16 **Abstract.** The World Meteorological Organization (WMO) Global Atmosphere Watch (GAW) coordinates high-quality
17 atmospheric greenhouse gas observations globally and provides these observations through the WMO World Data Centre for
18 Greenhouse Gases (WDCGG) supported by Japan Meteorological Agency. The WDCGG and the National Oceanic and
19 Atmospheric Administration (NOAA) analyse these measurements using different methodologies and site selection to
20 calculate global annual mean surface CO₂ and its growth rate as a headline climate indicator. This study proposes a third
21 hybrid method named semi-NOAA, which is used as an independent validation of the methods as described by NOAA and
22 WDCGG. We apply the semi-NOAA to incorporate observations from most WMO GAW stations and 3D modelled CO₂
23 fields from CarbonTracker Europe (CTE). We found that different observational networks (i.e., the NOAA, GAW, and CTE
24 networks) and analysis methods result in differences in the calculated global surface CO₂ mole fractions equivalent to the
25 current atmospheric growth rate over a three-month period. However, the CO₂ growth rate derived from these networks and
26 CTE model output shows good agreement. Over the long-term period (40 years), both networks with and without continental
27 sites exhibit the same trend in the growth rate (0.030 ± 0.002 ppm per year). However, a clear difference emerges in the short-
28 term (one month) change of the growth rate. The network that includes continental sites improves the early detection of
29 changes in biogenic emissions.

37 **1 Introduction**

38 Global mean surface temperature averaged over 2011-2020 has increased by about 1.09°C relative to the average temperature
39 of 1850–1900 (Gulev et al., 2021). The increasing amount of atmospheric carbon dioxide (CO₂), together with increases in
40 other greenhouse gases, is the main driver of the warming (Eyring et al., 2021). After being relatively stable between 180 ppm
41 (ice age) and 280 ppm (interglacial) for the last 800,000 years (Lüthi et al., 2008), the annual average CO₂ level of the
42 atmosphere has increased since the industrial revolution from roughly 277 ppm in 1750 to 415.7±0.2 ppm in 2021 (WMO,
43 2022), due to emissions of CO₂ related to human activities like burning of fossil fuels and land use changes (Friedlingstein et
44 al., 2022). Mean global atmospheric CO₂ annual growth rate (G_{ATM}) is an important constraint on the global carbon cycle.
45 Based on the most recent Global Carbon Budget (GCB) analysis (Friedlingstein et al., 2022), the total emission of CO₂ due to
46 human activities was 10.2 ± 0.8 GtC yr⁻¹ in 2020, of which 3.0 ± 0.4 GtC yr⁻¹ was captured by the ocean sink and 2.9 ± 1 GtC
47 yr⁻¹ by the terrestrial sink, leaving a net increase of 5.0 ± 0.2 GtC yr⁻¹ of CO₂ in the atmosphere, corresponding to an
48 atmospheric CO₂ mole fraction increase of 2.4 ± 0.1 ppm yr⁻¹.

49 As the atmosphere mixes the contributions of all sources and sinks, an observational global average CO₂ mole fraction can be
50 constructed if there are enough observations to represent the spatial and temporal variation across the globe. Since most land
51 masses are concentrated in the Northern Hemisphere, and the highest anthropogenic emissions (e.g. during winter) occur in
52 the relatively narrow latitudinal band between 30 °N and 60 °N, relatively large spatial and temporal gradients in CO₂ mole
53 fraction exist in and around that region. Due to convective and advective mixing, the average mixing time of air within the
54 same latitudinal bands varies from several weeks to a month. However, mixing between latitudinal bands is slower, especially
55 the exchange between the northern and southern hemispheres, which has an approximate interhemispheric transport time of
56 1.4 ± 0.2 years (Patra et al., 2011). The interplay of the latitudinal and interhemispheric differences in fossil fuel emissions
57 and seasonal exchange with land biota (Denning et al., 1995) creates a latitudinal and interhemispheric gradient that requires
58 a sufficiently dense network to capture a representative global annual mean.

59 However, measurement stations that are close to sources or sinks may not be representative of a large atmosphere volume and
60 the average signal at their latitude. Therefore, inclusion of these observations might introduce significant biases on the global
61 mean CO₂ and its growth rate. These biases can be avoided by filtering of data and a careful selection of spatially representative
62 stations, as done by NOAA in their use of 43 stations (Fig. 1) that are considered to be representative for the Marine Boundary
63 Layer (MBL reference network, <https://www.esrl.noaa.gov/gmd/ccgg/mb/mb.html>). An additional data processing step
64 developed by NOAA to further avoid biases due to unrepresentative local signals is filtering and smoothing, by using a
65 combination of a low pass filter and decomposition into a fitted long-term trend and seasonal cycle (Thoning et al., 1989),
66 hereafter referred to as the NOAA analysis. These fits can also be used to fill gaps for missing data, though care must be taken
67 to avoid extrapolation errors before and beyond the time covered by the data record of the station. The WMO Global
68 Atmosphere Watch (GAW) World Data Centre for Greenhouse Gases (WDCGG) also publishes global averages mole fraction
69 for CO₂ and the other major greenhouse gases. They use curve fitting and filter methods that are very similar to those developed
70 by NOAA, but WDCGG includes continental locations that are potentially influenced by local sources and sinks (Tsumumi et
71 al., 2009).

72 The NOAA MBL observations are all part of the NOAA cooperative global air sampling network and analysed in the same
73 laboratory. All NOAA flask-air observations are traceable to the WMO X2019 CO₂ scale that is maintained by NOAA Global
74 Monitoring Laboratory (GML). In contrast, the WDCGG data originate from multiple independent laboratories (including
75 NOAA GML), that together form a network of hundreds of stations coordinated by WMO GAW. Having a multitude of

76 independent laboratories carries an additional risk of biases due to differences in sampling, measurement, and analysis
77 methods, for example calibration scales, although much care is taken to avoid these by coordination in the network and use of
78 a common calibration scale from the WMO Central Calibration Laboratory (CCL) guided by a set of strict measurement
79 compatibility goals (WMO, 2022). The different selection of stations results in a larger seasonal cycle amplitude in WDCGG
80 results compared to those of NOAA and a small but quite consistent bias in global surface annual mean CO₂ mole fraction
81 (Tsutsumi et al., 2009). The NOAA estimate of global surface annual mean CO₂ mole fraction is expected to be negatively
82 biased (e.g. ~0.35 ppm lower than the WDCGG estimate, Tsutsumi et al., 2009) compared to a full global surface average
83 because areas with large sources are not represented. However, none of the two afore mentioned approaches represents those
84 parts that have the atmosphere with low CO₂ mole fraction levels, i.e. the full troposphere (up to ~8-15 km altitude) and the
85 stratosphere or the regions of the world with substantial observational gaps.

86 In this paper we propose a data integration method to estimate the global mean surface CO₂ and its growth rate, named semi-
87 NOAA, which is used as an independent validation of the methods as described by NOAA and WDCGG through a completely
88 independent and open-source implementation. We apply the semi-NOAA methodology to incorporate CO₂ data from the
89 GAW network (139 stations, Fig. 1) and a well-established 3D global transport model (TM5: Transport Model 5, Peters et al.,
90 2004, Krol et al., 2005). We investigate the influence of small differences between the three methodologies and whether these
91 are significant or not for calculating the global mean surface CO₂ and its growth rate, how consistent the semi-NOAA and
92 WDCGG approaches are with each other, and how they compare with NOAA analysis and estimates derived from a CO₂
93 simulation with the 3D transport model TM5. These 3D CO₂ results for 2001-2020 using TM5 are performed in the
94 CarbonTracker Europe framework (CTE, Peters et al., 2004, Van Der Laan-Luijkx et al., 2017), where the CO₂ uptake and
95 emission fluxes are optimized by the inversion system to minimize the mismatch between the *in situ* observations and the
96 modelled CO₂ mole fraction. CTE generally has a good representation of the CO₂ field, with mean biases with respect to
97 independent aircraft measurements of generally less than 0.5 ppm (Friedlingstein et al., 2022). Furthermore, the inferred CO₂
98 fluxes from CTE fit well within the ensemble of those of other inversions used for the evaluation of Global Carbon Budget
99 (e.g. Friedlingstein et al., 2022).

100 **2 Methods and data**

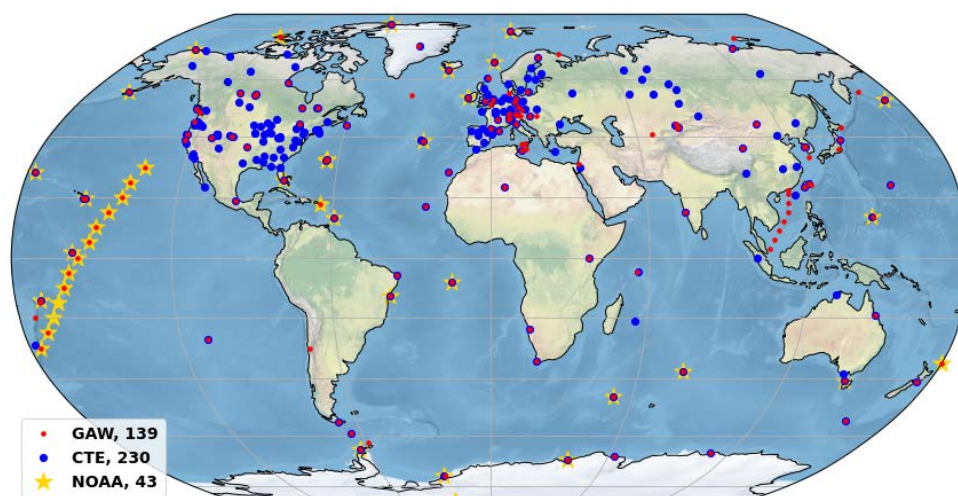

Figure 1. The selected GAW global network for CO₂ measurement (139 sites, red dots), the global network for the CTE evaluations (230 sites, blue dots), and the NOAA network (43 sites, yellow stars).

2.1 The WMO GAW observations and WDCGG analysis method

The WMO GAW network measurements are archived and distributed by WDCGG (World Data Center for Greenhouse Gases), hosted by the Japan Meteorological Agency. The GAW observations used in this study originate from 139 selected stations of the GAW network, and all observations are on the WMO standard scale, WMO-CO₂-X2019 (Hall et al., 2021). The details on the station selection are described in Tsutsumi et al., (2009), which mainly excludes stations located in the northern hemisphere that show large standard deviations from the latitudinal fitted curve. The remaining 139 stations show a more reasonable latitudinal scatter range (Fig. 1).

The WDCGG global analysis method (hereafter WDCGG method), as described in Tsutsumi et al., (2009), includes the mentioned station selection, a data fitting and filter (involves data interpolation and extrapolation), and calculation of the zonal and global mean mole fractions, trends, and growth rates. The procedure is also summarized in Text S1.

The output from the global analysis by the WDCGG method are used to compare against an alternative method (semi-NOAA) that we designed to follow as closely as possible the fit and filter method (Conway et al., 1994) deployed by NOAA and is described in the section 2.3.

2.2 CTE model output and station observations

CarbonTracker Europe (CTE) is a global model of atmospheric CO₂ and designed to keep track of CO₂ uptake and release at the Earth's surface over time (Van Der Laan-Luijkx et al., 2017). CTE incorporates an off-line atmospheric transport module (TM5, Peters et al., 2004, Krol et al., 2005) driven by ECMWF ERA5 data, and there are four prescribed fluxes (i.e. from ocean, biosphere, fire and fossil fuel), which are transported in the model, together with the transported initial CO₂ field. CTE also includes a data assimilation system that applies an ensemble Kalman filter to optimize the biogenic and ocean fluxes for a combination of plant-functional types and climate zones to improve the fit of the simulated concentrations with observations.

124 The optimized fluxes from the data assimilation have been used in Global Carbon Project (GCP) 2021 (Friedlingstein et al.,
125 2022), and CTE compares well to the other data assimilation systems used in GCP.

126 The CTE model data used here consisted of simulated monthly CO₂ mole fraction at 1x1 degree horizontal resolution and 25
127 levels in the vertical, the data period ranges from 2001 to 2020 which has no influence of model spin-up (Krol et al., 2018).
128 From the CTE output a set of simulated synthetic atmospheric CO₂ mole fractions with monthly resolution can be extracted
129 within grid cells where stations are situated. This study analyses monthly observation data (1980-2020) and synthetic time
130 series (2001-2020) by using the semi-NOAA method (section 2.3) and attempts to estimate global mean CO₂ mole fraction
131 and its growth rate. The observed CO₂ mole fractions are taken from 230 out of 290 global-wide distributed stations (Fig. 1,
132 the station selection is summarized in Text S2), the data come from the GLOBALVIEW-plus ObsPack data product (Kenneth
133 N., 2022), and include surface-based, shipboard-based and tower-based measurements.

134 2.3 The semi-NOAA method

135 The temporal pattern of CO₂ measurement records at locations around the globe can be explained as the combination of
136 roughly three components: a long-term trend, a non-sinusoidal yearly cycle (or seasonality), and short-term variations. This
137 study synchronizes monthly CO₂ records with the fitting and filter method obtained from the NOAA Global Monitoring
138 Laboratory (Thoning et al., 1989, Conway et al., 1994), without extrapolation. The station selection and CO₂ averaging method
139 are kept the same as in the WDCGG method (Text S1). This method will be referred to as the semi-NOAA method and will
140 be compared to the WDCGG method without extrapolation. The only difference from WDCGG method without extrapolation
141 is the fitting and filter method. All code for the method described here was developed in Python and is available as a Jupyter
142 notebook under a GPL license [<https://doi.org/10.18160/Q788-9081>]. The semi-NOAA method can be summarized by the
143 following three steps.

144 2.3.1. Fitting and filter

145 CO₂ records from each station can be abstracted as a combination of long-term trend and seasonality, which can be fitted by
146 a function consisting of polynomial and harmonics. We applied a linear regression analysis based on 3 polynomial coefficients
147 and 4 harmonics (Eq. 1) to fit CO₂ data using general linear least-squares fit (LFIT, Press et al., 1988).

$$148 \quad f(x) = a_0 + a_1 t + a_2 t^2 + \dots + a_k t^k + \sum_{n=1}^{n_h} (A_n \cos 2\pi n t + B_n \sin 2\pi n t) \quad (1)$$

149 where a_k , A_n and B_n are fitted parameters, t is the time from the beginning of the observation and it is in months and
150 expressed as a decimal of its year. k denotes polynomial number, $k = 2$. n_h denotes harmonic number, $n_h = 4$. Fig. 2
151 illustrates the function fit to CO₂ data to gain the annual oscillation (red line in Fig. 2a), is a combination of a polynomial fit
152 to the trend (blue line in Fig. 2a) and harmonic fit to the seasonality (green line in Fig. 2b).

153 The residuals are the difference between raw data and the function fit (black dots in Fig. 2c). The filtering method is based on
154 Thoning et al. (1989) which transforms CO₂ data from time domain to frequency domain using a Fast Fourier Transform
155 (FFT), then applies a low pass filter to the frequency data to remove high-frequency variations, and then transform the
156 filtered data back to the time domain using an inverse FFT. The short term (a cut-off value of 80 days, red line in Fig. 2c) and
157 long term (a cut-off value of 667 days, blue line in Fig. 2c) filters used here are the same as in NOAA method, and applied to
158 obtain the short term and interannual variations that are not determined by the fit function. The original part of the code is also
159 available as Python code from the NOAA website [<https://gml.noaa.gov/aftp/user/thoning/ccgcrv/>].

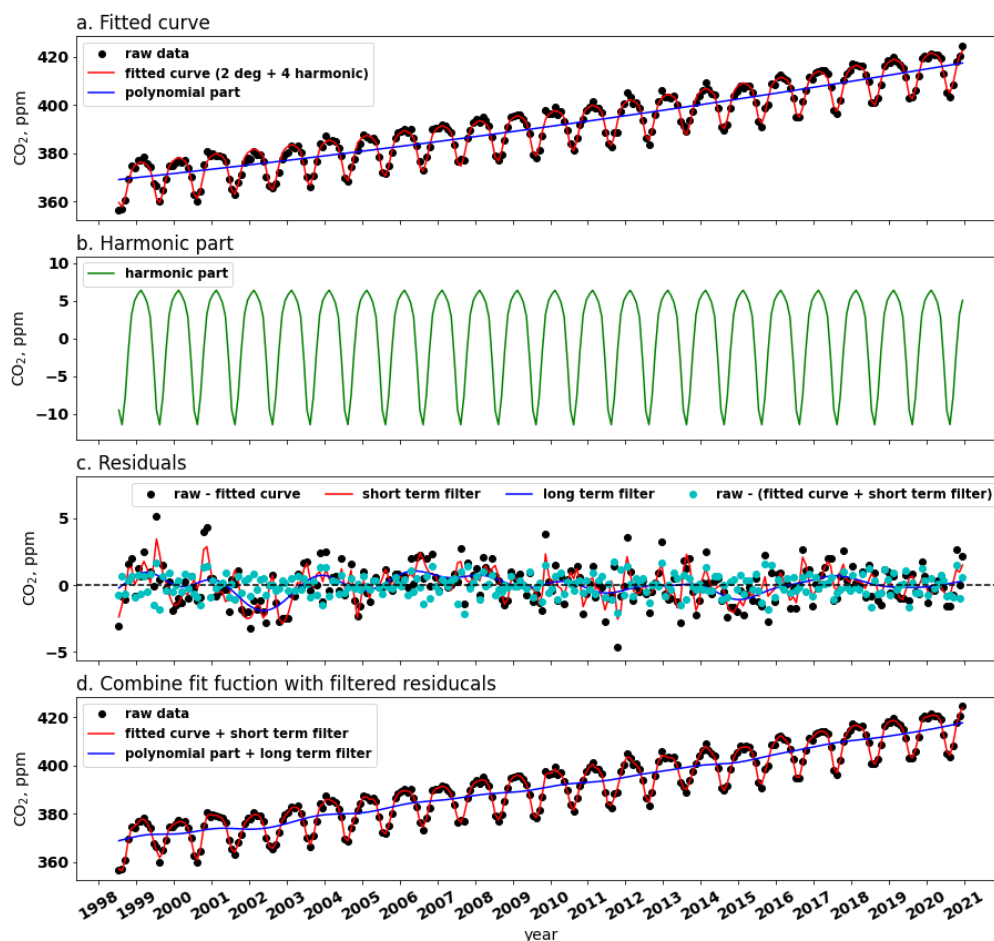

160 **2.3.2. Calculate smoothed CO₂ and long-term trend**

161 The results of the filtering residuals are then added to the fitted curve to obtain smoothed CO₂ and its long-term trend. The
 162 smoothed CO₂ comprises the fitted trend, the fitted seasonality and the smoothed residuals (red line in Fig. 2d), which only
 163 removes short-term variations or noise. The long-term trend comprises fitted trend and residual trend, which removes seasonal
 164 cycle and noise (blue line in Fig. 2d).

165 **2.3.3. Calculate CO₂ growth rate, G_{ATM}**

166 G_{ATM} is determined by taking the first derivative of the long-term trend. However, the growth is made up of discrete points,
 167 e.g. the black dots in Fig. 3a shows the trend points. In this case, a cubic spline interpolation is applied to the trend points, in
 168 which the spline curve passes through each trend points, as the blue line in Fig. 3a. G_{ATM} is obtained by taking the derivative
 169 of the spline at each trend point (Fig. 3b).

170

171 **Figure 2.** Example of analysed CO₂ data from PAL station (Pallas, Finland), illustrating semi-NOAA curve fitting and
 172 filter method. Panel (a) shows monthly averaged CO₂ (dots), curve fitting with 2-degree polynomial and 4-degree
 173 harmonics (red line), and long-term trend estimated by a 2-degree polynomial (blue line). Panel (b) shows seasonality
 174 estimated by 4-degree harmonics. Panel (c) shows the residuals of raw data from the function fit (black dots), the red

175 line is obtained by the short-term filter and the blue line is obtained by the long-term filter. The cyan dots show the
 176 residuals of raw data from the sum of fitted curve and smoothed residuals. Panel (d) shows final processed CO₂, which
 177 comprises fitted trend, fitted seasonality and smoothed residuals (red line). The blue line shows final trend which
 178 comprises fitted trend and residuals trend.

179
 180 **Figure 3.** Example of CO₂ growth rate, the raw data is the same as used in Fig. 2 from station PAL (Pallas, Finland).
 181 Panel (a) shows the trend points (black dots) and its cubic spline interpolation (blue line). Panel (b) shows the G_{ATM} at
 182 each trend point.

183 3 Results

184 Global averaged surface CO₂ and its G_{ATM} are calculated from the GAW observations from 139 sites (Fig. 1) using the
 185 WDCGG method with and without extrapolation and our semi-NOAA method, namely GAW (WDCGG+), GAW (WDCGG)
 186 and GAW (semi-NOAA). The semi-NOAA method is also applied to three CTE datasets: 1) observations from 230 sites
 187 selected in the CTE dataset (hereafter these sites are named as CTE network, Fig. 1) which comes from the ObsPack data
 188 product (Kenneth N., 2022), namely CTE_obs (semi-NOAA); 2) CTE model output at the sites (sampled at the same location,
 189 altitude and time), namely CTE_output (semi-NOAA); and 3) model output for full global grids (averaged over the first three
 190 levels, 0 to 0.35 km Alt.), namely CTE_global (semi-NOAA). We calculated the global means and its G_{ATM} by area-weighted
 191 averaging the zonal means over each latitudinal band (30°), as same as the CO₂ averaging method in Tsutsumi et al. (2009).
 192 A bootstrap method is used to estimate the uncertainties of global CO₂ mean and its G_{ATM}, which is an almost identical
 193 uncertainty analysis as presented by Conway et al. (1994) who constructed 100 bootstrap networks for the NOAA analysis.
 194 We construct 200 bootstrap networks which is consistent with the WDCGG analysis in Tsutsumi et al., (2009). For each
 195 bootstrap network, we randomly draw the same number of sites (as the actual network, e.g. 139 sites for GAW network) with
 196 replacement (or restitution) from the actual network, which means some sites are missing whereas others will be represented

197 twice or more often. We calculate global mean CO₂ mole fraction and its G_{ATM} for each network, and then calculate the
 198 statistics (i.e. mean and 68% confidence interval, CI) on the 200 networks. All uncertainties in this paper are reported as ±
 199 68% CI.

200 **3.1 Globally averaged surface CO₂ mole fraction and its G_{ATM}**

201

202 **Figure 4.** Comparison of globally averaged CO₂ mole fraction (a) and its G_{ATM} (b) from 1980 to 2020. Panel (a) shows
 203 the global monthly CO₂ mole fraction from 139 GAW sites (estimated from observations only) and those from 230 sites
 204 used in CTE (either from observations or model output) differs from NOAA estimates based on 43 MBL sites. Red
 205 and blue lines show the CO₂ derived from the GAW observations using semi-NOAA and WDCGG method without
 206 extrapolation, respectively. Green and orange lines show the CO₂ derived from observations and model output at the
 207 230 sites assimilated by CTE using semi-NOAA method, respectively. The dash lines show the mean over the available
 208 period. Panel (b) compares the global CO₂ growth rate derived from GAW observations using semi-NOAA (red line)
 209 and WDCGG method without extrapolation (blue line), CTE observations (green line) and model output (orange line)
 210 using semi-NOAA method, and the NOAA analysis (black line). The shadow area shows the uncertainty as 68%
 211 confidence interval obtained by the bootstrap analysis.

212 Global averaged surface CO₂ mole fraction derived from the GAW network (GAW (semi-NOAA) or GAW (WDCGG)) is
 213 0.329 or 0.336 ppm significantly ($p < 0.05$) higher than the NOAA analysis during 1980-2020 (red or blue line in Fig. 4a, Table
 214 S1a-b), this result is consistent with Tsutsumi et al., (2009) who found a 0.350 ppm higher global average in the GAW network
 215 during 1983-2006. The higher estimate from the GAW network can be explained by inclusion of more diverse sites, not only
 216 NOAA's MBL sites, but also more continental sites (Fig. 1). Both global CO₂ and its G_{ATM} derived from the GAW (semi-

217 NOAA) and GAW (WDCGG) are nearly overlapping (the red and blue lines) in Fig. 4a and 4b (as can also be seen by
218 comparing Fig. S1 and S2). The statistic metrics (Table S1a) show high agreement ($r=0.999$, $RMSE=0.053$ ppm, $ME=0.007$
219 ppm for the CO_2 mole fraction; $r=0.991$, $RMSE=0.081$ ppm yr⁻¹, $ME=0.005$ ppm yr⁻¹ for the G_{ATM}) between these two
220 methods, which confirms that the semi-NOAA method agrees well with WDCGG method without extrapolation. The
221 WDCGG method with extrapolation (i.e. GAW (WDCGG+)), where the long-term trend of each station is extrapolated to the
222 most long-running station period and added to its average seasonal variation to synchronize data period of all stations
223 (Tsutsumi et al., 2009), produces ~ 0.096 ppm significantly ($p<0.05$) higher values than the global surface CO_2 mole fraction
224 derived from the GAW (WDCGG) during the common period 1984-2020 (see Table S2), while the extrapolation has tiny
225 effect ($RMSE=0.062$ ppm yr⁻¹, $ME=-0.011$ ppm yr⁻¹, Table S2) on the CO_2 growth rate.

226 Global averaged surface CO_2 derived from CTE_obs (semi-NOAA) and CTE_output (semi-NOAA) are 0.422 ppm (1980-
227 2020) and 0.656 ppm (2001-2020) significantly ($p<0.05$) higher compared to the NOAA analysis, respectively (green and
228 orange lines in Fig. 4a). Comparing the global mean of CTE_obs (semi-NOAA) with CTE_output (semi-NOAA) during the
229 common period 2001-2020, we find a low bias (0.069 ppm in CTE_output, Table S1d-e and Table S3), which indicates that
230 the CTE model results can reproduce the global mean CO_2 levels reasonably well. The global annual CO_2 mole fraction from
231 CTE_obs (semi-NOAA), CTE_output (semi-NOAA) and CTE_global (semi-NOAA) is 0.368 (2001-2020), 0.299 (2001-
232 2020) and 0.186 (2001-2020) ppm significantly ($p<0.05$) higher than the result of the GAW (semi-NOAA), respectively (Table
233 S1d-f). The higher global mean from CTE_obs (semi-NOAA) and CTE_output (semi-NOAA) is mainly due to more sites in
234 the Northern Hemisphere in the CTE network compared to the GAW network. The lower bias between GAW (semi-NOAA)
235 and CTE_global (semi-NOAA) indicates that the GAW network provides a good representation of the low-level atmosphere
236 (i.e. 0 to 0.35 km altitude) at global scale (Table S1f), or the CTE model has a good performance in the low-level atmosphere.

237

238 **Figure 5.** Trend analysis of the global CO₂ growth rate from 1980 to 2020. Panel (a) shows the trends of CO₂ growth
 239 rate for the GAW network (red line), the CTE network (green line) and the NOAA network (black line) during the
 240 whole period 1980-2020, the CO₂ growth rate is derived from GAW (semi-NOAA), CTE_obs (semi-NOAA) and NOAA
 241 analysis (Fig. 4b). Panel (b) shows the trend of CO₂ growth rate for each month during 1980-2020, calculated as the
 242 derivative of the growth rate. The grey bands mark the period of three strong El Niño events, i.e. 1987-1988, 1997-1998
 243 and 2014-2016.

244 Despite differences in the global averaged surface CO₂ mole fractions derived from different networks and analysis methods,
 245 the G_{ATM} derived from GAW network, CTE network and its model output, and NOAA network agree well ($r > 0.903$,
 246 $RMSE < 0.192$ ppm yr⁻¹, $MAE < 0.158$ ppm yr⁻¹, $ME < 0.025$ ppm yr⁻¹, Table S1) during the common period (Fig. 4b). The trend
 247 analysis shows that the G_{ATM} increased steadily (0.030 ± 0.002 ppm per year each year) from 1980 to 2020 (Fig. 5a) based on
 248 the observations from the three networks (i.e. GAW, CTE and NOAA). This implies that over long-term period (here 40
 249 years) the networks with and without continental sites show the same trend of the G_{ATM}. Hence, the CO₂ advective transport
 250 and mixing plays a negligible role in estimating the long-term change of the G_{ATM}. However, there is a clear difference in the
 251 short-term (here one month) change of the G_{ATM} between the networks with and without continental sites (Fig. 5b). The El
 252 Niño event often diminishes net global C uptake (due to e.g. droughts, floods and fires) and increases global CO₂ growth rate
 253 (Sarmiento et al., 2010). The G_{ATM} derived from the GAW and CTE network (red and blue lines) increases earlier before the
 254 three strong El Niño events (marked as blue circles in Fig. 5b) and reaches the peak earlier during the El Niño events (marked
 255 as orange circles in Fig. 5b), compared to the G_{ATM} derived from the NOAA network (black line). This indicates that
 256 continental sites can help early detection of the change of G_{ATM} which is caused by biogenic emission or uptake changes. The

257 CTE network (green line) detects the change even earlier than the GAW network (red line) for the three El Niño events (Fig.
 258 5b), which is due to even more continental sites included in the CTE network (Fig. 1), although the more continental sites also
 259 induce the larger variability.

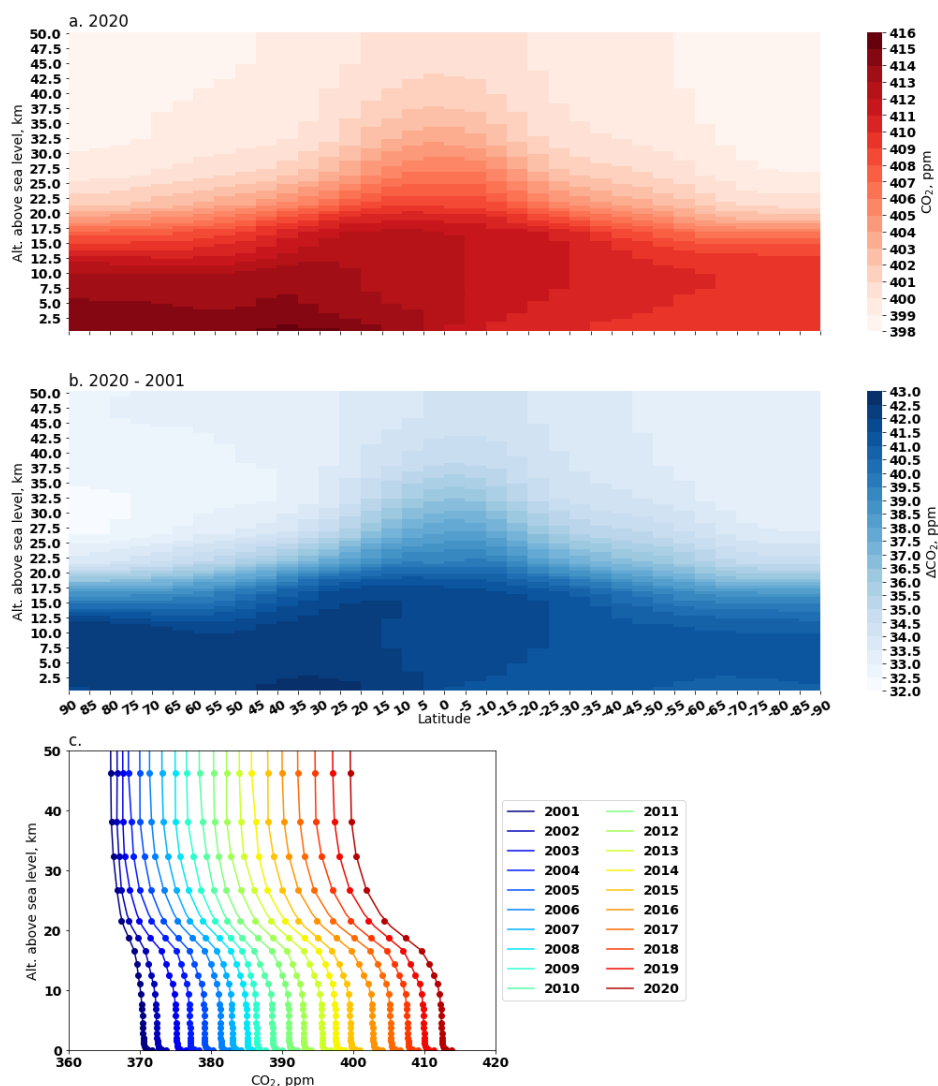

260 Table 1 shows the global annual CO₂ and its G_{ATM} derived from GAW (semi-NOAA), together with the uncertainty estimated
 261 by the bootstrap method. The global average surface CO₂ mole fraction has increased from 339.17±0.38 ppm in 1980 to
 262 413.06±0.16 ppm in 2020 (Table 1, Fig. S1). The uncertainty before 1990 is larger than after 1990, due to fewer measurement
 263 stations over the globe before 1990. The average G_{ATM} for the two decades before 2000 is about 1.54±0.08 ppm yr⁻¹, however,
 264 in the following two decades it increases to 1.91±0.05 ppm yr⁻¹ (2000-2009) and 2.41±0.06 ppm yr⁻¹ (2010-2019) (Table 1,
 265 Fig. S1).

266 **Table 1. Annual global averaged CO₂ mole fraction (Mean, ppm) and its G_{ATM} (ppm yr⁻¹) derived from GAW**
 267 **observations using semi-NOAA method. U(Mean) and U(G_{ATM}) respectively indicate the uncertainty of Mean and its**
 268 **G_{ATM} as 68% confidence interval. The annual value is averaged over the monthly values of the year.**

269 **3.2 Vertical profile of global CO₂ mole fraction**

270

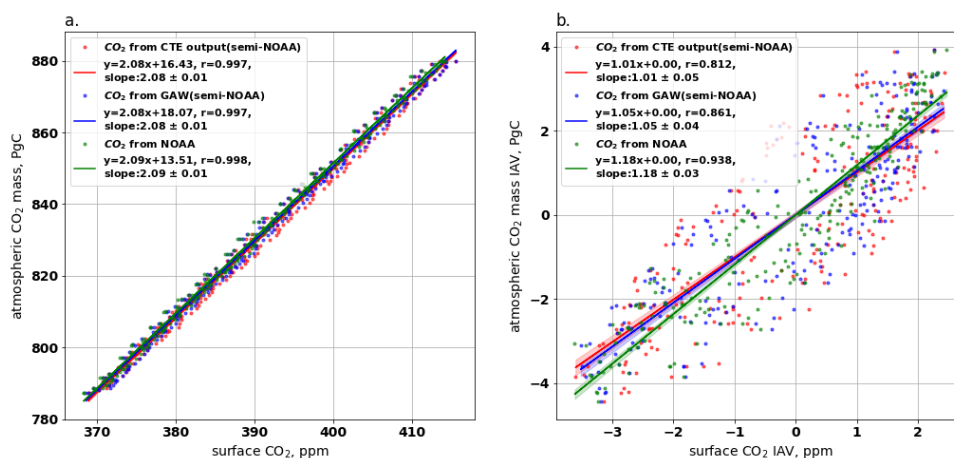

271 **Figure 6. Global vertical profile of CO₂ mole fraction derived from CTE model output. Panel (a) shows the vertical**
 272 **profile in 2020. Panel (b) shows the difference of the vertical profile between 2001 and 2020. Panel (c) shows the annual**
 273 **mean vertical profile from 2001 to 2020, the dots mark CTE vertical level heights and lines are the linear interpolation**
 274 **between the heights.**

275 The CTE model simulates CO₂ mole fraction over a global 3D grid, which allows us to view the modelled vertical CO₂ profile.
 276 In the lower atmosphere, highest CO₂ mole fraction are found in the Northern mid-latitude (dark red between 30 °N and 40
 277 °N, Fig. 6a), where more anthropogenic emissions take place, which are subsequently transported towards northern and
 278 southern latitudes. The latitudinal and interhemispheric gradient of atmospheric CO₂ found in Fig. 6a, is not only determined
 279 by the latitudinal and interhemispheric differences in fossil fuel emissions and seasonal exchange with terrestrial biota
 280 (Denning et al., 1995), but is also due to atmospheric transport (Patra et al., 2011). With increasing altitude, the gradient

281 between Northern and Southern hemisphere becomes small and levels out at higher altitudes (e.g. >50 km). When comparing
 282 the vertical profile change between 2001 and 2020 (Fig. 6b and 6c), the CO₂ mole fraction increases slower at the higher
 283 atmosphere (>25 km altitude) than the increase at the lower atmosphere (<25 km altitude). Fig. 6c shows that the vertical
 284 gradient (difference between 50 km and 0.05 km) changes from ~5 ppm for 2001 to ~13 ppm for 2020. The high vertical
 285 gradient in 2020 reflects the accumulation of CO₂ in the lower atmosphere, which is caused by continuous CO₂ emissions
 286 from the surface during 2001-2020 and slow vertical transport. The low vertical gradient in 2001 is partly due to low surface
 287 emission.

288 3.3 Relationship between the surface CO₂ mole fraction and atmospheric CO₂ mass

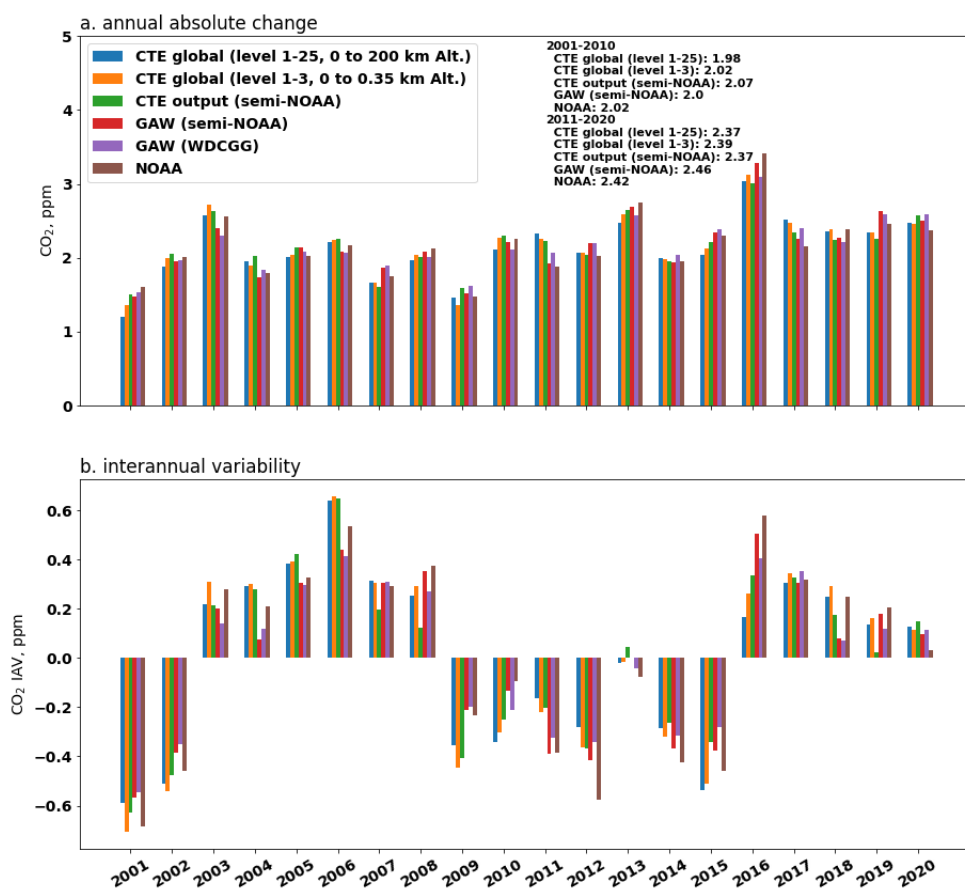

289
 290 **Figure 7. Relationship between the monthly surface CO₂ mole fraction and atmospheric CO₂ mass. The atmospheric**
 291 **CO₂ mass calculated from the 3D CTE output. In panel (a), the monthly surface CO₂ derived from the CTE_output**
 292 **(semi-NOAA), GAW (semi-NOAA) and NOAA analysis, presented as blue, red and green dots, respectively. Panel (b)**
 293 **compare the corresponding interannual variability (IAV) of the atmospheric CO₂ mass and the surface CO₂. The IAV**
 294 **is calculated as the anomaly departure from a quadratic trend.**

295 Atmospheric CO₂ mass calculated from the CTE output as a function of air mass and CO₂ concentration (Text S3), has
 296 increased from 789.46 PgC in 2001 to 877.88 PgC in 2020 (Fig. S3a). The spatial distribution of the atmospheric CO₂ mass
 297 can be seen in Fig. S3b and Fig. S3c. Monthly global surface CO₂ mole fraction derived from CTE output (red dots, Fig. 7a)
 298 at the 230 sites used in CTE with the semi-NOAA method (CTE_output (semi-NOAA)) and GAW observations (blue dots,
 299 Fig. 7a) at 139 GAW sites with the semi-NOAA method (GAW (semi-NOAA)) has a similar linear relationship (showing the
 300 same slope of 2.08 ± 0.01 PgC ppm⁻¹) as the monthly atmospheric CO₂ total mass derived from the CTE output. The NOAA
 301 CO₂ (green dots, Fig. 7a) shows a similar linear relationship (has a slope of 2.09 ± 0.01 PgC ppm⁻¹). The slope or conversion
 302 factor in Fig. 7a is slightly lower than the factor 2.12 PgC ppm⁻¹ used in Ballantyne et al. (2012) for the period 1980-2010.
 303 The small difference in conversion factor is expected, considering the different model and data used. We further compare the
 304 interannual variability (IAV, calculated as the anomaly departure from a quadratic trend) of the atmospheric CO₂ mass and
 305 the surface CO₂ (Fig. 7b), the coefficient of the linear relationship is very close to ~1.0, which indicates the temporal change
 306 in atmospheric CO₂ mass agrees with temporal change in surface CO₂ mole fraction. The NOAA network tracks atmospheric
 307 CO₂ change slightly better ($r = 0.938$) than the GAW ($r = 0.861$) and CTE ($r = 0.812$) networks, given the long resident time and
 308 well-mixed nature of atmospheric CO₂. Overall, the relationship found in Fig. 7 implies that the current surface CO₂ network
 309 can be a good indicator of the CO₂ mass change in the whole atmosphere through a linear relationship.

310 **3.4 Annual absolute change and interannual variability of global CO₂ mole fraction**

311

312 **Figure 8. Annual absolute change and interannual variability of global CO₂ mole fraction derived from different data**
 313 **(CTE model, GAW observation and NOAA observation) and analysis methods (semi-NOAA method, WDCGG method**
 314 **and NOAA method) for 2000-2020. Panel (a) shows the annual absolute change which is the difference between annual**
 315 **mean. Averages over 2001-2010 and 2011-2020 are also shown. Panel (b) shows the IAV which is calculated as the**
 316 **anomaly departure from a quadratic trend.**

317 Pressure-weighted average CO₂ in the lower atmosphere and whole atmosphere is derived from CTE output. The annual
 318 absolute change (calculated as the difference between annual mean) of CO₂ in the lower atmosphere (0 to 0.35 km altitude,
 319 orange bars in Fig. 8a) is more sensitive to surface sink and source than the change in the whole atmosphere (blue bars). The
 320 reason is that the whole atmosphere has a larger air volume than the lower atmosphere, and the change of the surface CO₂ is
 321 diluted due to horizontal and vertical transport. The CO₂ change derived from the observations of the GAW network (red bars
 322 for semi-NOAA method, purple bars for WDCGG method) and the NOAA network (brown bars), shows a small positive or
 323 negative difference from the CTE results over the different years. However, over the long term (e.g. decadal scale, 2001-2010
 324 and 2011-2020), the CTE model derived change of lower and whole atmospheric CO₂ shows good agreement (<0.09 ppm yr⁻¹)
 325 with the surface observation-based estimate, especially for the lower atmospheric CO₂ (<0.07 ppm yr⁻¹). Fig. 8b shows the
 326 IVA derived from CTE (blue, orange and green bars) follows a similar temporal pattern as the observation-based IVA derived

327 from the GAW and NOAA network (red, purple and brown bars), especially the IVA of the low-level atmosphere (orange
328 bars) show good agreement with the observation-based IVA ($r>0.971$, $RMSE<0.178$ ppm).

329 **4 Discussion**

330 During the past few decades, observational networks have been extended (e.g. from the NOAA MBL network) to the
331 continents (e.g. GAW network and CTE network, Fig. 1) in order to monitor global CO₂ concentrations and quantify CO₂
332 sources and sinks. Although the continental observations include contributions from both big sources of anthropogenic
333 emissions and big sources/sinks from terrestrial vegetation off/during the growing season, these continental observations show
334 an overall higher global surface CO₂ mole fraction in the global CO₂ analysis which indicates that they are influenced by a
335 net source. We find that the global mean derived from the GAW network is on average 0.329 (semi-NOAA method) or 0.336
336 (WDCGG method) ppm consistently higher than that derived from the NOAA network during 1980-2020, similarly ~0.350
337 ppm higher mole fraction in the GAW network was found in Tsutsumi et al. (2009) for 1983-2006. The CTE network even
338 leads to a higher global mean (0.422 ppm during 1980-2020), which is likely due to more observational sites locate in the
339 Northern Hemisphere where the highest anthropogenic emissions take place. This also explains the large fluctuation of CO₂
340 concentration during the winters and summers during 2001-2020 (green and orange lines, Fig. 4a). In future, we expect that
341 adding new observation sites (specially in Northern Hemisphere) into the current observational network (e.g. GAW network),
342 would lead to higher global surface CO₂ and a larger amplitude of the global CO₂ seasonal cycle in the global CO₂ analysis.
343 Although Friedlingstein et al. (2022) reported a 5.4% drop (~0.52 PgC) in fossil fuel CO₂ emissions in 2020 (due to restrictions
344 on e.g. transport, industry, power etc during the COVID-19 pandemic), the increase in annual CO₂ from 2019 to 2020
345 (2.60 ± 0.16 ppm yr⁻¹) remains at a similar level as from 2018 to 2019 (2.61 ± 0.05 ppm yr⁻¹). In principle, an equivalent drop of
346 roughly 0.25 ppm yr⁻¹ (according to the conversion factor 2.08 PgC ppm⁻¹ in Fig. 7a) or roughly 0.13 ppm yr⁻¹ (according to
347 the annual absolute change, red bars in Fig. 8a) in the growth rate should be visible for period 2019-2020 due to the declined
348 CO₂ emission. However, such short-term human activity induced change of the CO₂ growth rate may be hidden by the natural
349 variability. The bootstrap analysis is used in this study (also in Conway et al., (1994) and Tsutsumi et al., (2009)) to estimate
350 the uncertainty of the CO₂ temporal mean and its growth rate and to assess how sensitive the global value is to the distribution
351 of sampling sites. The relatively large uncertainty (± 0.16 ppm yr⁻¹) at the end of 2020 compared to previous years (Table 1)
352 is likely due to end-effect associated with the curve fitting and filter procedure. The end-effect is a tendency for the growth
353 rate to turn toward the mean value at the end of the record (Conway et al., 1994), therefore Conway et al. (1994) suggested
354 the last 6 months of the growth rate curves should be viewed with caution.

355 Our analysis shows that basing the CO₂ growth rate on GAW surface observations does not introduce a large bias (on average
356 agreement within 0.015 ppm yr⁻¹) compared to a full atmospheric analysis (Fig. 4b and 8, Table S1e-f). This full atmosphere
357 CO₂ was provided by the CTE model, in which the global annual mean CO₂ is significantly overestimated compared to GAW
358 observations (e.g. 0.299 ppm higher in CTE_output (semi-NOA), or 0.186 ppm higher in the CTE_global (semi-NOAA)
359 during 2001-2020). The overestimate derived from the CTE_output (semi-NOAA), i.e. CTE outputs at the CTE 230 sites, is
360 mainly due to more sites in the Northern Hemisphere in the CTE network than in the GAW network. The lower overestimate
361 derived from the CTE_global (semi-NOAA), i.e. CTE outputs at full global grids at the low-level atmosphere, implies that
362 the biases in CTE are not uniform spatially and attempt to balance out. We estimate the CTE bias by comparing the
363 observations and CTE outputs at the same sites, which results in 0.069 ppm low bias derived from the CTE outputs in
364 calculating the global surface CO₂ mole fraction.

365 Different observational networks (i.e. NOAA network, GAW network and CTE network) are analysed in this study, which
366 shows a difference in calculated global surface CO₂ mole fractions equivalent to the current atmospheric growth rate over a
367 three-month period. This implies that the station selection, especially if and how many continental observations are used, has
368 some but not a particularly strong influence on the derived global surface CO₂. Nowadays more and more continental
369 observations are established in order to monitor biogenic sources and sinks, and further provide insight into the climate change
370 and the associated ecosystem processes (Ciais et al., 2005, Ramonet et al., 2020). Such continental observations carry more
371 variability in measurements than the marine observations, which needs some caution when used in the mix of stations for
372 determining global surface CO₂ mole fraction. However, our study shows that continental sites can help early detect the change
373 of CO₂ growth rate caused by biogenic emission change (e.g. caused by El Niño events). Besides, current observational
374 networks (with and without continental sites) and CTE model show a good agreement within 0.025 ppm yr⁻¹ on the global
375 CO₂ growth rate over long-term period. This implies that the current observation networks (e.g. as shown in Fig. 1, represent
376 for multiple ecosystems, multiple sinks and sources, and different latitudes) have a similar good capacity to capture the global
377 surface CO₂ changes, although there is the spatial and temporal variability of the CO₂ growth rate (e.g. Conway et al. 1994).
378 We also notice that the uncertainty global CO₂ growth rate is approximately 0.07 ppm yr⁻¹, as derived from GAW (semi-
379 NOAA) and averaged over 1980-2020 (Table 1). In order to reduce this uncertainty, we recommend adding more stations to
380 the current observation network. We conducted an experiment (Fig. S4) which demonstrates that the uncertainty of the global
381 CO₂ growth rate exponentially increases as the number of land observation sites is reduced. To reduce the uncertainty to 0.02
382 ppm yr⁻¹ (equivalent to 1% of the global CO₂ growth rate), our experiment indicates that 332 land observation sites are required
383 (Fig. S4). However, the required number of sites also depends on their geographical distribution (i.e. CO₂ footprint coverage
384 of observation network, and the importance of the network design was addressed by Storm et al. (2022)), measurement
385 accuracy, and consistency.

386 Extrapolation beyond the measurement period extends knowledge gained from a limited period of measurements. During a
387 limited period of measurement, we can define the average seasonality, long-term trend, and short-term variation at a
388 measurement site. The long-term trend of individual site is extrapolated, for example by referring to the latitude reference
389 time series (Masarie and Tans, 1995) or the mean long-term trend over sites within a certain (e.g. 30°) latitudinal zone
390 (Tsutsumi et al., 2009), and then combining the extrapolated trend with average seasonality to produce the estimate beyond
391 measurement period. The extrapolation requires the assumption that the relationship of an individual site to the latitude
392 reference is invariant in time, however, the relationship between nearby sites is continuously changing (Masarie and Tans,
393 1995). Besides, the short-term variation is ignored or estimated from nearby sites, which introduces extra uncertainty from
394 extrapolation. In this study, we find that the WDCGG method with extrapolation (GAW (WDCGG+)) results in ~0.096 ppm
395 higher in the global surface CO₂ mole fraction than the WDCGG method without extrapolation (GAW (WDCGG)) using the
396 same GAW observations, although the extrapolation has a tiny effect on the growth rate (Table S2). Therefore, extrapolation
397 beyond the measurement period is not used in our analysis. With the increasing number of long-term measurements, this
398 extrapolation becomes less and less necessary.

399 5 Conclusions

400 The WMO Global Atmosphere Watch CO₂ network documents the gradual global accumulation of CO₂ in the atmosphere
401 due to human activities, and has been used to assess large-scale and long-term environmental consequence of fossil CO₂
402 emission and land use changes. Although the current CO₂ network is sparse due to operational costs and logistical constraints,
403 it has a good capacity to represent global surface CO₂ mole fraction and its growth rate and trends in atmospheric CO₂ mass

404 changes. The three different analysis methods yield very similar global CO₂ increase from 2001 to 2020, which gives
405 confidence to use either one of them in climate change study. The continuous monitoring of the atmospheric CO₂, basing on the
406 current GAW network together with reliable global data integration methods, provides essential information for policymakers
407 to support their efforts in mitigating the global warming.

408 **6 Data and Code Availability**

409 All data and code necessary to calculate the global mean surface CO₂ mole fraction and Atmospheric CO₂ mass is freely
410 available from ICOS Carbon Portal [<https://doi.org/10.18160/Q788-9081>]. The file list of results and code can be found in
411 Text S4.

412 **Acknowledgments**

413 We acknowledge Ingrid Lujckx for providing the TM5 data, WMO GAW Principal Investigators of the WMO GAW station
414 network for providing the observational data, Ed Dlugokencky for providing NOAA data and comments. Thanks to the support
415 from ICOS, GAW, NOAA and CTE group.
