## Abstract

Formic acid (HCOOH) is one of the most abundant organic acids in the atmosphere and affects atmospheric acidity and aqueous chemistry. However, the HCOOH sources are not well understood. In a recent field study, we measured atmospheric HCOOH concentrations at a coastal site in South China. The average concentrations of HCOOH were  $191 \pm 167$  ppt in marine air masses and  $996 \pm 433$  ppt in coastal air masses. A strong linear correlation between HCOOH concentrations and the surface area densities of submicron particulate matter was observed in coastal air masses. Post-campaign laboratory experiments confirmed that the photochemical aging of ambient aerosols promoted by heterogeneous reactions with ozone produced a high concentration of HCOOH at a rate of  $0.185 \text{ ppb h}^{-1}$  under typical ambient conditions at noon time. HCOOH production was strongly affected by nitrate photolysis, as this efficiently produces OH radicals that oxidise organics to form HCOOH. We incorporated this particle-phase source into a photochemical model and the net HCOOH production rate increased by about three times compared with the default Master Chemical Mechanism (MCM). These findings demonstrate that the photochemical aging of aerosols is an important source of HCOOH that should be included in atmospheric chemistry-transport models.

## 1. Introduction

Organic acids are ubiquitous in the troposphere and constitute a significant fraction of the total organics in both the gas and particle phases (Chebbi and Carlier, 1996). They also participate in the aqueous-phase chemistry of clouds, contribute to secondary organic aerosol

33 (SOA) formation through reactions within the condensed phase (Carlton et al., 2007; Ervens et  
34 al., 2004; Lim et al., 2010), and are proposed to enhance the formation of new particles in the  
35 atmosphere (Zhang et al., 2004). Formic acid (HCOOH) is among the most abundant organic  
36 acids in the atmosphere (Khare et al., 1999) and accounts for over 60% of the free acidity in  
37 precipitation in remote areas and more than 30% of that in polluted areas (Andreae et al., 1988;  
38 Keene et al., 1983; Keene & Galloway, 1988; Khare et al., 1999; Stavrou et al., 2012). This  
39 contribution is increasingly important due to the decline in the concentrations of anthropogenic  
40 nitrogen oxides (NO<sub>x</sub>) and sulfur dioxide. HCOOH serves as a significant sink of in-cloud  
41 hydroxyl radicals ( $\cdot\text{OH}$ ) and stabilised Criegee intermediates (SCIs) (Jacob, 1986), and thus  
42 influences aqueous-phase chemistry by affecting pH-dependent reaction rates, oxidant  
43 concentrations, and solubilities (Vet et al., 2014). HCOOH also plays a role in the formation of  
44 cloud condensation nuclei (Yu, 2000), due to its comparatively higher hygroscopicity at low  
45 critical supersaturations when incorporated into aerosols (Novakov and Penner, 1993). This, in  
46 turn, affects total indirect radiative forcing. Additionally, HCOOH may be involved in halogen  
47 chemistry through its heterogeneous reaction with solid sodium chloride in sea-salt aerosols  
48 (Xia et al., 2018).

49 Considering the abovementioned roles of HCOOH in atmospheric chemistry, it is essential  
50 to understand its sources and sinks. The main sources of HCOOH include direct emissions  
51 from terrestrial vegetation (Andreae et al., 1988), biomass and biofuel burning (Akagi et al.,  
52 2011; Goode et al., 2000; Yokelson et al., 2009), fossil-fuel combustion (Kawamura et al., 2000;  
53 Zervas et al., 2001a, b) and soil emissions (Sanhueza and Andreae, 1991). The secondary gas-  
54 phase formation mechanisms of HCOOH are mainly the oxidation of volatile organic  
55 compounds (VOCs), including ozonolysis of terminal alkenes (Neeb et al., 1997), alkyne  
56 oxidation (Bohn et al., 1996), OH-initiated isoprene oxidation (Paulot et al., 2009),  
57 monoterpene oxidation (Larsen et al., 2001), keto-enol tautomerisation (Andrews et al., 2012;  
58 Shaw et al., 2018) and  $\cdot\text{OH}$  oxidation of methyldioxy radicals ( $\text{CH}_3\text{O}_2\cdot$ ) (Bossolasco et al.,  
59 2014). HCOOH is primarily removed from the atmosphere through wet and dry deposition,  
60 with a minor sink of being photo-oxidation by  $\cdot\text{OH}$  (Atkinson et al., 2006). However, with  
61 these mechanisms included, HCOOH concentrations remain significantly underestimated by  
62 previous models (Baboukas et al., 2000; Bannan et al., 2017; Chaliyakunnel et al., 2016; Le  
63 Breton et al., 2012; Millet et al., 2015; Yuan et al., 2015), indicating a substantial missing source  
64 of HCOOH.

65 In addition to gas-phase production pathways, HCOOH can also be generated through  
66 heterogeneous or condensed-phase processes. Aqueous reactions of formaldehyde (HCHO)  
67 (Chameides and Davis, 1983; Jacob, 1986), glyoxal (Carlton et al., 2007) and other species  
68 with  $\cdot\text{OH}$  (aq) can produce HCOOH, particularly in moderately acidic environments (Jacob,  
69 1986). A recent chamber experiment has revealed that formaldehyde can be efficiently  
70 converted to HCOOH through a multiphase pathway that involves its hydrated form,

71 methanediol. This pathway has been shown to generate up to four times more formic acid  
72 compared to all other known chemical sources combined in a chemistry-climate model, and  
73 the modified model largely reproduced observed ambient concentrations of HCOOH (Franco  
74 et al., 2021). Moreover, Gao et al. (2022) proposed a new bidirectional deposition-emission  
75 process, in which HCOOH deposits rapidly in night-time dew and is re-emitted subsequently  
76 from the dew as it evaporates on the following day.

77 Many laboratory chamber studies have demonstrated that the photochemical aging of  
78 organic aerosols can also produce HCOOH (Henry and Donahue, 2012; Malecha and  
79 Nizkorodov, 2016; Mang et al., 2008; Pan et al., 2009; Walser et al., 2007; Zhang et al., 2021).  
80 The photochemical aging of aerosols occurs through the reactive uptake of oxidants onto  
81 particle surfaces, altering their chemical compositions and physical properties (George et al.,  
82 2015). In the condensed organic phase, HCOOH can be produced through the photodegradation  
83 of SOA (Henry and Donahue, 2012; Malecha and Nizkorodov, 2016). Additionally, the  
84 oxidants such as  $\cdot\text{OH}$ , nitrogen dioxide ( $\text{NO}_2$ ), and nitrite ions/nitrous acid (HONO) produced  
85 from the photolysis of particulate nitrate ( $\text{NO}_3^-$ ) can also efficiently oxidise organics to produce  
86 HCOOH (Zhang et al., 2021). Apart from laboratory experiments, Paulot et al. (2011) observed  
87 a marked positive correlation between HCOOH concentrations and submicron organic aerosol  
88 masses in field measurements conducted in three distinct areas: coastal, urban, and polar, and  
89 suggested that aerosol aging produces HCOOH. The aforementioned results show that there is  
90 a need for a quantitative assessment of the contribution of the photochemical aging of aerosols  
91 to HCOOH production in the ambient atmosphere.

92 In this study, we measured HCOOH concentrations at near-ground level at a coastal site in  
93 Hong Kong, China, for two months during autumn 2021. We examined the characteristics of  
94 HCOOH concentrations and their correlation with related species' concentrations or other  
95 parameters. We then conducted a chamber study to measure the rate of HCOOH production  
96 during the aging of ambient aerosols and extrapolated the results to the real atmosphere. We  
97 incorporated this HCOOH-formation mechanism into a model using a parameterisation  
98 involving fine particulate matter concentration, surface area density, light intensity, and ozone  
99 ( $\text{O}_3$ ) concentration, and then performed simulations to evaluate the HCOOH production rate  
100 from the photochemical aging of aerosols. Furthermore, we showed that  $\text{NO}_3^-$  photolysis acted  
101 as a crucial source of  $\cdot\text{OH}$  during the aging process. Our results enhanced the understanding of  
102 HCOOH sources and model simulations of ambient HCOOH concentrations.

## 103 2. Methods

### 104 2.1. Field observations

105 Ambient measurements of the atmospheric concentrations of HCOOH and related  
106 species/parameters were conducted from 13 August to 31 October 2021 at the Hong Kong

107 Environmental Protection Department's Cape D'Aguilar Super Site (CDSS; 22.21°N,  
108 114.25°E), which is situated a few hundred meters away from the nearest coastline of the South  
109 China Sea (Fig. S1). During the study period, the air quality of this coastal site was initially  
110 predominantly influenced by marine air masses from the South China Sea and subsequently by  
111 the coastal air masses transporting regional anthropogenic pollution from East China. The site  
112 was also affected by biogenic emissions from local vegetation and ship emissions transported  
113 mainly from about 8 kilometres away. There were no other significant anthropogenic sources  
114 nearby.

115 The species quantified were HCOOH, HONO, trace gases (nitric oxide, NO<sub>2</sub>, carbon  
116 monoxide (CO), sulfur dioxide (SO<sub>2</sub>), and O<sub>3</sub>), volatile organic compounds (VOCs),  
117 oxygenated VOCs, aerosol mass concentrations (1- $\mu$ m particulate matter (PM<sub>1</sub>), PM<sub>2.5</sub>, and  
118 PM<sub>10</sub> concentrations), aerosol size distributions, aerosol ionic compositions, NO<sub>2</sub> photolysis  
119 frequency ( $j$ NO<sub>2</sub>), and meteorological parameters (temperature (T), relative humidity (RH),  
120 wind direction, and wind speed). A detailed description of the measurement of HCOOH  
121 concentration is provided below, and information on other measurements is summarised in  
122 Table S1.

123 The concentration of HCOOH was measured at 172.91 atomic mass unit (amu) using an  
124 iodide-adduct time-of-flight chemical ionisation mass spectrometer (I<sup>-</sup>-ToF-CIMS, Aerodyne  
125 Research), as we used in our previous study at the same site (Xia et al., 2022). A comprehensive  
126 description of the use of the I<sup>-</sup>-ToF-CIMS can be found in previous studies (Lee et al., 2014;  
127 Aljawhary et al., 2013). Briefly, humidified iodomethane-containing N<sub>2</sub> air was passed through  
128 an inline ioniser (containing polonium-210) to generate iodide ions (I<sup>-</sup>) and iodide-water ions,  
129 which served as the reagent ions, and the HCOOH produced was detected as IHCOOH<sup>-</sup>. The  
130 background concentration of HCOOH was determined every 2 days by injecting zero air and  
131 was found to be 60.9 ppt. HCOOH calibration was performed three times on-site and once in  
132 the laboratory immediately following the field campaign using diluted gas standards generated  
133 by a permeation tube (KIN-TEK) with a permeation rate of 90.87 ng min<sup>-1</sup>. HCOOH sensitivity  
134 varies with RH as water competes with HCOOH for I<sup>-</sup> (Lee et al., 2014). Thus, the HCOOH  
135 sensitivity was measured at various RHs, as shown in Fig. S2. The sensitivity remained stable  
136 at a given RH, with a variation of less than 5% throughout the campaign.

137 The ToF-CIMS was housed in an air-conditioned shelter at an indoor air T maintained at  
138 25–28 °C. The shelter was located approximately 15 m away from the CDSS station. The  
139 sampling tube was a 0.5-m long perfluoroalkoxy-Teflon tube (1/2 in. outer diameter), the inlet  
140 of which was situated on the sidewall of the shelter, 1.5 m above the ground. To achieve laminar  
141 flow in the sampling tube, a flow rate of 25 Lpm was adopted, with a residence time of 0.1 s.  
142 The ToF-CIMS drew ~2 Lpm sample air, and the remaining airflow was discarded. The  
143 sampling tube was replaced with a new tube every 2 days to reduce inlet artifacts. We  
144 investigated possible inlet artifacts by injecting known concentrations of HCOOH into a used

145 sampling inlet and found that the artifacts had a negligible effect on the measured HCOOH  
146 concentration (difference < 3%). The remaining instruments were housed in the CDSS station,  
147 with their sampling inlets located ~1.5 m above the roof.

## 148 2.2. Hybrid Single-Particle Lagrangian Integrated Trajectory (HYSPLIT) and Extended 149 Aerosol Inorganic Model IV (E-AIM IV) models

150 Hourly 24-h backward trajectories were obtained using the HYSPLIT model  
151 (<https://www.ready.noaa.gov/hypub-bin/trajsrc.pl>). The input parameters were Global Data  
152 Assimilation System 1° for the meteorology data; 22.21°N and 114.25°E for the location; and  
153 60 m for the endpoint height. Air masses were classified as marine or coastal, based on their  
154 source regions. A unique period was identified as a haze period, during which there was a  
155 transition from marine air masses to coastal air masses under stagnant conditions (wind speed  
156 < 3 m s<sup>-1</sup>). A detailed classification can be found in Fig. S3.

157 The aerosol water content (AWC) and pH were predicted by the E-AIM IV online in batch  
158 mode (<http://www.aim.env.uea.ac.uk/aim/model4/model4d.php>). The thermodynamic model  
159 was constrained by hourly field-measured molar concentrations of NH<sub>4</sub><sup>+</sup>, sodium ions (Na<sup>+</sup>),  
160 sulfate ions (SO<sub>4</sub><sup>2-</sup>), NO<sub>3</sub><sup>-</sup>, and chloride ions (Cl<sup>-</sup>) in PM<sub>2.5</sub>; gas-phase ammonia concentrations;  
161 ambient T; and RH. Initial concentrations of protons (H<sup>+</sup>) and hydroxide ions were estimated  
162 based on the ion balance of the major water-soluble ions. The input of Na<sup>+</sup> into the model  
163 (Na<sup>+</sup><sub>(eq)</sub>) was calculated as a sum of the equivalent concentrations of Na<sup>+</sup>, potassium ions,  
164 magnesium ions, and calcium ions (Eq. (1)). The model also considered water dissociation and  
165 allowed all possible solids to form in the system. Parameters p, q, r, and s (options in batch  
166 mode) were set to 3, meaning that the input portions of ammonium (NH<sub>4</sub><sup>+</sup>), NO<sub>3</sub><sup>-</sup>, SO<sub>4</sub><sup>2-</sup>, and  
167 Cl<sup>-</sup> always remained in the condensed phase and did not produce corresponding gas-phase  
168 species, such as nitric acid (HNO<sub>3</sub>) and hydrochloric acid. The aqueous-phase NO<sub>3</sub><sup>-</sup>  
169 concentration was calculated by dividing the moles of aqueous NO<sub>3</sub><sup>-</sup> by the AWC. Aerosol pH  
170 was calculated as the negative logarithm of the concentration of H<sup>+</sup>.

$$171 \quad [Na^+]_{eq} = [Na^+] + [K^+] + 2[Mg^{2+}] + 2[Ca^{2+}] \quad (1)$$

## 172 2.3. Laboratory experiments

173 We illuminated ambient aerosols collected on filters or aqueous solutions in a dynamic  
174 chamber to mimic HCOOH formation in the atmosphere. The overall experimental setup is  
175 illustrated in Fig. S4. The dynamic chamber has a dimension of 25-cm length × 15-cm width ×  
176 4-cm height with the top side sealed by a transparent Teflon film. Each aerosol filter or solution  
177 sample was placed in a quartz Petri dish (inner diameter: 35 mm, inner height: 7 mm) at the  
178 chamber's centre. Aerosol filter sampling details can be found in Text S1. A high-pressure  
179 xenon (Xe) lamp was used to simulate sunlight and its spectral irradiance is displayed in Fig.  
180 6d. Compared with standard air mass 1.5 solar irradiation (AM 1.5) corresponding to a solar  
181 zenith angle of 48.2°, the Xe lamp exhibited a smaller flux at 300–326 nm but a larger flux at  
182 326–420 nm. An air stream from a zero-air generator (EnviroNics, model 7000) served as the

183 carrier gas that delivered reaction products to the chamber's outflow. The weather conditions  
184 that prevailed during the field campaign were mimicked by maintaining the reactor's T at  
185 approximately 28 °C and adjusting the RH in the chamber to 70% by passing the carrier gas  
186 through a water bubbler. Prior to the introduction of a sample into the chamber, the background  
187 HCOOH concentration was monitored for 10 min with the light on and zero air added. After 1  
188 h of irradiation, 100 ppb of O<sub>3</sub> was introduced via a dynamic calibrator (EnviroNics® Series  
189 6100) and monitored using an O<sub>3</sub> analyser (Thermo Scientific Model 49i). An AM 1.5 filter  
190 (which removes light below 360 nm) and a 300–800 nm filter (which allows the passage of  
191 300-800 nm light) were applied to the Xe lamp to investigate the effect of the irradiation  
192 wavelength on the formation of HCOOH.

193 We conducted an experiment to explore the role of nitrate photolysis on the proposed  
194 particle-phase mechanism. A sample solution was prepared by mixing formaldehyde (HCHO,  
195 Sigma-Aldrich, 37 wt% in water) and sodium nitrate (NaNO<sub>3</sub>, Honeywell, 99.5% purity). The  
196 resulting solution contained 0.15 wt% HCHO and 0.2 M NaNO<sub>3</sub>, and was adjusted to pH 2.7  
197 by the addition of sulfuric acid (H<sub>2</sub>SO<sub>4</sub>, Sigma-Aldrich, 98% purity), as this was the E-AIM  
198 model's prediction of the average aerosol acidity during the entire campaign. We assumed  
199 that ·OH produced by NO<sub>3</sub><sup>-</sup> photolysis was the rate-limiting species due to its significantly  
200 lower abundance relative to organics and HCHO was taken as a representative example of  
201 potential precursors of HCOOH. However, it is important to note that the production rate of  
202 HCOOH from the oxidation of organics may be overestimated in the solution experiment  
203 because ·OH generated by nitrate photolysis can also react with other oxidizable species in the  
204 ambient atmosphere.

205 The average rate of production (ppb·s<sup>-1</sup>) of HCOOH (P<sub>HCOOH</sub>) during the 1-h irradiation  
206 was calculated by the following equation (Eq. (2)), derived from (Peng et al., 2022):

$$207 \quad P_{\text{HCOOH}} = \int_0^{60} (C_{\text{HCOOH}} - C_{\text{HCOOH-bkg}}) dt \times \frac{Q}{V} / 60 \quad (2)$$

208 where Q is the carrier gas flow rate (4 L min<sup>-1</sup>); V is the reactor chamber volume (1.875 L);  
209 and C<sub>HCOOH</sub> and C<sub>HCOOH-bkg</sub> (ppb) are the concentrations of HCOOH in the chamber after and  
210 before adding the sample, respectively. The photolytic loss of HCOOH was ignored, as the  
211 cross-section of HCOOH was beyond the spectral range of the Xe lamp (Burkholder et al.,  
212 2020).

213 We attempted to extrapolate the laboratory results to account for the field-observed  
214 concentrations of HCOOH. As photochemical aging occurs on aerosol surfaces and a strong  
215 correlation between the surface area (Sa) and the concentration of HCOOH observed in the  
216 field, the extrapolation was conducted based on Sa. The Sa in the chamber was calculated as  
217 the Sa of the filter divided by the chamber's volume, assuming that only the first layer of the  
218 aerosols was illuminated. Although this might have resulted in an underestimation of the Sa  
219 density in the chamber, this assumption was reasonable, because particles in the lower layers

220 would receive less light than those in the uppermost layer due to the light-screening effect of  
221 the first layer (Ye et al., 2017). The aging process was also influenced by light intensity, and as  
222 we discovered that the major oxidant was generated by the photolysis of particulate  $\text{NO}_3^-$  (See  
223 **Results**, section 2), the light intensity was normalised based on the photolytic frequency of  
224 aqueous  $\text{NO}_3^-$  ( $J_{\text{NO}_3^-(\text{aq})}$ ) due to the absence of an absorption coefficient for particulate  $\text{NO}_3^-$ .  
225 Although there is a redshift of the particulate  $\text{NO}_3^-$  absorption wavelength compared with the  
226 aqueous-phase  $\text{NO}_3^-$  absorption wavelength, our results should be reliable because we used  
227  $J_{\text{NO}_3^-(\text{aq})}$  as a reference for normalisation rather than for calculating an accurate  $J_{\text{NO}_3^-(\text{aq})}$  (Du  
228 and Zhu, 2011; Zhu et al., 2008). The  $J_{\text{NO}_3^-(\text{aq})}$  under the Xe lamp was  $8.85 \times 10^{-6} \text{ s}^{-1}$  and the  
229 daytime average  $J_{\text{NO}_3^-(\text{aq})}$  in the ambient air at our site was  $1.12 \times 10^{-5} \text{ s}^{-1}$  (Text S2). Both  
230  $J_{\text{NO}_3^-(\text{aq})}$  values were calculated assuming a quantum yield equal to 1. The normalised HCOOH  
231 production rate in the ambient air ( $P_{\text{HCOOH-nml}}$ ) was calculated using the following equation (Eq  
232 (3)):

$$233 \quad P_{\text{HCOOH-nml}} = P_{\text{HCOOH}} \times \frac{S_{\text{aamb}}}{S_{\text{acha}}} \times 1.266 \quad (3)$$

234 where  $S_{\text{aamb}}$  represents the field-measured Sa density;  $S_{\text{acha}}$  denotes the Sa density calculated  
235 for the chamber; and 1.266 is the ratio of the ambient  $J_{\text{NO}_3^-(\text{aq})}$  to the chamber  $J_{\text{NO}_3^-(\text{aq})}$ . For the  
236 aging process involving  $\text{O}_3$ , the photolytic rate constant of  $\text{O}_3$  generating  $\text{O}^1\text{D}$  ( $J_{\text{O}_3 \rightarrow \text{O}^1\text{D}}$ ) in the  
237 chamber ( $1.31 \times 10^{-5} \text{ s}^{-1}$ ) was also normalised to the average daytime  $J_{\text{O}_3 \rightarrow \text{O}^1\text{D}}$  ( $1.84 \times 10^{-5} \text{ s}^{-1}$ )  
238 under ambient conditions (Text S2). For the results of the aqueous solution, the  
239 concentrations of HCHO and  $\text{NO}_3^-$  were also normalised.

#### 240 2.4. Chemical box model

241 The Framework for 0-D Atmospheric Modeling (F0AM version 4.2.1) (Wolfe et al., 2016)  
242 coupled with Master Chemical Mechanism (MCM v3.3.1, <http://mcm.york.ac.uk>) (Jenkin et  
243 al., 2015) was employed to evaluate the HCOOH production rate from photochemical aging of  
244 aerosols compared with other sources at the field site. The physical loss due to dilution process  
245 was treated as a first-order loss with a rate coefficient of  $1/86,400 \text{ s}^{-1}$ , consistent with previous  
246 studies (Li et al., 2014; Yuan et al., 2015). The dry deposition rate was determined based on the  
247 deposition velocity and the boundary layer height (BLH). For HCOOH, a deposition velocity  
248 of  $1 \text{ cm s}^{-1}$  was employed (Müller et al., 2018). A sensitivity analysis of the deposition velocity  
249 was also conducted. The diurnal profile of BLH was acquired from a previous study at another  
250 coastal site in Hong Kong (Su et al., 2017). Wet deposition was not considered as there was no  
251 rainfall except on 3 October and 7 October. We simulated the averaged diurnal cycle for the  
252 whole campaign with field-observed relevant species constrained hourly in the model.  
253 Simulations were also performed daily for a 2-week period, from 24 September to 7 October.  
254 The details of input data are described in Text S3. The model was executed for three replicates  
255 to stabilise the intermediate species it generated, and the results from the final run were used

256 for further analysis.

257 The local sources of HCOOH at this site mainly consist of ship and biogenic emissions.  
258 The box model used in this study did not account for the contribution of ship emissions since  
259 the modelling period was dominated by continental outflows which is unfavourable for the  
260 transportation of HCOOH from ship emissions to our site as evidenced by the relatively low  
261 concentrations of NO<sub>x</sub> in the modelling period. To estimate the biogenic emissions, we used  
262 the algorithm of the Model of Emissions of Gases and Aerosols from Nature version 2.1  
263 (MEGAN v2.1) (Guenther et al., 2012), assuming instantaneous dilution into the whole box. It  
264 is worth noting that this approach may introduce some uncertainties in estimating biogenic  
265 emission at a specific location. The specific parameters used can be found in Text S3. For  
266 secondary formation mechanisms, we followed Yuan et al. (2015) by enhancing the secondary  
267 production of HCOOH by modifying the HCOOH yields obtained by the ozonolysis of alkenes  
268 and other unsaturated species, and by adding chemical processes (vinyl alcohol oxidation;  
269 photo-tautomerisation of vinyl alcohol; and the reactions of HCHO + HO<sub>2</sub> and CH<sub>3</sub>O<sub>2</sub>· + ·OH)  
270 to the MCM. However, the model used in this study was unable to account for the downward  
271 transport of HCOOH produced in clouds through a newly proposed multiphase pathway  
272 (Franco et al., 2021) due to its inability to assess the contribution of vertical mixing and aqueous  
273 phase chemistry.

## 274 3. Results and Discussion

### 275 3.1. Field measurements of HCOOH concentrations

276 The field site was exposed to two distinct types of air masses; initially, it was largely  
277 exposed to marine air masses, and later to coastal air masses. Marine air masses ( $T = 29.4 \pm$   
278  $2.0$  °C,  $RH = 85.8 \pm 7.0$  %) were warmer and more humid than coastal air masses ( $T = 25.7 \pm$   
279  $2.3$  °C,  $RH = 77.0 \pm 6.0$  %), and exhibited low concentrations of O<sub>3</sub> ( $15.0 \pm 8.9$  ppb) and high  
280 concentrations of NO<sub>x</sub> ( $6.2 \pm 4.5$  ppb). Conversely, coastal air masses were characterised by  
281 high concentrations of O<sub>3</sub> ( $53.6 \pm 14.2$  ppb) and low concentrations of NO<sub>x</sub> ( $1.9 \pm 1.6$  ppb).  
282 The high concentrations of NO<sub>x</sub> in the marine air masses are attributable to the emissions from  
283 ocean-going container ships that passed the site approximately 8 km to the south. A haze event  
284 occurred from 24 September to 2 October, due to a transition from marine to coastal air masses  
285 under stagnant conditions. O<sub>3</sub> concentrations steadily increased during the first 5 days, peaked  
286 on 29 September, and remained high until the end of the haze period (Fig. 1). Therefore, the  
287 potential HCOOH formation mechanism was analysed separately for these three distinct  
288 periods.

289 Ambient HCOOH concentrations significantly varied during the three periods. The average  
290 HCOOH concentration in marine air masses was  $191 \pm 167$  ppt; this was higher than those over  
291 the remote ocean, due to local emission sources, but significantly lower than those in urban  
292 environments (Table 1). In contrast, the ambient HCOOH concentrations in coastal air masses

293 were substantially higher, averaging  $996 \pm 433$  ppt, comparable with other measurements at  
294 rural or urban background sites. During the haze period, the concentrations of HCOOH  
295 displayed a pattern similar to the concentrations of  $O_3$ , with the daytime peak concentration  
296 increasing from 674 to 2790 ppt. A pronounced diurnal variation in the concentration of  
297 HCOOH was observed throughout the entire campaign, as illustrated in Fig. 2, consistent with  
298 other studies (Millet et al., 2015; Yuan et al., 2015). HCOOH concentrations rapidly increased  
299 after sunrise, peaking at approximately 1 pm (local time), and then quickly decreasing in the  
300 late afternoon, due to the weaker sunlight and lower BLH than earlier in the day.

301 HCOOH is widely recognised as a secondary photochemical product. Table 2 presents the  
302 Pearson correlation coefficients ( $r$ ) between the concentration of HCOOH and those of other  
303 air pollutants or other meteorological parameters during the three distinct periods. The  
304 concentration of  $HNO_3$  was strongly correlated with the concentration of HCOOH throughout  
305 the entire field campaign, consistent with other studies (Bannan et al., 2017; Millet et al., 2015).  
306 This finding suggests that HCOOH is predominantly generated through secondary  
307 photochemical mechanisms at this site, as  $HNO_3$  is a secondary photochemical product  
308 resulting from the reaction between  $\cdot OH$  and  $NO_2$ . The positive linear relationship between the  
309 concentrations of  $O_3$  and HCOOH also implies the secondary source of HCOOH.

310 A previous laboratory study revealed that HCOOH can be produced by the photochemical  
311 aging of aerosols (Malecha and Nizkorodov, 2016), which may be an important process in  
312 ambient air. In the coastal air masses and haze period, there was a strong correlation between  
313 the concentrations of HCOOH and PM, particularly between the concentrations of HCOOH  
314 and  $PM_{10}$ . This was also observed by Paulot et al. (2011) and suggests that HCOOH may be  
315 produced from PM. The  $Sa$  of  $PM_{10}$  was also highly correlated with the concentration of  
316 HCOOH in both coastal air masses and haze periods, indicating that HCOOH is mainly  
317 produced from reactions on aerosol surfaces. However, in the marine air masses, the  
318 concentration of HCOOH was not related to aerosols due to the low particle concentrations in  
319 such masses. To further explore the potential role of aerosol aging in HCOOH production, we  
320 plotted the correlation of HCOOH concentrations with  $Sa \times O_3$ ,  $Sa \times NO_3^-$ , and  $Sa \times O_3 \times NO_3^-$   
321 for the coastal air masses (Fig. 3). We found that the correlation coefficient significantly  
322 increased when  $Sa$  was combined with the concentration of  $O_3$  or  $NO_3^-$  or with the  
323 concentrations of both species, compared with these three factors being considered separately.  
324 This finding suggests that the HCOOH observed in the coastal air masses was not  
325 predominantly derived from gas-phase  $O_3$  oxidation of VOCs; rather, it was derived from  
326 heterogeneous or condensed-phase reactions on aerosol surfaces. The results during the haze  
327 period were similar. Therefore, photochemical aerosol aging may play a key role in HCOOH  
328 production as the aging process involves the reactive uptake of oxidants onto particle surfaces.

### 329 3.2. Laboratory experiments

330 Figure 4a presents the results of a typical aerosol-filter irradiation experiment. Upon turning

331 on the light, HCOOH was instantaneously produced, indicating a rapid transfer from the  
332 condensed-phase to the gas phase through photochemical reactions. Within 3 minutes, the  
333 HCOOH concentration reached 11.1 ppb, but when the light was turned off, the HCOOH  
334 concentration quickly returned to nearly background concentrations. This suggests that  
335 HCOOH was produced predominantly via photochemical reactions. The HCOOH  
336 concentration exhibited a logarithmic decay after its first peak concentration and this decay  
337 also occurred continued after its second peak concentration, which may be attributable to either  
338 the evaporative loss of HCOOH or the photochemical loss of oxidants (Ye et al., 2017). When  
339 the AM 1.5 filter was added, the HCOOH concentration decreased by approximately 48.1%  
340 within 5 min, and after the filter was removed, the HCOOH concentration returned to the  
341 logarithmic decay line. This suggests that there was only minor evaporation of HCOOH from  
342 the condensed-phase due to the increased temperature of aerosol surfaces under light irradiation.  
343 However, the addition of the 300–800 nm filter reduced the HCOOH concentration by only  
344 13.2%, indicating that the photochemical production of HCOOH primarily occurs at  
345 wavelengths lower than 360 nm. Given the agreement between the wavelength at which  $\text{NO}_3^-$   
346 absorbs light (290–350 nm) and the wavelength of HCOOH production ( $< 360$  nm), and the  
347 high correlation between the ambient HCOOH concentration and the product of Sa density and  
348  $\text{NO}_3^-$  concentration (as shown in Fig. 3), we infer that  $\cdot\text{OH}$  produced from  $\text{NO}_3^-$  photolysis  
349 were the major oxidants in the particle phase and thus drove HCOOH production. The  
350 production of HCOOH was also found to be dependent on  $\text{O}_3$ , as the concentration of HCOOH  
351 increased by 64.7% after the addition of 100 ppb of  $\text{O}_3$ .

352 We next extrapolated the production rate of HCOOH observed in the chamber to ambient  
353 conditions, using the method described in Section 2.3, to assess the role played by the  
354 photochemical aging of aerosols in HCOOH production. Table 3 summarises the HCOOH  
355 concentrations and production rates observed in the chamber experiments, and the normalised  
356 HCOOH production rates in ambient air under light and light +  $\text{O}_3$  conditions, respectively.  
357 The average  $P_{\text{HCOOH-nml}}$  without the addition of  $\text{O}_3$  was determined to be  $0.106 \text{ ppb h}^{-1}$ . The  
358 addition of 100 ppb of  $\text{O}_3$  increased  $P_{\text{HCOOH-nml}}$  by  $0.079 \text{ ppb h}^{-1}$ , indicating that the  
359 heterogeneous reaction between  $\text{O}_3$  and aerosols made a non-negligible contribution to HCOOH  
360 production. To quantify the contribution of this particle-phase pathway, we established a  
361 relationship between  $P_{\text{HCOOH-nml}}$  and three parameters:  $\text{PM}_{2.5}$  concentration (cPM), which  
362 represents the reactant concentration; Sa, which represents the available reaction area; and  
363  $j\text{NO}_2$ , which represents the light intensity. After multiplying these three factors, we discovered  
364 a strong linear correlation between  $P_{\text{HCOOH-nml}}$  and  $\text{cPM} \times \text{Sa} \times j\text{NO}_2$  (Fig. 4b). The intercept  
365 was set to zero, as there should be no HCOOH production when  $\text{cPM} \times \text{Sa} \times j\text{NO}_2$  is zero.  
366 Based on the correlation, we derived an equation (Eq. (4)) for calculating  $P_{\text{HCOOH-nml}}$  with  
367 assumption that  $P_{\text{HCOOH-nml}(\text{O}_3)}$  increased linearly with  $\text{O}_3$  concentration. This equation was then  
368 incorporated into a box model to assess the importance of this production pathway compared

369 to other sources (See Section 3.3).

$$370 P_{\text{HCOOH-nml}} = 0.0091x + 0.010_3 \times 0.0064x, \quad x = \text{cPM} \times \text{Sa} \times \text{jNO}_2 \quad (4)$$

371 Photolysis of particulate  $\text{NO}_3^-$  is an important source of  $\cdot\text{OH}$  (Zellner et al., 1990; Mack  
372 and Bolton, 1999). To investigate the potential production of HCOOH from this source, an  
373 irradiation experiment was conducted on a solution (Fig. 4c). The concentration of HCOOH  
374 increased linearly with time and did not reach a stable state after 90 min of illumination. This  
375 differs from the aerosol experiments and might have been due to the continuous evaporation of  
376 water from the solution caused by the heating effect of the light source, which would have  
377 concentrated the solution. To determine the appropriate time to calculate  $P_{\text{HCOOH}}$ , we also  
378 plotted the time series of HONO concentrations. This showed that the HONO concentration  
379 stabilised after 1 h of irradiation, suggesting that  $\text{NO}_3^-$  photolysis also reached a steady state.  
380 As  $\cdot\text{OH}$  produced from  $\text{NO}_3^-$  photolysis were the only oxidants present in the system, the actual  
381 HCOOH production rate at the initial HCHO concentration should have followed the same  
382 trend as the HONO concentration. Therefore, we chose 1 h after turning on the light as the  
383 appropriate time to quantify  $P_{\text{HCOOH}}$ , and found that at this time,  $P_{\text{HCOOH}}$  in the chamber was  
384 21.9 ppt  $\text{s}^{-1}$ .

385 We also attempted to extrapolate the results to ambient air, similar to the aerosol filter  
386 experiments. To do so, in addition to normalising Sa and light intensity, we needed to normalise  
387 the HCHO and  $\text{NO}_3^-$  concentrations. The average concentration of gas-phase HCHO ( $\text{HCHO}_{(\text{g})}$ )  
388 measured on 28 September was 2.35  $\mu\text{g cm}^{-3}$ . By using a ratio of 0.03 between the  
389 concentration of HCHO in the particle phase ( $\text{HCHO}_{(\text{p})}$ ) and the concentration of HCHO in the  
390 gas phase (Toda et al., 2014), the concentration of  $\text{HCHO}_{(\text{p})}$  was calculated to be 0.07  $\mu\text{g cm}^{-3}$ ,  
391 which is comparable to the concentrations that have been reported in previous studies (Klippel  
392 and Warneck, 1980; Toda et al., 2014). Based on the aqueous volume of aerosol calculated by  
393 the E-AIM model (0.02  $\mu\text{l m}^{-3}$ ), the HCHO mass concentration in the aqueous phase was found  
394 to be 3.5  $\text{g L}^{-1}$ . The  $\text{NO}_3^-$  concentration on the aerosol surface was determined to be 0.98 mol  
395  $\text{L}^{-1}$ . Therefore, the  $P_{\text{HCOOH}}$  in ambient air attributable to the aqueous oxidation of HCHO was  
396 estimated to be 0.41 ppb  $\text{h}^{-1}$ , which is 285% higher than the  $P_{\text{HCOOH}}$  attributable to the  
397 photochemical aging of ambient particles. This greater-than-100% contribution could be  
398 attributable to the simplicity of the solution system. In ambient air, other oxidisable species,  
399 such as halides (Peng et al., 2022; M. Xia et al., 2022) could also react with the  $\cdot\text{OH}$  produced  
400 from  $\text{NO}_3^-$  photolysis, which competes with HCHO. In summary,  $\text{NO}_3^-$  photolysis appears to  
401 be a critical source of oxidants during the photochemical aging process of aerosols.

### 402 3.3. Box model simulation

403 We next use a box model (see Methods 2.4) to evaluate the production and loss of HCOOH  
404 in four scenarios (Table 4) which include the default MCM mechanism (S1), modified with  
405 gas-phase reactions following Yuan et al. (2015) (S2), further addition of the photochemical  
406 aging source (S3), and further adding of a biogenic source (S4). Figure 5 presents a

407 comprehensive analysis of HCOOH budget of campaign-averaged diurnal profile. In the base  
408 case (Default MCM), the highest net production rate of HCOOH ( $P_{\text{HCOOH-net}}$ ) is  $0.018 \text{ ppb h}^{-1}$ ,  
409 significantly lower than the observed average rate of increase in HCOOH concentrations of  
410  $0.095 \text{ ppb h}^{-1}$  from 6 am to 1 pm. Despite an increase of  $P_{\text{HCOOH-net}}$  to  $0.031 \text{ ppb h}^{-1}$  in modified  
411 case, the modelled value still lower than the observed rate of change. In both cases, the reaction  
412 of  $\text{CH}_2\text{OO}$  Criegee intermediate biradicals with  $\text{H}_2\text{O}$  was identified as the major source of  
413 HCOOH, accounting for about 68% of the currently known sources.  $\text{CH}_2\text{OO}$  is formed from  
414 seven excited biradicals that originate from the  $\text{O}_3$  oxidation of various alkenes and unsaturated  
415 compounds (Saunders et al., 2003). Among these,  $\text{CH}_2\text{OOE}$  is the largest contributor to the  
416 production of  $\text{CH}_2\text{OO}$  (Fig. S5) and is generated by the ozonolysis of isoprene.

417 Incorporating the photochemical production of HCOOH from particles into the F0AM  
418 model (S3) resulted in substantial improvements in predictions. The peak  $P_{\text{HCOOH-net}}$  increased  
419 to  $0.073 \text{ ppb h}^{-1}$ , which is more than double that of the modified case. Among the secondary  
420 production mechanisms considered, the production of HCOOH from particles was found to be  
421 the largest source, accounting for 52.1% of the secondary production (Fig. 5c). The biogenic  
422 emissions (S4) also played an important role, contributing to 34.4% of the total production (Fig.  
423 5d). After considering all sources, including primary emissions and secondary productions, the  
424 modelled  $P_{\text{HCOOH-net}}$  ( $0.094 \text{ ppb h}^{-1}$ ) was much closer to the observed increase rate of HCOOH  
425 ( $0.095 \text{ ppb h}^{-1}$ ).

426 Figure 6 presents the observed and modelled concentrations of HCOOH using different  
427 mechanisms for the averaged diurnal profile throughout the whole campaign. It is evident that  
428 the predicted HCOOH concentration increased substantially after incorporating the  
429 productions from the photochemical aging of aerosols. However, the modelled HCOOH  
430 concentration is still lower than the observed value in Scenario 4, where all sources are included.  
431 The discrepancy may be explained by the inadequate treatment of physical processes in the box  
432 model, such as deposition, convection, and advection. The primary loss of HCOOH is via  
433 deposition, owing to its high solubility in water. To account for uncertainty in the deposition  
434 velocity ( $V_d$ ) of HCOOH, we conducted a sensitivity test of HCOOH production to various  $V_d$   
435 values in Scenario 4 (Fig. S6). The results revealed that a smaller deposition velocity results in  
436 higher modelled HCOOH concentrations. The daytime peak concentration increased by about  
437 20% when  $V_d$  decreased from  $1.00$  to  $0.50 \text{ cm s}^{-1}$ . The field-observed  $V_d$  of HCOOH ranges  
438 from  $0.43 \text{ cm s}^{-1}$  to  $1.10 \text{ cm s}^{-1}$  (Müller et al., 2018), and thus given the high humidity at the  
439 study site, the observed  $V_d$  of HCOOH of  $0.5 \text{ cm s}^{-1}$  should have been close to the lower limit.  
440 Although the modelled concentration with  $V_d = 0.50 \text{ cm s}^{-1}$  were similar to observed values,  
441 the model failed to accurately predict the timing of the initial increase, peak, and sharp decrease  
442 in HCOOH concentrations, indicating that other physical process, such as vertical mixing, also  
443 influence the HCOOH concentration. Therefore, to account for the complex physical processes,  
444 we employed a bimodal physical loss rate due to vertical dilution that varied with time of day

445 (1/21,600 s<sup>-1</sup> in daytime and a much smaller value of 1/518,400 s<sup>-1</sup> at night), as suggested by  
446 Yuan et al. (2015). It is clear that the model performed better in predicting the diurnal pattern  
447 using the bimodal physical loss rate compared to a constant value (Fig. 6).

448 After applying a bimodal physical loss rate, the model also predicts better in the continuous  
449 simulation of two weeks (Fig. S7), except for 30 September and 1 October. The observed  
450 HCOOH concentrations on these two days were significantly lower than the modelled values  
451 due to a lower nitrate proportion (13.5%) on 30 September compared to other days during the  
452 model period (22.2%). Therefore, the simplified parameterization using PM<sub>2.5</sub> may  
453 overestimate the production of HCOOH from photochemical aging of aerosols in areas with  
454 high PM concentrations but a low nitrate proportion. An improved parameterization using the  
455 concentrations of nitrate and organics should be developed in future studies.

456 To evaluate the role of aerosol photochemical aging on HCOOH production in a broader  
457 context, we also examined the HCOOH data over the remote marine boundary layer obtained  
458 from the Atmospheric Tomography Mission (ATom) aircraft campaign which was conducted  
459 around the globe during April-May 2018 (Wofsy et al., 2021) (Text S5). Our results show that  
460 the photochemical aging of aerosols was insignificant in remote ocean areas due to the low PM  
461 and nitrate concentrations found there. However, when these regions are affected by aged fire  
462 plumes containing higher levels of organics and nitrate, photochemical aging of aerosols  
463 accounts for the substantial sources of HCOOH. These results suggest the photochemical aging  
464 appears to be important in relatively polluted atmospheres.

## 465 4. Conclusion and implications

466 This study demonstrates high rates of HCOOH production from the photochemical aging  
467 of real ambient particles and the potential importance of this pathway in the formation of  
468 HCOOH under ambient conditions at a coastal site in Hong Kong. Incorporating aerosol  
469 photochemical aging significantly improved the performance of a widely used chemical box  
470 model, increasing the net HCOOH production rate by approximately three times compared to  
471 the default MCM. This underscores the significance of condensed-phase photochemistry and  
472 the necessity of incorporating its mechanisms into atmospheric models. However, the box  
473 model primarily accounts for local chemistry and does not fully capture the complex physical  
474 processes, primary emissions, and regional transport. Therefore, future research utilizing a  
475 chemical transport model that incorporates these factors is required to quantify the contribution  
476 of this aging pathway to the ambient HCOOH over a larger spatial scale.

477 Our solution irradiation experiments demonstrated the crucial role of NO<sub>3</sub><sup>-</sup> photolysis in  
478 HCOOH production via the production of ·OH. This suggests that NO<sub>3</sub><sup>-</sup> photolysis not only  
479 influences the aerosol-based production of inorganic species (such as HONO (Ye et al., 2017)  
480 and halogens (Peng et al., 2022; M. Xia et al., 2022)), but also the aerosol-based production of  
481 water-soluble organics. Our proposed parameterization was based on the mass concentration

482 of PM<sub>2.5</sub> as one contributing factor, which may lead to bias in the prediction of HCOOH  
483 production in other environments with different nitrate proportions. Future investigations are  
484 necessary to enhance our understanding of the underlying mechanisms in the photochemical  
485 aging of aerosols and develop an improved parametrization that considers the proportion of  
486 nitrate and organics in PM<sub>2.5</sub>.

487 The substantial production of HCOOH from condensed-phase photochemical reactions  
488 implies that this pathway may affect the composition and the volatility of SOA. In addition to  
489 HCOOH, other low-molecular-weight organic acids, such as acetic acid, may be produced via  
490 this mechanism, as observed in our irradiation experiments. Improving the constraints on the  
491 photochemical aging of aerosols will not only aid the understanding of the budget of these  
492 organic acids but also affect their SOA chemistry.

### 493 Data availability

494 The data that support the findings of this study are openly available in Zenodo at  
495 <https://10.5281/zenodo.8415792>. Other raw data are also available from the corresponding  
496 author, upon reasonable request.

### 497 Authors' contributions

498 T. W. arranged the field campaign and designed the laboratory irradiation experiment. Y. J. and  
499 M. X. conducted the field campaign and photochemical filter experiments. M. X. revised the  
500 model code. Y. J. conducted the photochemical solution experiments, analysed the data, ran the  
501 model, and wrote the draft manuscript. T. W. and M. X. revised the manuscript.

### 502 Competing interests

503 One author (Tao Wang) is a member of the editorial board of Atmospheric Chemistry and  
504 Physics. The authors have no other competing interests to declare.

### 505 Acknowledgements

506 We thank the Hong Kong Environmental Protection Department for allowing us to use the field  
507 study site and for providing data on VOCs, OVOCs, trace gases, PM mass concentrations, and  
508 ion compositions; the Hong Kong Observatory for providing the meteorological data; the Hong  
509 Kong Polytechnic University Research Facility in Chemical and Environmental Analysis for  
510 providing the ToF-CIMS; and Dr Zhao Jue for providing PM<sub>2.5</sub> filters, whose work is supported  
511 by projects (PolyU Project of Strategic Importance No. ZE2K and RGC-GRF No. 15203920).  
512 We are grateful to Steven Poon for his help with logistics.

795

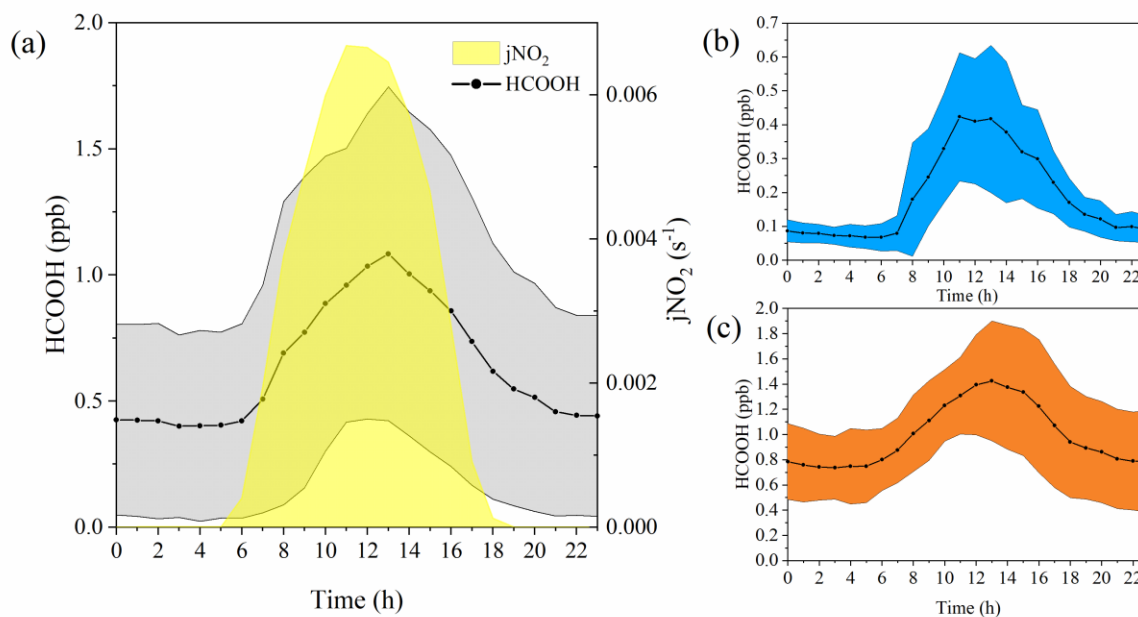

796

797 **Fig. 1** Times series of temperature (T); relative humidity (RH); nitrogen dioxide photolysis  
 798 frequency ( $j\text{NO}_2$ ); concentrations of ozone ( $\text{O}_3$ ), nitrogen oxides ( $\text{NO}_x$ ), and formic acid  
 799 ( $\text{HCOOH}$ ); and surface area density (SA) during the field campaign. Data were not collected  
 800 from August 29 to September 10 due to the persistently clean weather conditions, similar to  
 801 those during the initial stage of the campaign. The gap in data collection from October 8 to  
 802 October 17 was due to a rainstorm. Any other short gaps were caused by instrument  
 803 maintenance.

804 **Table 1** Summary of worldwide field-observed formic acid ( $\text{HCOOH}$ ) concentrations

Location	Type	Time	$\text{HCOOH}$ (ppb)	Reference
Pasadena, USA	urban	2010.06-07	$2.0 \pm 1.0$	(Yuan et al., 2015)
Kensington, London	urban background	2012.01-02 2012.07-08	0.63 (winter) 1.33 (summer)	(Bannan et al., 2017)
Shanghai, China	suburban	2017.06.18-12.23	$2.08 \pm 1.89$	(Xu et al., 2020)
Yorkville, USA	rural	2016.08.15-10.13	$1.17 \pm 0.85$	(Nah et al., 2018)
North Pacific Pacific and Atlantic	marine and marine	2008.07.29-08.19 2017.09-10 2018.04-05	$30 \pm 39.8$ ppt < 0.1	(Miyazaki et al., 2014) (Chen et al., 2021)
Colorado, USA	forest	2016.02.01-03.01 2016.04.15-05.15 2016.07.15-08.15 2016.10.01-11.01	$55 \pm 57$ ppt (winter) $30 \pm 24$ ppt (spring) $1.2 \pm 0.91$ (summer) $0.81 \pm 0.48$ (autumn)	(Fulgham et al., 2019)
Alabama, USA	deciduous forest	2013.06-07	2.5 (peak average daytime)	(Millet et al., 2015)
Hong Kong, China	coastal	2021.08.13-10.31	$0.58 \pm 0.53$	This study

805

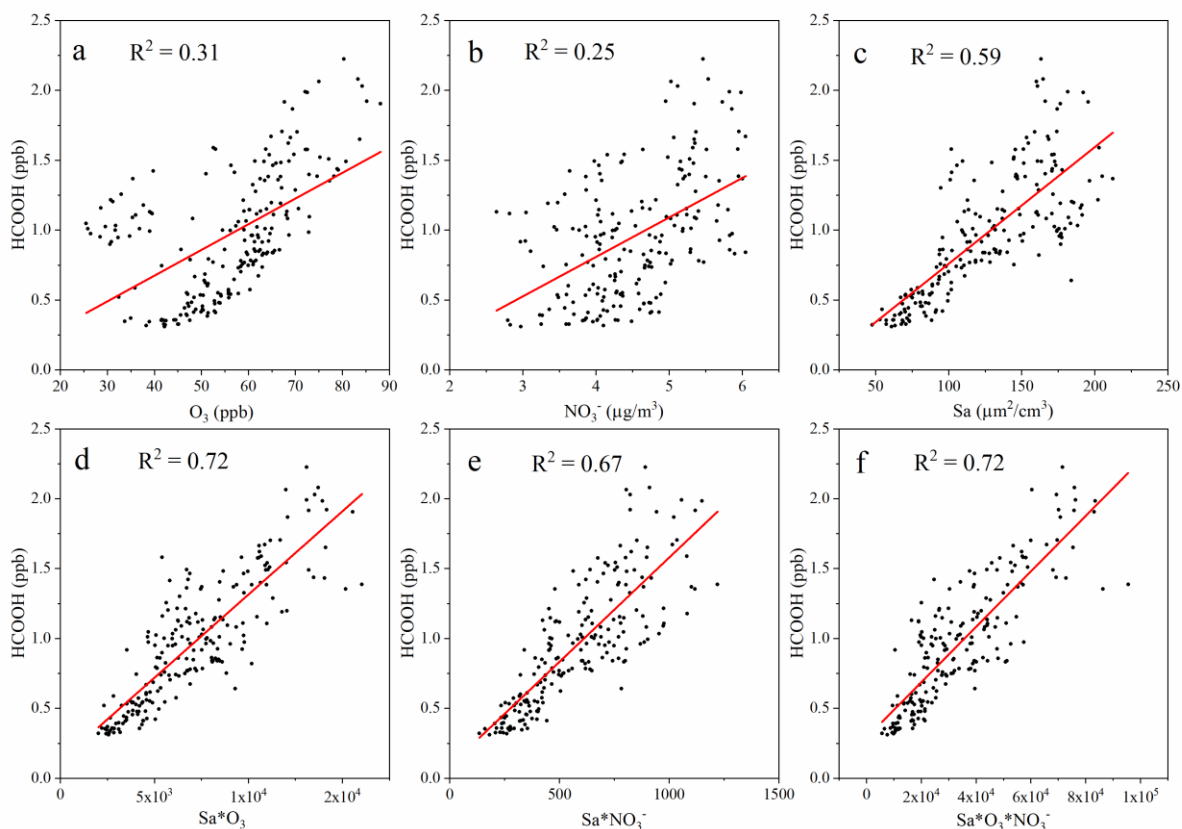

806  
 807 **Fig. 2** Diurnal variation in the concentrations of formic acid (HCOOH) in different periods. (a)  
 808 Diurnal cycle of HCOOH concentrations and frequency of nitrogen dioxide photolysis ( $j\text{NO}_2$ )  
 809 for the whole campaign; (b) and (c) diurnal cycle of HCOOH concentrations in marine and  
 810 coastal air masses, respectively. The shading represents the standard deviations of the  
 811 measurements.

812 **Table 2** Pearson correlation coefficient ( $r$ ) matrix between the concentration of formic acid and  
 813 other air pollutants, and related meteorological parameters, during three distinct periods.

Parameter	Coastal	Haze	Marine	Parameter	Coastal	Haze	Marine
$j\text{NO}_2$	0.41	0.58	0.65	Sa	0.73	0.68	-0.03
T	-0.27	0.70	0.72	Sa $\times$ $\text{NO}_3^-$	0.85	0.56	0.15
RH	-0.56	-0.51	-0.65	Sa $\times$ $\text{O}_3$	0.83	0.74	0.31
$\text{PM}_1$	0.79	0.66	0.05	$\text{HNO}_3$	0.75	0.59	0.69

$\text{NH}_3$	0.37	0.46	0.16	benzene	0.63	0.55	0.05

815

816 **Fig. 3** Scatter plot of the concentration of formic acid (HCOOH) and (a) the concentration of  
 817 ozone ( $O_3$ ); (b) the mass concentration of nitrate ions ( $NO_3^-$ ) in  $PM_{2.5}$ ; (c) the surface area  
 818 density ( $Sa$ ) of  $PM_1$  ( $\mu\text{m}^2 \text{cm}^{-3}$ ); (d) the product of  $Sa$  and the concentration of  $O_3$ ; (e) the  
 819 product of  $Sa$  and the concentration of  $NO_3^-$ ; and (f) the product of  $Sa$ , the concentration of  $O_3$ ,  
 820 and the concentration of  $NO_3^-$  in coastal air masses.

821  
 822 **Fig. 4** Results of the irradiation experiments. (a) Typical variation in formic acid (HCOOH)  
 823 concentrations during irradiation (in aerosols collected on 2 November 2020). AM 1.5 and  
 824 300–800 nm filters were added after the addition of 100-ppb ozone. (b) The correlation between  
 825  $P_{\text{HCOOH-nml}}$  and 2.5- $\mu\text{m}$  particulate matter ( $\text{PM}_{2.5}$ ) concentration ( $\text{cPM}$ )  $\times$  surface area ( $\text{Sa}$ )  $\times$   
 826 nitrogen dioxide photolytic frequency ( $J_{\text{NO}_2}$ ). (c) Variations in the concentrations of HCOOH  
 827 and nitrous acid (HONO) as a function of time after illumination of an aqueous solution of  
 828 formaldehyde and sodium nitrite at  $\text{pH} = 2.7$ . The vertical black line indicates the time at which  
 829 HONO stabilised. (d) Comparison of the irradiation spectrum of the xenon lamp used in this  
 830 study and standard air mass 1.5 solar irradiation (AM 1.5).

831 **Table 3** Summary of formic acid (HCOOH) concentrations and production rates observed in  
 832 chamber experiments and normalised HCOOH production rates in ambient air under light and  
 833 light + ozone ( $\text{O}_3$ ) conditions, respectively.  $\text{HCOOH}_{(\text{O}_3)}$  denotes the increased concentration of  
 834 HCOOH after the addition of 100 ppb  $\text{O}_3$ .

Date	$\text{HCOOH}_{(\text{light})}$ (ppt)	$\text{HCOOH}_{(\text{O}_3)}$ (ppt)	$P_{\text{HCOOH}(\text{light})}$ (ppt s <sup>-1</sup> )	$P_{\text{HCOOH}(\text{O}_3)}$ (ppt s <sup>-1</sup> )	$P_{\text{HCOOH-nml (light)}}$ (ppb h <sup>-1</sup> )	$P_{\text{HCOOH-nml (O}_3)}$ (ppb h <sup>-1</sup> )
