**Abstract.** The tectonic evolution of rift basins can strongly influence the petrophysical properties of its sedimentary infills at various scales and, therefore, influence the characteristics of present resources. Understanding the tectonic evolution of a rift basin is therefore decisive, as it can have consequences for the parameters that influence the planning of geothermal doublets. In this framework, this study gives a detailed interpretation of the syn- and post-rift episodes in the West Netherlands Basin, since Jurassic times. Despite multiple studies on the geotectonic setting of the West Netherlands Basin, a detailed understanding of its syn- and post-rift phases in the context of geothermal exploration is still fundamentally lacking. With a renewed interpretation of a seismic 3D cube, covering a large portion of the onshore section of the basin, we identified two important Jurassic rifting episodes and one Cretaceous inversion event. Rifting caused compartmentalisation of the main producing geothermal target in the area; the Late Jurassic Nieuwerkerk Formation. Yet, the central portions of the half-grabens show good potential for geothermal exploration. Subsequent inversion could have caused local breaching of the aquifer, forming a potential risk. Therefore, only non to moderately inverted areas should be considered for geothermal exploration. This study provides a better understanding of the multi-phase rifting history in the West Netherlands Basin, providing important constraints on the reservoir-seal integrity and with that, the amount of heat that can be safely produced from a geothermal reservoir rock. Aiming to contribute to the energy transition, this study provides an integrated picture of the West Netherlands Basin and shows how a basin’s geological history can affect its geothermal resources.

## 1 Introduction

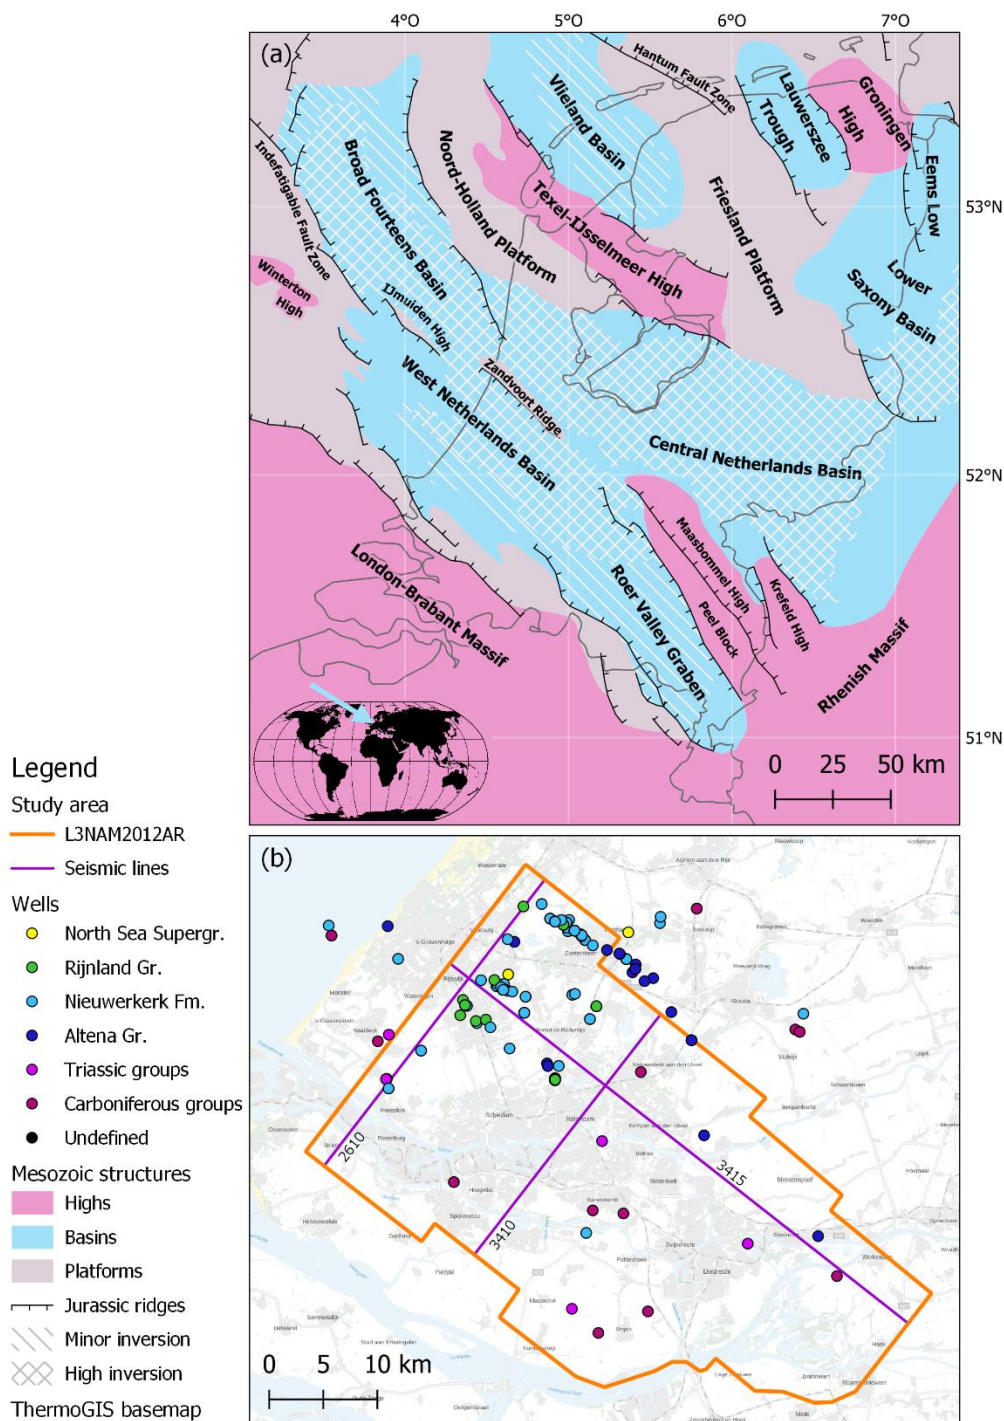

Subsurface fluid flow systems hosted in rift basins can form part of the resources that are indispensable in the global challenge to cut greenhouse gas emissions and cover current and future needs with sustainable energy sources. Basins’ bounding faults and the laterally and vertically varying characteristics of sedimentary basins’ fills control the distribution, abundance and

recoverability of these resources (Gawthorpe and Leeder, 2000), including the heat flow needed for high ( $T > 150^{\circ}\text{C}$ ) to low ( $T < 90^{\circ}\text{C}$ ) enthalpy geothermal systems (Carapezza et al., 2022). As a frontrunner in Europe, the Netherlands recognizes the contribution of geothermal energy to be crucial for a successful energy transition (e.g. Kramers et al., 2012; Willems and Nick, 2019; Mijnlief, 2020).

35 The West Netherlands Basin (WNB) (Fig. 1a) is a former prosperous hydrocarbon province where the interest changed to geothermal energy in the past decade. Having an energy-demanding greenhouse horticulture, a dense population, which includes the cities of Rotterdam and The Hague, and an average geothermal gradient of  $31^{\circ}\text{C km}^{-1}$  (Bonté et al., 2012), the WNB is considered one of the best case studies for low-enthalpy geothermal exploration (Kramers et al., 2012; Croijmans et al., 2016; Willems et al., 2017b; Willems, 2017; Vondrak et al., 2018; Willems and Nick, 2019; Willems et al., 2020; Boersma et al., 2021). With the hydrocarbon exploitation in the WNB, an extensive data collection was gathered (e.g. seismics and well data), publicly available at [nlog.nl](http://nlog.nl) (e.g. Duin et al., 2006; Kombrink et al., 2012). Up to 2023, 14 geothermal doublets (i.e. cold-water injection and hot-water production wells) were realised in the area (Geothermie Nederland, 2023), targeting aquifers hosted by the post-rift Cretaceous Rijnland Group, syn-rift Jurassic Nieuwerkerk Formation and pre-rift Triassic Buntsandstein. Financial budgets for geothermal projects are much tighter than for traditional hydrocarbon exploration, making exploration risks hardly affordable. Therefore, understanding of the key parameters used for the planning of geothermal systems is decisive. Despite the wealth of mentioned datasets and studies, research is still needed to leverage such results and to increase the feasibility of geothermal systems. Aquifer thickness and heterogeneity is one of the key parameters, influencing the injectivity and doublet life time (Willems et al., 2020).

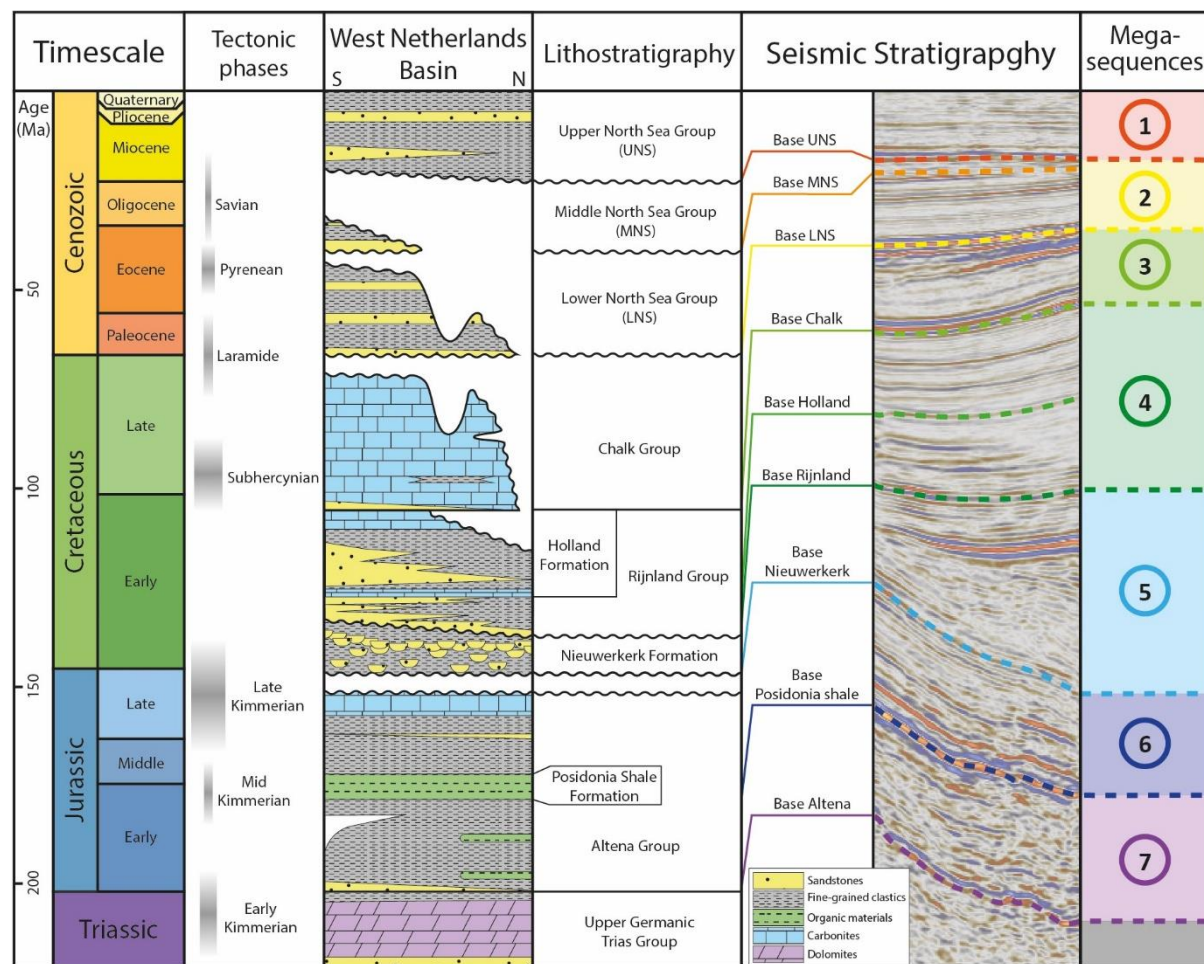

40 Presently, the main target for geothermal exploration in the WNB is the Jurassic Nieuwerkerk Formation (Willems et al., den 2017b; Vondrak et al., 2018). This formation was interpreted as deposited in a fluvial-deltaic environment during the main rifting phase that shaped the basin, resulting in sharp lateral thickness and facies variations (van Wijhe, 1987; den Hartog Jager, 1996; Willems et al., 2020). Post-rift Late Cretaceous and Cenozoic inversion (e.g. van Wijhe, 1987; van Balen et al., 2000; de Jager, 2003; Deckers and van der Voet, 2018), together with the basin's rifting history (van Wijhe, 1987), could have controlled the architecture of the main rift phase, making the reconstruction of the Jurassic tectono-sedimentary sequence, and therefore the thickness of its reservoir rocks, not straightforward.

This work focuses on: 1) the tectonic evolution of the WNB, 2) the development of its syn-rift infill and the fault activation, and 3) reactivation within the basin. Using a public dataset, including 3D seismics and well data, we reconstruct the main subsurface structures of the study area and document multiple rifting phases that are followed by basin inversion. Consequently, we discuss the implications of our interpretation in the framework of the geothermal systems in the WNB.

**Figure 1:** (a) Map of the Netherlands, showing the main structural elements during Jurassic times with the areas affected by the subsequent inversion marked. The seismic 3D cube is displayed in orange. This map was produced by combining the maps from Wong et al. (2007) & Kombrink et al. (2011). (b) Map of the study area, highlighted in orange, showing all used wells and the seismic cross sections presented in figures 3, 4 and 5.

**Figure 2: Lithostratigraphic chart, showing the timing of tectonic events, simplified stratigraphy of the studied section of the West Netherlands Basin, age of key horizons, and typical seismic stratigraphy for the study area. Stratigraphic column adapted from van Adrichem Boogaert & Kouwe (1993) & Jeremiah et al. (2010) and the timing of tectonic events adjusted from Wong et al. (2007) with the results from this study.**

70

## 2 Geological framework

The West Netherlands Basin (WNB) is a NW-SE elongated basin in the western sector of the onshore Netherlands (Fig. 1a). The WNB developed above a former Paleozoic basin, forming part of the Southern Permian Basin, and partly retraces its structural trend (e.g. Ziegler, 1992; van Balen et al., 2000; Michon et al., 2003; Worum et al., 2005). Break-up of Pangea marks the onset of E-W oriented extension in NW Europe by the start of the Mesozoic (e.g. Ziegler, 1992). Regionally, the Triassic is characterised by uplift due to the Early Triassic Hardegsen tectonic phase (Geluk et al., 1996) and the Late Triassic Early Kimmerian tectonic phase (Geluk and Röhling, 1997). An Early Jurassic faulting phase is also recognized in the area, causing

75

differential subsidence in the basin's various subunits (van Balen et al., 2000). Followed by a Middle Jurassic uplift, referred  
80 to as the Mid Kimmerian tectonic phase (Herngreen et al., 2003).

Yet, despite the above documented phases, Late Permian to Middle Jurassic times are generally considered to be part of the  
pre-rift stage within the WNB (e.g. den Hartog Jager, 1996; Racero-Baena and Drake, 1996; van Balen et al., 2000; Vondrak  
et al., 2018; Willems et al., 2020). The WNB, characterised by horst and graben structures, is considered to be Late Jurassic  
(Kimmeridgian) to Late Cretaceous (Barremian), wherefore this period is marked as the syn-rift phase (van Wijhe, 1987; den  
85 Hartog Jager, 1996; de Jager, 1996; Racero-Baena and Drake, 1996; Vondrak et al., 2018). In particular, the WNB developed  
during several discrete pulses of short duration from which the strongest phase occurred during the Late Jurassic, recognized  
as the Late Kimmerian tectonic phase (van Wijhe, 1987; de Jager, 1996; Racero-Baena and Drake, 1996; van Balen et al.,  
2000). The rifting resulted in the fragmentation of the WNB in several sub-basins, where local differential subsidence resulted  
in large thickness variations within the Late Jurassic basin infill. After the conclusion of the rifting phases by the Albian, the  
90 WNB entered a post-rift subsidence phase (van Wijhe, 1987), until basin inversion, spanning from the Late Cretaceous to the  
Miocene (e.g. Ziegler, 1992; de Jager, 2003; Worum and Michon, 2005; Deckers and van der Voet, 2018; Kley, 2018).

The Late Permian to Cenozoic sedimentary succession of the WNB, described in detail in van Adrichem Boogaert and Kouwe  
(1993) and TNO-GDN (2023), starts with the Late Permian Zechstein Group, which does not include evaporites in the study  
area. This group is overlain by the clastic Triassic Under-Germanian Group, which includes the Volpriehausen, Detfurth and  
95 Hardeggen formations. On top, the Middle to Late Triassic Upper-Germanian Group is made of mixed carbonates and  
(silici)clastics. Our seismic interpretation starts with the overlying Early to Middle Jurassic Altena Group (Fig. 2), which is  
primarily composed of shallow-marine clays, but also carbonates and sandstones. The Altena Group includes the Posidonia  
Shale Formation, which forms a key seismic reflector. In the study area, the overlying Late Jurassic-Early Cretaceous Schieland  
Group includes only the Nieuwerkerk Formation, which is one of the main targets for geothermal exploration in the WNB (see  
100 above). It is characterised by lateral thickness variations associated with extensional faulting, and includes sandstones and  
shales that are both vertically stacked and laterally interfingered. Above, is positioned the Cretaceous Rijnland Group, which  
includes the Vlieland Subgroup and Holland Formation. The clastics of the Vlieland Subgroup were deposited in a  
transgressional setting that turned into a shallow to deep marine environment in which the carbonate and siliciclastic sediments  
of the Holland Formation were deposited. The Late Cretaceous carbonates of the Chalk Group were deposited in a shallow  
105 marine environment during the main inversion phase. The Cenozoic succession is known as the North Sea Supergroup,  
composed of the clastics of the Lower, Middle and Upper North Sea Groups (e.g., van Adrichem Boogaert and Kouwe, 1993;  
Duin et al., 2006).

### 3 Data and methods

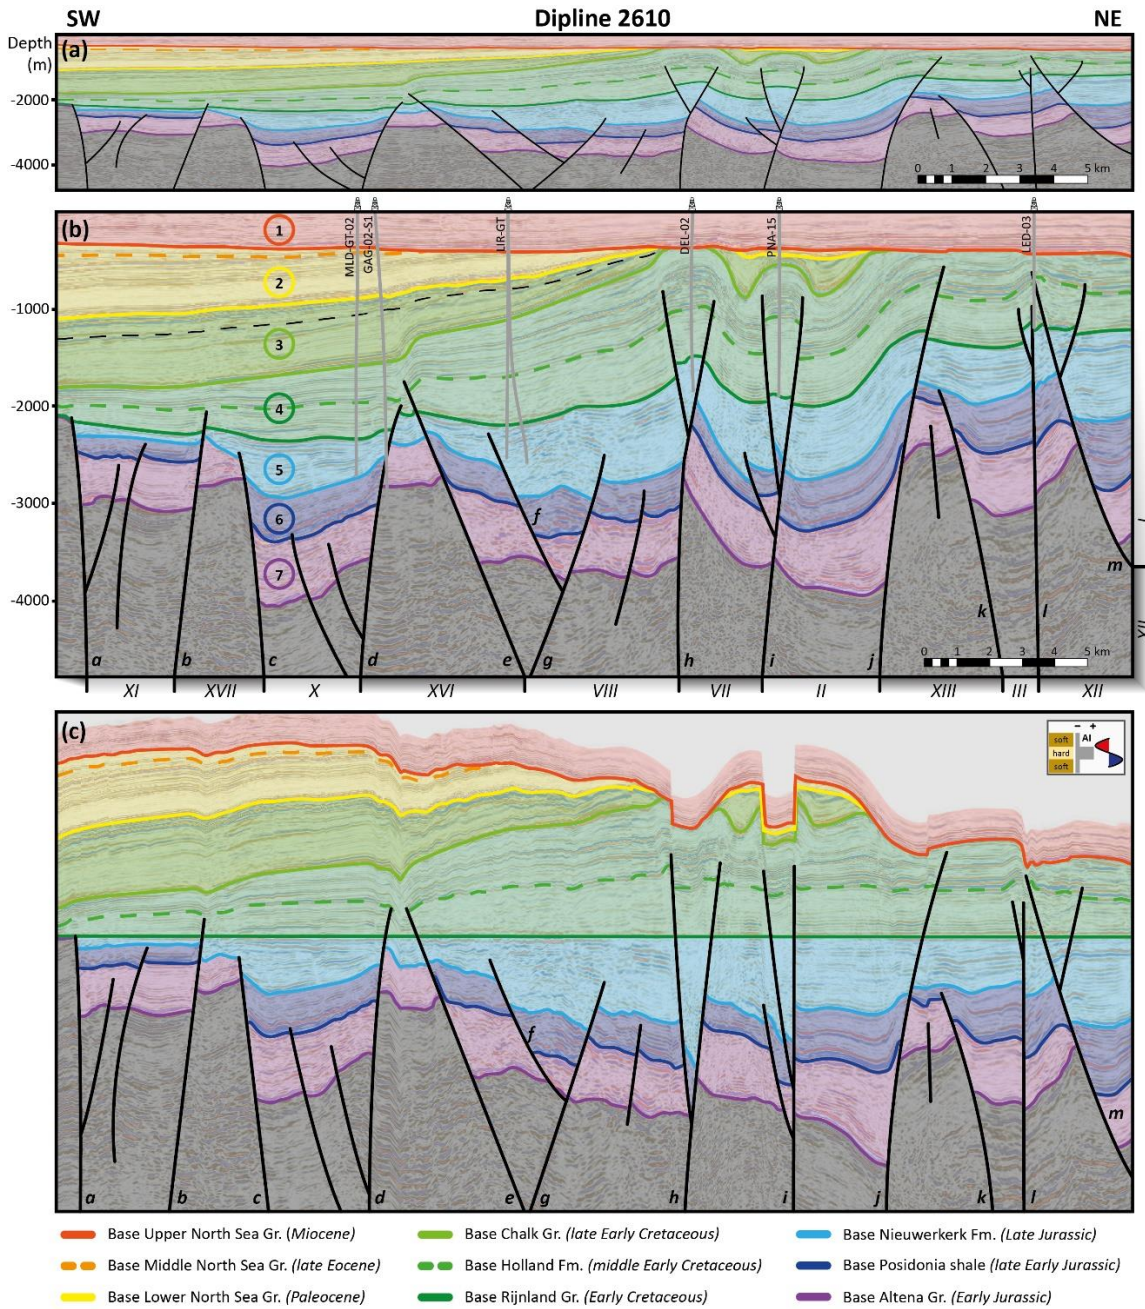

This study uses the L3NAM2012AR seismic 3D depth cube and well data (Fig. 1b), publicly available on nlog.nl, along with  
110 technical information (including data and procedure for depth conversion) about the survey. The seismic coverage has a surface

area of roughly 1300 km<sup>2</sup>, with 2678 dielines (2500-5178) and 1714 strikelines (2273-3987), penetrating to a depth of 6 km. The 3D cube was depth reprocessed and converted by Shell in 2011, using 59 wells for the depth conversion. We will use the depth converted version of this seismic cube, as the velocity cube is not publicly available. Additional wells are available, from which we have used a total of 94 inside and 31 closeby the study area, with a maximum depth of 4 km, and the deepest drilled  
115 formation being the Carboniferous Limburg Group.

Interpretation is done using Petrel 2020.3 software. We have followed the well-established workflow for interpretation of seismic datasets in extensional settings (e.g. O’Sullivan et al., 2022), which involves a reconstruction of the seismic stratigraphy by integrating well data with the identification of different seismic facies, unconformities, and brightly marked reflective horizons. In detail, 9 horizons were interpreted for the whole 3D cube. Such a 3D interpretation has allowed us to  
120 identify the major faults of the basin and produce thickness maps of the syn-rift deposits, shedding light on the tectono-sedimentary evolution of the single sub-basins. For the horizon interpretation, seismic to well tie was achieved by using the available well tops provided by TNO on nlog.nl. For each horizon, a grid of 25 dielines x 25 strikelines was made using a guided approach (guided autotracking + seeded 3D tools of Petrel). A continuous checking of the geological consistency of the interpretation was carried out during the interpretation, by considering the seismic facies of the mapped horizons and the  
125 occurrence of regional unconformities, as seen in Figure 2.

In detail, the bases of the Cenozoic Upper, Middle and Lower North Sea Groups, the base of the upper Cretaceous Chalk Group, the bases of the lower Cretaceous Holland Formation and Rijnland Group, the base of the upper Jurassic Nieuwerkerk Formation, the Posidonia Shale Formation and the base of the Altena Group were mapped (Fig. 2). Those horizons were selected either for their easily recognizable seismic facies or for their structural appearance (e.g. unconformities). The results  
130 section will describe 2 dielines and 1 strikeline that are considered representative for all structures found in the seismic 3D cube (Figs. 3-5). Also, 6 thickness maps and a depth map will be discussed (Fig. 6). The thickness maps were produced in Petrel by computing the difference in elevation between the base of the overlying package and the base of the package itself. Although such a difference is not the actual thickness, given the horizons are characterised by very gentle dip (mostly less than 5°), it represents a reliable proxy. Exceptions are those areas of steeply dipping layers associated with tight folds. Also, the  
135 difference in elevation returns artefacts across faults, in which the top and bottom horizons are located in the hanging wall and footwall, respectively. Those two exceptions are recognisable in maps as narrow ribbons of anomalous thickness values, mostly overlapping the major faults.

140 **Figure 3: Dipline 2610 displayed with three different scales; (a): 1:1 scale, displayed with the interpreted horizons, megasequences**  
**and faults; (b): 1:3 scale, displayed with the interpreted horizons, megasequences and faults, together with projected wells and the**

## 4 Results

### 4.1 Seismic sections

Here we present two SW-NE sections oriented perpendicular to the main trend of faults affecting the WNB, and one section oriented NW-SE (Fig. 1b). Up to the top of the Triassic, the stratigraphic succession can be divided into 7 megasequences, here described from top to bottom. For each section, we present a 1:1 and 1:3 vertically exaggerated interpreted lines, along with a 1:3 vertically exaggerated one, flattened for the base of the Rijnland Group. The non-interpreted sections can be found in the Supplementary Materials.

#### 4.1.1 Dipline 2610

Dipline 2610 (Fig. 3) is located on the NW edge of the study area (Fig. 1b). The section is crosscutting the Pijnacker (PNA-15) and Rijswijk (DEL-02) abandoned oil fields, and the Gaag (GAG-02-S1) and the De Lier (LIR-GT wells) producing gas fields. The Leidschendam (LED-03) abandoned gas field and two producing geothermal energy projects (MLD-GT-02 & LIR-GT wells) are nearby.

The first megasequence is positioned between the top of the seismic cross-section and the base of the Upper North Sea Group. The package is characterised by sub-horizontal reflectors and an evident erosional surface at the bottom, forming an angular unconformity and toplap surface. Megasequence 2 is found beneath this erosional surface, towards the SW. This megasequence is eroded in the NE part of the section and contains the Middle and Lower North Sea Groups. To the SW, the package is slightly tilted, dipping a few degrees towards the SW. An unconformable contact divides megasequences 2 and 3. In detail, towards the SW, reflectors of megasequence 2 and 3 are parallel to each other, whereas in the Westland Graben (structure VIII, Fig. 3b), an erosional unconformity is dividing them (the unconformity is also found in the well PNA-15). Megasequence 3 is composed of the Chalk Group, which is thinning towards the NE. Around well PNA-15 we observe two growth synclines capped by the unconformity with the overlying megasequences 1 and 2. The upper part of this megasequence is locally divided from the central and lower ones by an unconformity (dashed black line, Fig. 3b). The apparent NE-ward thinning of this megasequence is mostly due to the erosional surface that marks the base of megasequence 1. The underlying megasequence 4 comprises the Rijnland Group. Oppositely to megasequences 2 and 3, this package is thinning towards the SW and it is affected by synclines and fault-cored anticlines, across which no remarkable thickness changes are observed, as illustrated in the flattened section (Fig. 3c). Despite some local anomalies (associated with the flattening procedure and the presence of faults) the flattened profile shows that megasequence 4 has a regional thinning, which does not change across the faults and folds. It is worth mentioning that none of the major faults seen in the section propagates across the upper portion of megasequence 4, leaving the first 3 megasequences un-faulted. Megasequence 5, which corresponds to the Nieuwerkerk Formation, is characterised by abrupt thickness changes across the numerous faults affecting the megasequence. Below, megasequence 6, composed of the upper part of the Altena Group and based by the Posidonia Shale Formation, is characterised by parallel

reflectors and thickness variations related to erosion atop structural highs. Last, megasequence 7, comprising the lower part of the Altona Group, displays both parallel reflectors and a few growth geometries at fault-bounded sub-basins.

180 The seismic line crosses 12 major faults. Some of them display normal offsets, while others show normal offset in the lowermost tracts and reverse displacement in the upper portions, which is a diagnostic feature of fault inversion (Williams, 1989). All major faults affect the megasequences 5 to 7, whereas only those showing evidence of positive inversion propagate into megasequence 4. As previously mentioned, megasequences 1 to 3 are basically un-faulted. In detail, faults labelled *a* to *d*, define horst and graben structures. In the graben structures, megasequence 5 is characterised by half-grabens, whereas in  
185 the horst the thickness of megasequences 5 to 7 is strongly reduced. None of these faults show remarkable evidence of inversion and the lowermost part of megasequence 4 seals all of them. Faults *e* and *h* bind a pop-up structure resulting from the inversion of these two former normal faults and the uplift of the previous sub-basin depocenter. Faults *f* and *g*, which show no evidence of inversion, were part of the array of extensional faults within this depocenter. In detail, the inversion of the SW boundary fault *e* caused fault-propagation-folding registered by “contractional” growth strata in megasequence 3. Inversion of the NE  
190 boundary fault *h* was accompanied by the development of an antithetic fault, forming a second-order pop-up structure that is affecting megasequence 4. To the NE, fault *i* is SW-dipping and syn-sedimentary with respect to megasequence 5. Its inversion is accompanied by the development (or inversion) of two conjugate NE-dipping faults and produces another second-order pop-up structure, whose development is recorded by growth geometries in megasequence 3. Fault *j* displays evidence of positive inversion and, more importantly, bounds a semi-graben (the Voorburg Graben, structure II, Fig. 3b) in which megasequence 7  
195 displays clear evidence of growth-wedge geometry. The NE-dipping fault *k* is also bounding a semi-graben (the Zoetermeer Graben, structure III, Fig. 3b) in which both megasequence 5 and 7 are characterised by thickness variations. Accordingly, the fault has been active during the deposition of megasequences 5 and 7. It is worth mentioning that it has not been reactivated during inversion. Last, fault *l* is NE-dipping and has been active during deposition of megasequence 5. It is slightly inverted as suggested by the gentle anticline deforming megasequence 4. Apart from the clear evidence of fault inversion (i.e. reverse  
200 offset) folding of reflectors both in the hanging- and footwalls of some faults (e.g. in the footwall of fault *l* or in the hanging wall of faults *e* and *k*), reveals possible buttressing effect upon inversion (i.e. folding and second order faulting of the hanging wall and footwall without slip reversal along the master fault).

#### 4.1.2 Dipline 3410

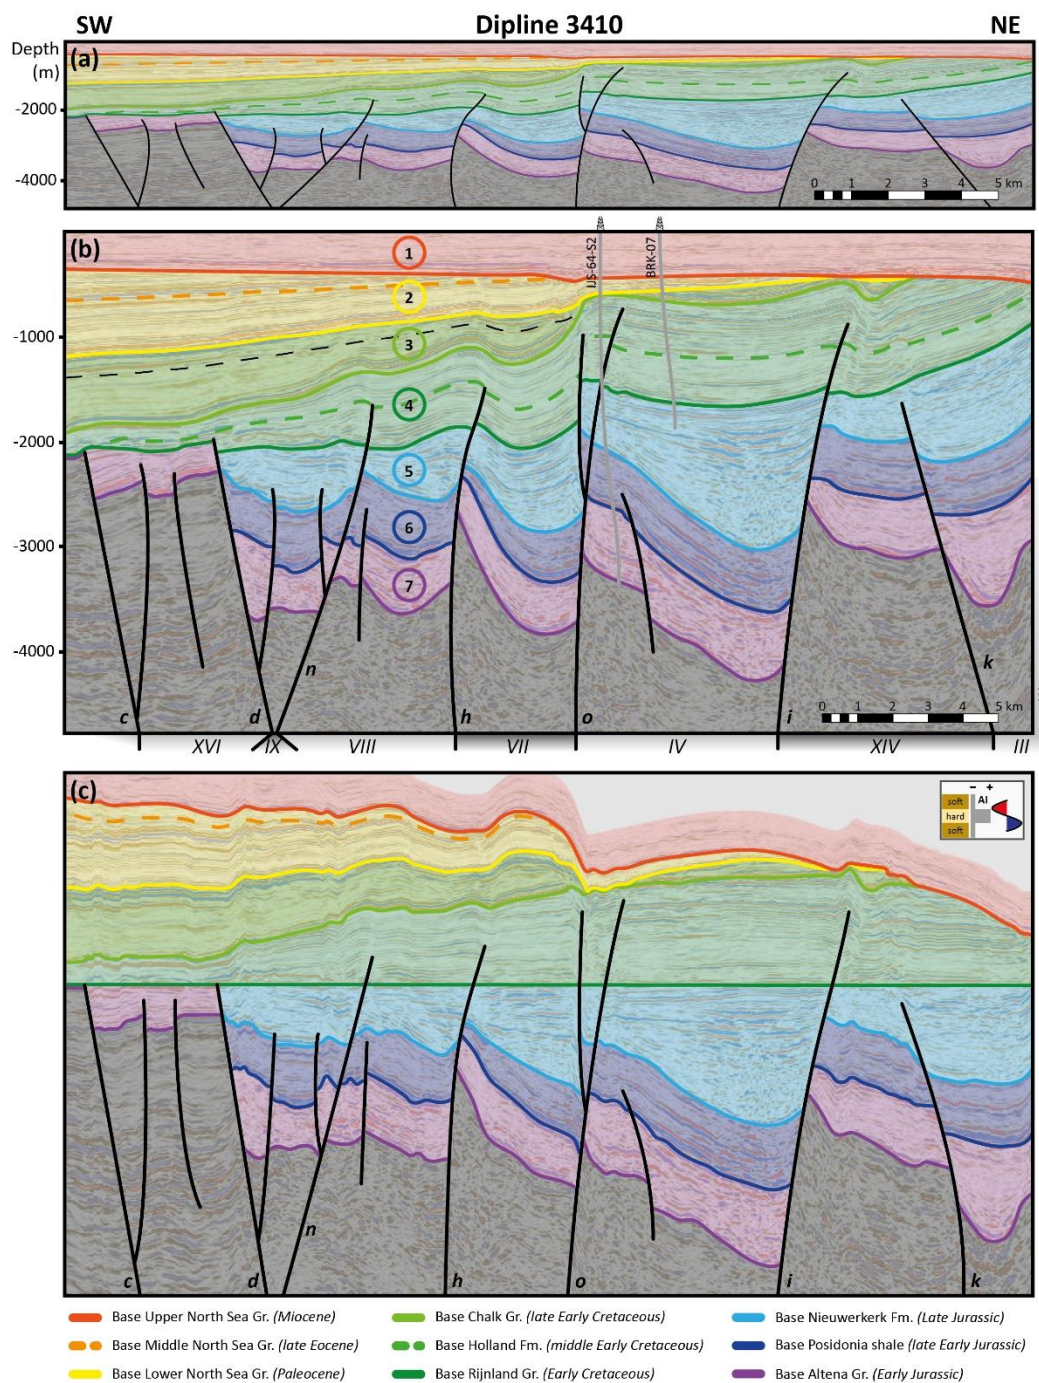

Dipline 3410 (Fig. 4) is located 16 km to the SE of dipline 2610 (Fig. 1b). The section crosses the Rotterdam and Oud-  
205 Beijerland Noord producing oil fields and the Pernis and Hekelingen producing gas fields. Close-by are the IJsselmonde (IJS-64-S2) and Berkel (BRK-07) abandoned oil fields.

Also here, megasequence 1 shows sub-horizontal reflectors based on an extensive erosional surface. Below, in the SW part of the section, megasequence 2 shows gently tilted parallel reflectors that become eroded towards the NE. Again, an unconformable contact separates megasequences 2 and 3, the latter showing substantial thinning towards the NE as well.  
210 Megasequence 3 displays low-amplitude synclinal and anticlinal structures, well evident at its base, capped by the

unconformably overlying megasequence 2. Similarly to the seismic line shown in figure 3, also in this line we observe an unconformity between the uppermost part of the megasequence 3 and the central and lower part of it (black dashed line in Fig. 4b). Such an unconformity appears to be gently folded. The underlying megasequence 4 shows parallel reflectors thinning towards the SW, as well evident in the flattened seismic profile (Fig. 4c), disrupted by faults. In the NE part of the section, the megasequence is partly eroded and directly toplapping onto megasequence 1. None of the major faults propagate across the top part of megasequence 4, which leaves the first 3 megasequences un-faulted. Below, megasequence 5 is affected by a number of faults and displays abrupt thickness changes. The thickness changes are even better visible on the flattened section, where the package shows at least four distinct asymmetric fault-bounded half-grabens. Also here, the underlying megasequence 6 is characterised by parallel reflectors and, contrasting to section 2610, megasequence 6 does not show significant thickness changes. The lowermost megasequence 7 displays both parallel layers, slight thickness changes and a fault-bounded half-graben at the NE part of the section.

Seven major faults are recognized in this seismic section, both normal and partly (in the lowermost tracts) inverted. Megasequences 5 to 7 are affected by all the faults, whereas only the faults showing positive inversion are propagating into megasequence 4, leaving megasequences 1 to 3 un-faulted. Part of the faults (*c*, *d*, *h*, *i* and *k*) from dipline 2610 extend in this section. In detail, faults *c* and *d* bind a structural high (the De Lier High, structure XVI, Fig. 4b) with small horst and graben structures. Here, megasequence 5 is absent and both structures and faults are capped by the uppermost part of megasequence 4. Fault *c* and the smaller faults within the bound structure show notable evidence of inversion. However, contrasting to section 2610, where fault *d* does not display clues of inversion, here inversion of the NE boundary of fault *d* resulted in the development of antithetic fault *n*. Together, the faults formed a set of small pop-up structures and a fault-propagation fold atop fault *n*, registered in megasequence 4. Faults *h* and *i* show a similar geometry, being SW-dipping and syn-sedimentary with respect to megasequence 5. Inversion of both faults is accompanied by the development of fault-propagation folds in megasequence 4. It is interesting to mention that both faults formed second-order pop-up structures in section 2610. In between faults *h* and *i*, fault *o* is recognized and together, these three faults bind two elegant semi-grabens (the Rijswijk and Pijnacker grabens, structures VII and IV, Fig. 4b) in which megasequence 5 shows clear growth geometries. Inversion of fault *o* caused the development of an antithetic fault, forming a second-order pop-up structure. Both the development of the fault-propagation folds and the second-order pop-up structure as result of the inversion of faults *d*, *h*, *o* and *i* recorded by growth geometries in megasequence 3. Last, also here, fault *k* is not inverted, but more importantly, it is binding a semi-graben (the Zoetermeer Graben, structure III, Fig. 4b) in which both megasequence 5 and 7 are characterised by thickness variations. Like in section 2610, evidence for fault inversion is clear with folding of reflectores (e.g. in the hanging wall of fault *d* and footwall of fault *i*) revealing a buttressing effect upon inversion.

**Figure 4: Dipline 3410 displayed with three different scales; (a): 1:1 scale, displayed with the interpreted horizons, megasequences and faults; (b): 1:3 scale, displayed with the interpreted horizons, megasequences and faults, together with projected wells and the unconformity within megasequence 3 (marked by the black dotted line). Below the section, the sub-basins and highs are numbered as in figure 6 ((XVI): De Lier High, (IX): Spijkenisse Graben, (VIII): Westland Graben, (VII): Rijswijk Graben, (IV): Pijnacker Graben, (XIV): Lansingerland High, (III): Zoetermeer Graben); (c): the 1:3 scaled section flattened for the base of the Rijnland Group, displayed with the interpreted horizons, megasequences and faults.**

245

250 **Figure 5: Strikeline 3415 displayed with three different scales; (a): 1:1 scale, displayed with the interpreted horizons, megasequences and faults; (b): 1:3 scale, displayed with the interpreted horizons, megasequences, faults and projected wells. The strikeline intersects fault i several times, wherefore the fault can be recognized multiple times. Below the section, the sub-basins and highs are numbered as in figure 6 ((II): Voorburg Graben, (XIV): Lansingerland High, (IV): Pijnacker Graben, (XV): Ridderkerk High, (V): Biesbosch Graben); (c): the 1:3 scaled section flattened for the base of the Rijnland Group, displayed with the interpreted horizons, megasequences and faults.**

255

### 4.1.3 Strikeline 3415

Strikeline 3415 (Fig. 5) runs perpendicular to the previously described lines and crosses the NE part of the study area (see Fig. 1b), the Werkendam abandoned oil field (WED-02) and the undeveloped Werkendam-Diep gas field. Closeby is the GSD-01 well, the Pijnacker (PNA-04-S1 & PNA-12) abandoned oil field and a producing geothermal energy project (PNA-GT wells).

260 Megasequence 1 is characterised by subhorizontal reflectors and is bottomed by an erosional surface. Megasequence 2 is characterised by thickness variation associated with uplift and erosion, whereas megasequence 3 displays growth geometries

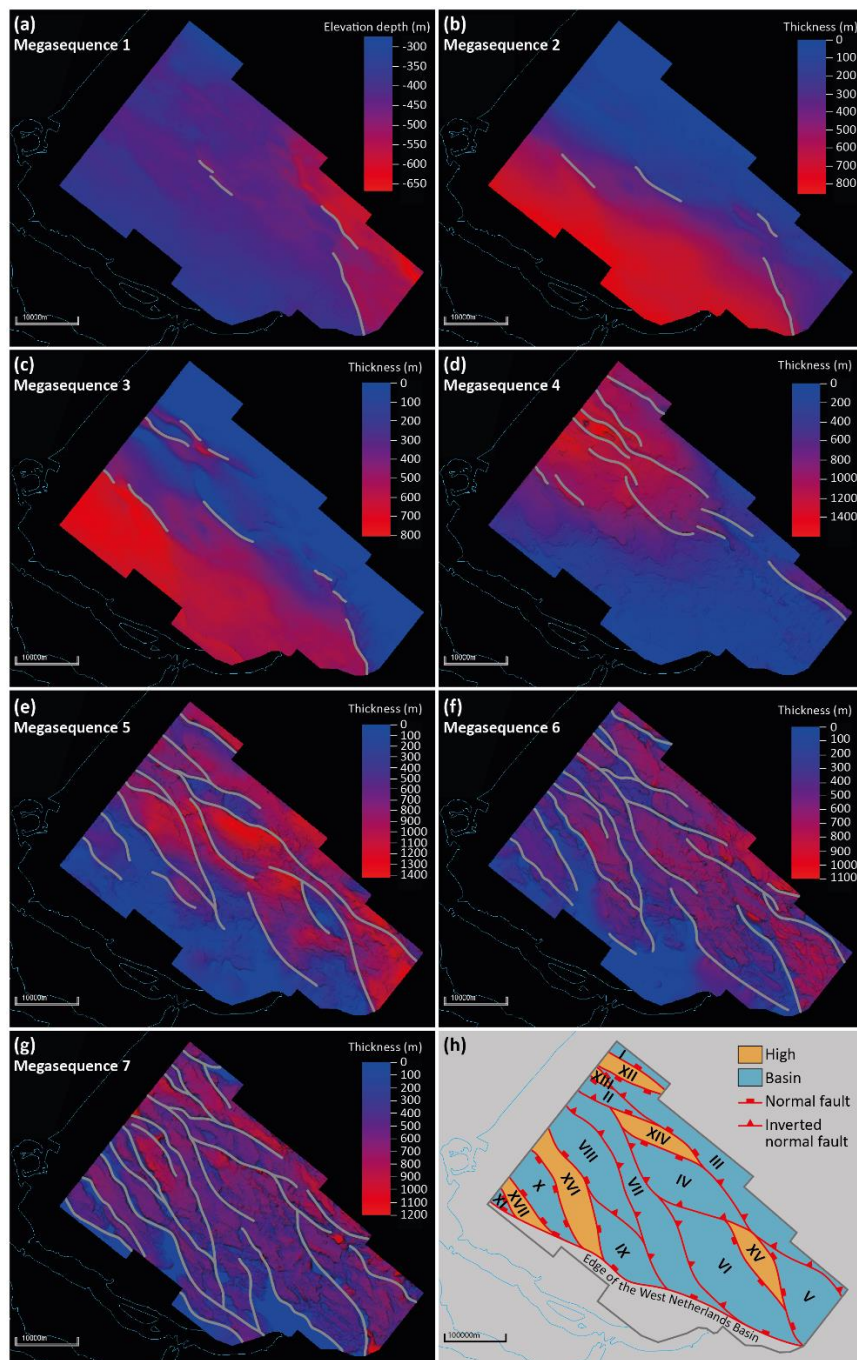

with respect to faults *i* and *o*. Megasequence 2 toplaps megasequence 3, the latter disappearing towards the SE. The base of megasequence 2 truncates open anticlines and synclines, with evident erosion of megasequences 3, 4 and 5. Megasequence 4 shows thinning towards the SE with parallel reflectors and no distinct thickness variations across short distances. Below, megasequence 5 is characterised by thickness variations across short distances. No clear boundary faults can be identified in this line for the growth-structures hosted in megasequence 4, evidencing that the major faults are oriented at low angle to this seismic section. Also, within the package of megasequence 5, differing appearances of reflectors are observed, pointing towards variations of seismic facies. Underlying megasequence 6 does not show remarkable thickness variations, whereas lowermost megasequence 7 shows some slight changes in thickness.

As section 3415 is oriented at a low angle to the main faults, less intense deformation and thickness variations are observed. Fault *i* is oriented parallel to section 3415 and, as it extends throughout the whole 3D cube, this fault crosses the section several times. The fault bends along the section when going to the SE. Minor folding is observed in megasequence 4 atop these sections of fault *i*, but no distinct inversion structures are present. Last, in the middle of the section, a second-order pop-up structure related to fault *o* (section 3410) is recognized. All faults, except the horst structures related to faults *i* and *o*, are capped by megasequence 4, whereas the faults of the horst structures are capped by the top-part of the latter.

#### 4.2 Thickness maps

Here, we present the thickness maps of megasequences 2 to 7 (Fig. 6b-g) and the depth map of the base of megasequence 1 (Fig. 6a). Megasequence 1 represents the youngest unit, therefore the depth map of its base is representative of its thickness. Overall, megasequence 1 shows a constant thickness. Towards the E, an abrupt increase in depth is observed, related with the only fault crosscutting this megasequence. Megasequence 2 shows a general thinning towards the NE, which is related to the overlying erosional surface, but we also observe the occurrence of narrow NNW-SSE and NW-SE elongated areas with an increased thickness. As seen in the seismic cross sections (Figs. 3 and 4), megasequence 3 deposited during faults' inversion. This latter package displays an overall NE-ward thinning, related to the overlying erosional surface that is present at the base of megasequence 1, with both NNW-SSE and (mostly) NW-SE elongated areas of increased/reduced thickness. Contrasting to megasequence 3, megasequence 4 displays an overall thinning towards the S, with no localised areas of increased/decreased thickness. Megasequence 5 (the main geothermal target interval) is characterised by an overall thickness increase towards the NE. Areas of increased/reduced thickness are mostly lozenge-shaped with boundary faults being NW-SE and NNW-SSE oriented. Towards the S, megasequence 5 is almost absent due to erosion and/or non-deposition. Sub-basins filled by megasequence 5 are asymmetric, as evidenced by the sudden thickness change toward NE compared to a more gentle thickness decrease towards the SW. Such an observation is suggestive of a first order architecture composed of half-graben structures bounded by SW-dipping master faults.

The interpretation of the thickness maps of megasequences 6 and 7 is less straightforward. These thickness maps show the effects of erosion during the deposition of megasequence 5, e.g., in the horst structure between faults *b* and *c* in section 2610 (Fig. 3). This effect is seen in the map as NNW-SSE oriented ribbons of reduced thickness, resembling horst structures. If we

295

300

**Figure 6:** (a): Depth map of megasequence 1, with present faults displayed in grey; (b-g): thickness maps of megasequences 2–7 with present faults displayed in grey; (h): Simplified map showing the structural elements formed as consequence of the first and second rifting episodes, the different highs and basins are numbered and named; (I): Waddinxveen Graben, (II): Voorburg Graben, (III): Zoetermeer Graben, (IV): Pijnacker Graben, (V): Biesbosch Graben, (VI): Dordrecht Graben, (VII): Rijswijk Graben, (VIII): Westland Graben, (IX): Spijkenisse Graben, (X): Maasland Graben, (XI): Voorne Graben, (XII): Moerkapelle High, (XIII): Zoetermeer High (XIV): Lansingerland High, (XV): Ridderkerk High, (XVI): De Lier High, (XVII): Hoek van Holland High.

remove the effect of those ribbons from the thickness maps of megasequences 6 and 7, and we rely on the occurrence of growth geometries (such as the growth wedge seen in megasequence 7 in the Voorburg Graben, structure II, close to fault *j*, Fig. 3b), we observe that the thickness distribution of megasequence 7 displays NW-SE elongated graben/semigraben, filled by growth strata and separated by horst structures. An outstanding example occurs in the northern corner of the map, where a 20 km long NW-SE elongated horst (the Lansingerland High, structure XIV, Fig. 6h) bound by two depocenters is observed. Megasequence 6 displays similar thickness variations, but none of the thickener areas show growth wedge geometries, suggesting that thickness variations relate to later erosion rather than to syn-sedimentary creation of accommodation space.

## 310 **5 Discussion**

### **5.1 Tectonic evolution**

The interpretation of the L3NAM2012AR seismic 3D cube has allowed us to subdivide the investigated sedimentary succession into seven megasequences, corresponding to units spanning in age from Jurassic to Present times. Megasequences are delimited either by the occurrence of unconformities (base of megasequences 1, 2, 4 and 5), or by the transition from growth geometries (e.g. stratigraphic fanning/expansion-tapering, convergent reflectors) to parallel geometries. Based on our observations, the evolution of the studied portion of the WNB from the Jurassic onward can be assessed.

The first observed tectonic period can be dated to the Early Jurassic, which is the biostratigraphic age of the sedimentary rocks of megasequence 7. NW-SE elongated regions of decreased and increased thicknesses (Fig. 6g) are interpreted as related to Early to Middle Jurassic fault-bounded horst and graben structures, respectively. Growth geometries within this megasequence are observed, like the half-graben in the Voorburg Graben (structure II, associated with fault *j*, Fig. 3b). Coherently, megasequence 7 is interpreted as a syn-rift sequence, with the thickness of syn-rift infill increasing towards the NE. Regionally, this rifting stage is synchronous with the final stage of the first rifting event that has shaped the North Sea Rift system (e.g. Fossen et al., 2021). This rifting event seems to coincide with the regionally recognized Early Kimmerian tectonics (Fig. 2) (Geluk and Röhling, 1997; Duin et al., 2006). The overlying megasequence 6 displays areas of slight thickness variation, but no growth geometries occur in it, therefore, it is to be considered post-rift. Overall, both megasequence 6 and 7 display a slight NE-ward thickening, with the thickening direction being perpendicular to the direction of the main normal faults that were active during the Early Jurassic rifting stage. According to the widely recognised features in rift systems (e.g. Franke, 2013; Peron-Pinvidic et al., 2019), we interpret megasequence 6 as the post-rift passive infill of the accommodation space created synchronously with the deposition of megasequence 7. Since the timing of deposition of megasequence 6 corresponds to the inception of the thermal North Sea Rift Dome underneath the central North Sea (van Wijhe, 1987; Ziegler, 1992), an alternative hypothesis could be that thinning of megasequence 6 is somehow related with this lithospheric-scale bulging process. Given the centre of the dome was located far N (between NW Scotland and SE Norway) (Ziegler, 1992; Wong et al., 2007), N-ward thinning of megasequence 6 should be observed, which is not the case, wherefore this hypothesis can be discarded.

335 Deposition of the overlying megasequence 5 started in the Late Jurassic, during a second pulse of extensional faulting. This stage is coeval with the second phase of rifting observed in the North Sea, further to the N (e.g. Færseth, 1996), which induced an enhancement crustal extension, known as the Late Kimmerian tectonics (van Wijhe, 1987; Ziegler, 1992; de Jager, 1996; Racero-Baena and Drake, 1996; van Balen et al., 2000). In the WNB, this extensional phase is simultaneous with igneous activity (Sissingh, 2004), a characteristic of continental rifting (e.g. Franke, 2013; Gouiza and Paton, 2019). We observe that all the normal faults (excluding those showing evidence of reverse reactivation) are sealed by the upper portion of this  
340 megasequence. Several syn-depositional wedges (most of them being half-grabens) are observed in this megasequence, such as those associated with faults *h*, *o* and *i* in Figure 4. The various sub-basins active during this second extensional pulse are lozenge-shaped and they are bounded by NW-SE and NNW-SSE striking faults (Fig. 6e), the “zigzag” arrangement of faults being a typical feature when pre-existing faults occur (e.g., Henstra et al., 2019). Many horst and graben structures active during this second rifting phase retrace structures developed during the first rifting stage, such as the ones seen in the NW part  
345 of the study area (e.g. the Westland Graben, structure VIII, Fig. 6h). The observation that during the first rifting stage the structures were NW-SE oriented, allowed us to infer that those NW-SE striking structures were reactivated during the second rifting phase. Accordingly, we deduce that the NNW-SSE striking normal faults formed during the second rifting phase. Such an inference is coherent with natural examples and analogue models of multiphase rift systems, where it is commonly observed that oblique inherited structures can be reactivated synchronously with the formation of new faults oriented perpendicular to  
350 the stretching direction (e.g. McClay and White, 1995; Mart and Dauteuil, 2000; Henza et al., 2010; Brune et al., 2014; Naliboff and Buiter, 2015; Zwaan et al., 2016; Zwaan and Schreurs, 2017). An alternative hypothesis is that the lozenge-shaped structures are pull-apart basins or ridges associated with transtensive/transpressive faults. We discard this hypothesis for the studied area, as we do not observe the diagnostic features of wrench tectonics, such as positive/negative flowers, branch faults, restraining/releasing bends, antithetic faults and/or strike-slip duplexes (e.g. Riedel, 1929; Wilcox et al., 1973; Harding, 1974; Aydin and Nur, 1982; Sanderson and Marchini, 1984; Woodcock and Fischer, 1986; Sylvester, 1988; among others) in the  
355 L3NAM2012AR seismic 3D dataset. Similarly to megasequences 7 and 6, megasequence 5 thickens towards the NE, suggesting that these megasequences form part of the same multiphase rift system.

After diminishing the rifting-related Jurassic crustal extensions (e.g. Ziegler, 1992), the WNB entered a post-rift phase by the Early Cretaceous (van Wijhe, 1987), during which megasequence 4 deposited. None of the observed extensional faults were  
360 active at that time. Post-rift infill of the WNB is well represented by megasequence 4 on the flattened displays of sections 2610 and 3410 (Figs. 3b & 4b) and on the thickness map, showing a NW-SE elongated, 20 to 40 km wide, post-rift basin (Fig. 6d). Such a broad basin does not overlap the syn-rift grabens and, therefore, it likely relates to large-scale sagging rather than to the simple passive infill of the previously developed half-grabens.

On top of the post rift megasequence 4, the Lower Cretaceous megasequence 3 sedimented during a shortening stage. Positively  
365 inverted normal faults with associated growth geometries and buttressing-related structures are observed in this megasequence (e.g. associated with faults *e* and *i* in Fig. 3). This Late Cretaceous period of inversion likely corresponds to the Late Cretaceous Subhercynian inversion phase (Fig. 2) (e.g. Ziegler, 1992; van Wijhe, 1987; de Jager 2003, Worum and Michon, 2005). During

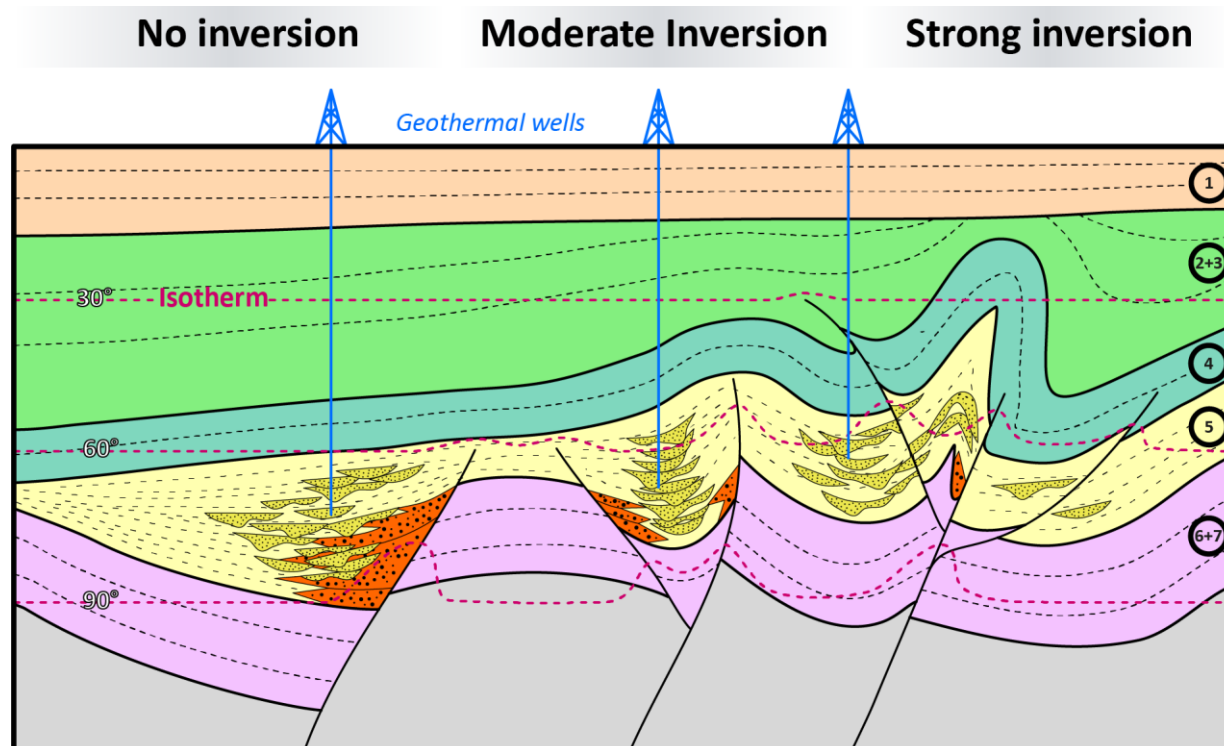

370 this stage, both faults of the NW-SE and NNW-SSE systems have been inverted or deformed during buttressing. Yet, we were not able to individuate newly formed reverse faults, which are needed to constrain the shortening direction. While the NE-section of the WNB got inverted and uplifted, its SW-flank became subject to subsidence and developed into a marginal basin, referred to as the Voorne Trough (Deckers, 2015) and well illustrated by the SW-ward thickness increase of megasequence 3 (Fig. 6c). The upper portion of megasequence 3 could already include a post-inversion succession. In fact, a local unconformity divides the upper from the central and lower portions of this megasequence, as illustrated in figures 3 and 4. This is consistent with regional constraints, indicating that the Subhercynian inversion ceased after the Campanian (de Jager, 2003), whereafter  
375 deposition of the chalk of megasequence 3 continued for the entire Late Cretaceous (van Balen et al., 2000; van der Voet et al., 2019).

Megasequence 2 is separated from the underlying megasequence 3 by a regional unconformity. No growth wedge geometries are observed in this megasequence, suggesting that the gentle folding of its base is associated with compaction of the underlying sediments and/or the passive infill/draping of a paleo-topography. Both syn-inversion megasequence 3 and post-  
380 inversion megasequence 2 thin out toward the NE, indicating that uplift of the NE sector of the study area started during faults' inversion but continued during the deposition of megasequence 2, as also evidenced by the SW-tilting of the erosional unconformity separating the two megasequences. The erosional unconformity at the base of megasequence 2 corresponds to the timing of the Laramide tectonic phase that peaked during the Middle Paleocene (Deckers, 2015) and caused basin uplift in the area of the WNB (Deckers and van der Voet, 2018; Kley, 2018). The erosional unconformity at the top of megasequence  
385 2, instead, reflects the broad basin uplift (de Jager, 2003), likely initiated by the Alpine Orogeny (Worum and Michon, 2005). Lastly, the depth map of the base of megasequence 1 displays two large plateaus, separated by an ENE-dipping fault formed during the second extensional phase and reactivated during these times.

## 5.2 Implications for geothermal systems

The WNB harbours well developed geothermal reservoir rocks and is covered by a good data-collection, inherited from former  
390 hydrocarbon exploration. Presently, the most exploited geothermal reservoir units are the Late Jurassic Nieuwerkerk Formation (megasequence 5; second syn-rift) and, subordinately, the Cretaceous sandstones (megasequence 4, postrift and pre-inversion). An additional reservoir is represented by the Triassic sandstones, which occur at deeper structural levels, and have not been mapped in this work. Yet, although the observed first rift is Early Jurassic in age, its rifting architecture might be applicable to the Triassic reservoir. Rift initiation already happened during the Triassic (e.g. Ziegler, 1992; van Wijhe, 1987), wherefore  
395 the Early Jurassic rift possibly is a remnant from Triassic extensional tectonics. The Triassic sandstones are known for having a reduced reservoir quality (Boersma et al., 2020). Yet, underneath the Zoetermeer High (structure XIII in figs. 3b and 6h), the reservoir quality might be better. Here, the structural high seems to have been relatively stable throughout the evolution of the basin, as evidenced by fault *k* showing no signs of reactivation during inversion (Fig. 3). Therefore, the Triassic reservoir might be less fractured with shallower burial conditions than in the surrounding grabens.

400

**Figure 7: Summarizing figure, showing the Jurassic geothermal play of the West Netherlands Basin. The expected best spots for geothermal exploration are the central portions of the growth synclines, where the fluvial sands (yellow dotted material) are present, geothermal gradients are highest and interference from foot-wall erosion (orange dotted material) and residue hydrocarbons (black material) is minor. The isotherms are based on a geotherm of  $31^{\circ}\text{C km}^{-1}$  (Bonté et al., 2012). The sketched layers correspond to the interpreted megasequences, indicated in the circles on the right side.**

405

Among the two Jurassic-Cretaceous reservoirs, the Nieuwerkerk Formation is the most promising, facilitating a deeper reservoir (spanning in depth from -0.5 km m to -3 km) and, given the geothermal gradient of the area (Fig. 7,  $31^{\circ}\text{C km}^{-1}$ ; Bonté et al., 2012), likely offering temperatures up to  $90^{\circ}\text{C}$ , which is perfect for low enthalpy geothermal systems. Instead, temperatures for the Cretaceous sandstones probably do not exceed  $60^{\circ}\text{C}$ . The Nieuwerkerk Formation was deposited during the second rifting event in the Late Jurassic (megasequence 5) and the multi-phase extensional setting led to the development of a compartmentalised reservoir, made up of lozenge shaped sub-basins. Given the fluvial nature of the Nieuwerkerk Formation (e.g. Willems et al., 2017b; Vondrak et al., 2018; Willems et al., 2020), the lateral and vertical compartmentalization of sands and shales is a characteristic that must be taken into account in the reservoir's geothermal exploration. In rift systems involving continental to coastal clastic syntectonic sedimentation, it is well known that the more coarse grained facies are located close to the faults and along the axis of grabens and half-grabens (e.g., Gawthorpe and Leeder, 2000). In agreement, we expect the fluvial channels and other coarse grained sediments to be located in the core of half-grabens or in their inner limb (i.e. the limb close to the master fault). Furthermore, close to the master fault, foot-wall erosion can cause the deposition of a different sedimentary facies, possibly interfering with the targeted reservoir rock. Contrasting to petroleum systems, in which structural highs are the preferential target for hydrocarbon exploration (hydrocarbons are lighter than water), half-

410

415

420 grabens are the most suitable sites for geothermal exploration. Indeed, half-grabens are found at deeper levels, thus ensuring hotter temperatures with respect to limbs and structural highs. Combining all that is stated above allows us to individuate the core of half-grabens, i.e. syn-tectonic layers in the core of half-grabens, as preferential sites for geothermal exploration. Here, the chances of finding hot and thick fluvial sand packages, thus ensuring a higher net to gross ratio, are increased.

Such a simple template is modified during faults' reactivation and buttressing associated with the inversion stage. Such an inversion can produce (1) the uplift of the former structural-stratigraphic reservoirs, i.e. the half-grabens, with the consequent decrease of water temperatures and, eventually, (2) fracturing of reservoirs by second order faults and brecciation when the amount of inversion increases. All the above discussed features are schematically illustrated in Figure 7, where normal faults, positively inverted normal faults, half-grabens, geotherms, and sweet spots are outlined.

Given the template illustrated in Figure 7 and assuming that the most suitable areas for geothermal exploration are half-grabens associated with either non-inverted or moderately inverted normal faults, we can identify areas suitable for further investigation within the L3NAM2012AR seismic 3D cube. Examples of such areas are the central portions of the Pijnacker, Rijswijk and Westland grabens (structures IV, VII and VIII, figs. 4, 6e and 6h). Here, the grabens contain a thick (1 to 1,4 km in thickness) package of Nieuwerkerk Formation, while displaying no to moderate inversion. The deepest portions of these grabens are located away from the master fault, preventing interference by material originating from foot-wall erosion. The centres of these grabens are located at depths roughly between 2 and 3 km, giving the present sand bodies expected temperatures between 60°C and 90°C (based on a geotherm of 31°C km<sup>-1</sup>; Bonté et al., 2012). In areas like this, additional work is required to assess the fluvial reservoir architecture (Willems et al., 2017a) in more detail and properly locate injection and recovery wells (i.e. geothermal doublets) within coarse grained sediments. In this sense, a future work on the deep analysis of seismic attributes is to be developed, to find a good proxy for mapping fluvial systems.

## 440 6 Conclusion

With a renewed seismic interpretation, the tectonic evolution of the WNB, the fault activation and reactivation and development of its syn-rift infill was re-assessed. From Jurassic times onwards, seven megasequences were documented: (1) a first NE-SW oriented rifting phase during the Early Jurassic; (2) a post-rift phase during the Middle Jurassic; (3) a second WSW-ENE oriented rifting phase during the Late Jurassic, partly controlled by the Early Jurassic rifting phase; (4) an Early Cretaceous post-rift sag phase; (5) faults' inversion during the Late Cretaceous; (6) broad basin uplift during the Paleocene to Oligocene; (7) a minor reactivation event during the Miocene.

Multi-phase rifting during the Jurassic led to compartmentalization of the second syn-rift infill, which is the main geothermal target in the WNB; the Late Jurassic fluvial-deltaic Nieuwerkerk Formation. We expect its channel sands to be present in the deepest, central portions of the half-grabens, where the highest temperatures are expected. Here, interference by foot-wall erosion and residue hydrocarbons is expected to be minor. The Cretaceous inversion needs to be taken into account, as an

increasing amount of inversion can cause breaching of the reservoir and uplift of the targeted half-grabens, hence lowering the temperature. Therefore, only non to moderately inverted areas should be considered for geothermal exploration.

Hence, we conclude that for a geothermal play in a multi-phase rift setting with a fluvial-deltaic infill, the best spots for geothermal exploration can be found in the central portions of non to moderately inverted half-grabens.
