced smoke in the UTLS one week before the eruption, but
408 the transport patterns of smoke and volcanic aerosols have been distinct (Osborne et al., 2022) and the likelihood for
409 both plumes to mix is relatively small. The Ulawun eruption injected SO₂ which remained relatively confined in the
410 Southern Hemisphere, but we cannot rule out that both plumes got mixed in the tropics (Kloss et al., 2021). The
411 relatively small amount of SO₂ injected by Ulawun (< 0.1 Tg) was not considered in the estimates provided in this
412 paper. Another interesting feature observed after the Raikoke eruption was the formation of a distinct plume which
413 rose into the stratosphere. The plume formed a vortex circulation which remained coherent for several weeks
414 (Gorkavyi et al., 2021) rising in the stratosphere of 10 km over the course of 2-3 months. While this plume shared
415 similar optical properties to smoke, Knepp et al. (2022) concluded that this layer was mostly composed of large
416 sulfuric acid droplets but did not refute the possible presence of a fine ash component. More recently (Khaykin et al,
417 2023) found that 24% of the total SO₂ mass was contained in the volcanic vortex with a confined anticyclonic
418 circulation detected by wind doppler lidar from Aeolus. A warm anomaly of 1 K was also evident GPS RO Cosmic
419 data demonstrating that the heating of the plume was indeed responsible for its internal circulation and maintenance.
420 Moreover, the properties of the plume observed by CALIOP showed the persistence of ash that likely induced

421 internal heating in the plume consistent with earlier observations of volcanic clouds after the Kelud and Puyehue-
422 Cordon eruptions (Jensen et al., 2018; Vernier et al., 2013, 2016). While the presence of fine ash in the Raikoke
423 could likely explained the maintenance of the vortex as observed after PyroCbs events but with a much faster ascent
424 rate, the interplay between ash and sulfate and influence on radiative calculations is still not understood (Vernier et
425 al., 2016; Stenchikov et al., 2021; Zhu et al., 2020). In addition, we cannot fully rule out that remnants of smoke
426 from the PyroCbs in Canada one week before the eruption could have played a role in the transport of the plume.
427 The increased lifetime of this plume may have produced a larger climate impact than expected since this effect is not
428 included in the simple model provided in this paper (Figure 8).

429 Finally, the recent eruption of Hunga Tonga Hunga Ha'apai demonstrated that sub-marine eruption can inject
430 significant amount of H₂O in the stratosphere (Milan et al., 2022, Vogel et al., 2022; Sellitto et al., 2022) which is
431 known to have oppositive cooling climate effects than sulfate aerosol. The water vapor can reduce the lifetime of
432 SO₂ by providing OH radicals and affect aerosol size distribution through condensational growth (Zhu et al., 2022).
433 Such effects are not included in the simple climate estimates provided here and would limit its applicability in the
434 case of HTHH if only the climate impacts of sulfate aerosols are considered.

435 **9. Conclusion**

436 VolRes is an international coordinated initiative to study the atmospheric impacts of volcanic eruptions, now
437 involving more than 250 researchers worldwide. The 2019 Raikoke eruption triggered significant responses by the
438 VolRes community through exchanges of information via the mailing list and the preparation of SO₂ profile
439 recommendations for modelers made available a week after the eruption only. Our paper gives a brief overview of
440 how the community responded to this volcanic eruption, which is documented extensively in the Raikoke special
441 issue. We then described how early estimates of SO₂ emission and height, a fundamental parameter which dictates
442 the plume lifetime and its impacts, were derived from satellite observations. These estimates were used by VolRes to
443 calculate SAOD, radiative forcings and surface temperature changes as part of the initial eruption response. We
444 revisited the initial SO₂ injection profiles by addressing saturation effects due to high SO₂ column density to
445 improve plume injection heights. We highlight remaining challenges in accurately representing the vertical
446 distribution for moderate- SO₂ explosive eruptions in the lowermost stratosphere due to limited vertical sensitivity of
447 current satellite sensors (+/- 2 km accuracy) and low horizontal resolution of lidar observations. We found that using
448 revisited SO₂ injection heights and reduced SO₂-aerosol conversion timescale in a simple volcanic aerosol model
449 (EVA_H) improves SAOD estimates relative to available observations from the GloSSAC dataset. The protocol for
450 fast estimation of aerosol optical properties, radiative forcing and surface temperature response to volcanic eruption
451 has since been implemented in a seamless webtool (Volc2Clim, <https://volc2clim.bgs.ac.uk/>). The computationally
452 inexpensive nature of the webtool makes it ideal for rapid assessment of the volcanic climate effect and for
453 propagating large uncertainties that characterize early observations of volcanic clouds. Further development of the
454 underlying simple models as well as continued use of complex models explicitly modelling aerosol chemistry,
455 microphysics and transport remain critical given the complex nature of volcanic events. For example, the Raikoke
456 eruption took place in connection with two eruptions of Ulawun in June and August 2019 and just after a PyroCb

457 event which transported smoke into the stratosphere which were not considered in our original or revised
458 calculations. In addition, the recent HTHH eruption demonstrated that water vapor can also be injected into the
459 stratosphere which can affect SO₂ and aerosol lifetime but also with a radiative forcing that is opposite to volcanic
460 sulfate aerosols.

 824 **(continuous colored lines) and observed (GloSSAC v2.1, black dashed line). The light blue shading and line**
 825 **shows the first projection made at the time of the eruption and its confidence interval based on an injection**
 826 **height of 15+/-5km and SO₂ mass of 1.5+/-0.5 Tg. The yellow line shows the second projection made at the**
 827 **time of the eruption using the VolRes IASI initial profile. The orange line shows a new projection using the**
 828 **new VolRes IASI June 22 profile presented in this study (Figure 3). The violet line uses the same profile, but**
 829 **the SO₂-to-aerosol conversion timescale in EVA_H reduced by 66%.**

Date	Data type	Activities	Data variables	Platform	Add. Information
06/24	Satellite	SO2 and plume height maps 06/24 & 06/25	SO2 total column (DU) and concentration (ppmv ?)	TROPOMI/Sentinel 5P	Polar Orbit/ESA
06/24	Satellite	Aerosol maps and profiles when ?	Aerosol extinction (km-1)	NPP/OMPS	Polar Orbit/NASA
06/25	Satellite	SO2 maps 06/21 & 06/22	SO2 total column (DU)	Metop/IASI	Polar Orbit/Eumetsat
06/25	Satellite	Ash and SO2 total column	Ash signature (11-12 um) and SO2 UTLS (VCD DU)	AHI/HIMAWARI-8	Geo Orbit/JAXA
06/25	Satellite	Plume heights and optical properties	Backscatter and depolarization at 532 and 1064 nm	CALIOP/CALIPSO	Polar Orbit/NASA
06/25	Satellite	Maps of plume height and properties 06/23	Height (km) and AOD, angstrom coeff, SSA	MISR/Terra	Polar Orbit/NASA
06/25	Model	Volcanic plume maps at 100 and 140 hPa	Aerosol extinction at XX nm	WACCM	Model type
06/25	Model	Impacts on stratospheric aerosol	Stratospheric AOD	GEOS-5	
06/26	Satellite	Mass distribution profile on 06/23	Mass per levels (kt)	TROPOMI/Sentinel 5P	Polar Orbit/ESA
06/26	Satellite	SO2 plume vertical information	SO2 mixing ratio (ppbv)	MLS/Aura	Polar Orbit/ESA
06/26	Model	Radiative and climate impacts	RF TOA (w/m2)	??	
06/28	Model	Trajectory simulation of Raikoke dispersion	Plume height (km)	Langley Trajectory Model	GEOS-5 wind data
07/03	Satellite	Plume height and properties	Backscatter and depolarization at 532 and 1064 nm	CALIOP/CALIPSO	Polar Orbit/ESA
07/09	Model	SO2 and ash plume dispersion 06/21 to 06/25	Ash and SO2 mass concentration	ICONN-ART	
07/10	Ground-based lidar	Vertical plume profiles 07/05	Scattering ratio at 532 nm	OHP/LTA	
07/10	Satellite	Plume height and properties	Backscatter and depolarization at 532 and 1064 nm	CALIOP/CALIPSO	Polar Orbit/NASA
07/10	Satellite	Latitudinal time series	Aerosol extinction (km-1)	NPP/OMPS	NASA
07/16	Satellite	Animation of aerosol maps at 12.5 km, 13.5 km, 14.5 km and 16.5 km across the NH. 06/11 to 07/14	Aerosol extinction (km-1)	OMPS/NPP	Polar Orbit/NASA
07/17	Ground-based lidar	Volcanic aerosol profiles 06/29 and 07/08	RSC 1064 nm	SIRTA	
07/19	Satellite	Maps of SO2 centered in Indonesia/Australia (from 06/26 to 07/12), Ulawun eruption	SO2 DU	TROPOMI/Sentinel 5P	Polar Orbit/ESA
07/20	Satellite	Animation of aerosol maps at 18.5 km from 06/27 to 07/17	Aerosol extinction (km-1) at 674 nm	OMPS/NPP	Polar Orbit/NASA
07/21	Ground-based lidar	Volcanic aerosol profiles on 07/18 and 07/20	Scattering Ratio at 532 nm	OHP LTA	
08/07	Satellite	Animation of aerosol maps at 20.5 km	Aerosol extinction (km-1) at 674 nm	OMPS/NPP	Polar Orbit/NASA
08/24	Satellite	Volcanic plumes cross-section 11-20 Aug 2019	Scattering Ratio at 532 nm	CALIOP/CALIPSO	Polar Orbit/NASA
09/04	Balloon	Aerosol concentration profiles on 08/26 in Wyoming	Aerosol concentration for r>0.005 um, 0.092, 0.15, 0.28	Balloon	WOPC
09/17	Ground-	Atmospheric profiles of aerosols and	Backscatter profiles at 532 nm	Lidar LOA
