23 **Abstract:**

24 The formation of ice in clouds is an important process in mixed-phase clouds, and
25 the radiative properties and dynamical developments of clouds strongly depend on
26 their partitioning between liquid and ice phases. In this study, we investigated the
27 sensitivities of the cloud phase to ice-nucleating particle (INP) concentration and
28 thermodynamics. Moreover, passive satellite retrieval algorithms and cloud products
29 were evaluated to identify whether they can detect cloud microphysical and
30 thermodynamical perturbations. Experiments were conducted using the ICOSahedral
31 Nonhydrostatic model (ICON) at the convection-permitting resolution of about 1.2 km
32 on a domain covering significant parts of central Europe, and were compared to two
33 different retrieval products based on SEVIRI measurements. We selected a day with
34 multiple isolated deep convective clouds, reaching a homogeneous freezing
35 temperature at the cloud top. The simulated cloud liquid pixel fractions were found to
36 decrease with increasing INP concentration both within clouds and at the cloud top.
37 The decrease in cloud liquid pixel fraction was not monotonic but was stronger in
38 high INP cases. Cloud-top glaciation temperatures shifted toward warmer
39 temperatures with increasing INP concentration by as much as 8 °C. Moreover, the
40 impact of INP concentration on cloud phase partitioning was more pronounced at the
41 cloud top than within the cloud. Moreover, initial and lateral boundary temperature
42 fields were perturbed with increasing and decreasing temperature increments from 0
43 to +/-3K and +/-5K between 3 and 12 km. Perturbing the initial thermodynamic state
44 was also found to affect the cloud phase distribution systematically. However, the
45 simulated cloud-top liquid pixel fraction, diagnosed using radiative transfer
46 simulations as input to a satellite forward operator and two different satellite remote
47 sensing retrieval algorithms, deviated from one of the satellite products regardless of
48 perturbations in the INP concentration or the initial thermodynamic state for warmer
49 sub-zero temperatures, while agreeing with the other retrieval scheme much better,
50 in particular for the high INP and high convective available potential energy (CAPE)
51 scenarios. Perturbing the initial thermodynamic state, which artificially increases the
52 instability of the mid- and upper-troposphere, brought the simulated cloud-top liquid
53 pixel fraction closer to the satellite observations, especially in the warmer mixed-
54 phase temperature range.

55

56 **Keywords:** Mixed-phase clouds, deep convection, INP, thermodynamics, satellite
57 forward operator, remote-sensing retrieval algorithms

58

59 **Key points:**

- 60 1. Cloud properties are retrieved using a satellite forward operator and remote
61 sensing retrieval algorithms with ICON simulations as input. To our knowledge,
62 it is the first time this approach has been used to retrieve cloud phase and other
63 microphysical variables.
- 64 2. Glaciation temperature shifts towards a warmer temperature with increasing
65 INP concentration both within the cloud and at the cloud top. Initial
66 thermodynamic states affect the cloud phase distribution significantly as well.
- 67 3. Simulated cloud-top liquid pixel fraction matches the satellite observations in
68 the high INP and high CAPE scenarios.

69

70 1. Introduction

71 In the temperature range between 0 and -38°C , ice particles and supercooled liquid
72 droplets can coexist in mixed-phase clouds. Mixed-phase clouds are ubiquitous in
73 Earth's atmosphere, occurring at all latitudes from the poles to the tropics. Because
74 of their widespread nature, mixed-phase processes play a critical role in the life cycle
75 of clouds, precipitation formation, cloud electrification, and the radiative energy
76 balance on both regional and global scales ([Korolev et al., 2017](#)). Deep convective
77 clouds are always mixed-phase clouds, and their cloud tops reach the homogeneous
78 freezing temperature, -38°C , in most cases. Despite the importance of mixed-phase
79 clouds in shaping global weather and climate, microphysical processes for mixed-
80 phase cloud formation and development are still poorly understood, especially ice
81 formation processes. It is not surprising that the representation of mixed-phase
82 clouds is one of the big challenges in weather and climate models ([McCoy et al.,
83 2016](#); [Korolev et al., 2017](#); [Hoose et al., 2018](#); [Takeishi and Storelvmo, 2018](#); [Vignon
84 et al., 2021](#); [Zhao et al., 2021](#)).

85

86 The distribution of cloud phase has been found to impact cloud thermodynamics and
87 Earth's radiation budget significantly ([Korolev et al., 2017](#); [Matus and L'Ecuyer,
88 2017](#); [Hawker et al., 2021](#)). The freezing of liquid droplets releases latent heat and
89 hence affects the thermodynamic state of clouds. Moreover, distinct optical
90 properties of liquid droplets and ice particles exert different impacts on cloud's
91 shortwave and longwave radiation. Simulation and observation studies reported that
92 the cloud phase in the mixed-phase temperature range of convective clouds is
93 influenced by aerosol and plays a significant role in the development into deeper
94 convective systems ([Li et al., 2013](#); [Sheffield et al., 2015](#); [Mecikalski et al., 2016](#)).
95 Observational studies reveal that the cloud phase distribution is highly temperature-
96 dependent and influenced by multiple factors, for example, cloud type and cloud
97 microphysics ([Rosenfeld et al., 2011](#); [Coopman et al., 2020](#)). Analyzing passive
98 satellite observations of mixed-phase clouds over the Southern Ocean, [Coopman et
99 al. \(2021\)](#) found that cloud ice fraction increases with increasing cloud effective
100 radius. Analysis of both passive and active satellite datasets reveals an increase in
101 supercooled liquid fraction with cloud optical thickness ([Bruno et al., 2021](#)).

102

103 A number of in-situ observations of mixed-phase clouds have been made in the past
104 several decades, covering stratiform clouds ([Pinto, 1998](#); [Korolev and Isaac, 2006](#);
105 [Noh et al., 2013](#)) and convective clouds ([Rosenfeld and Woodley, 2000](#); [Stith et al.,
106 2004](#); [Taylor et al., 2016](#)). Aircraft-based observations of mixed-phase clouds
107 properties reveal that the frequency distribution of the ice water fraction has a U-
108 shape with two explicit maxima, one for ice water fraction smaller than 0.1 and the
109 other for ice water fraction larger than 0.9, and the frequency of occurrence of mixed-
110 phase clouds is approximately constant when the ice water fraction is in the range
111 between 0.2 and 0.5 ([Korolev et al., 2003](#); [Field et al., 2004](#); [Korolev et al., 2017](#)).
112 These findings are very useful constraints of numerical models ([Lohmann and
113 Hoose, 2009](#); [Grabowski et al., 2019](#)). However, in-situ observations of mixed-phase
114 cloud microphysics are technically difficult and sparse in terms of spatial and
115 temporal coverage. Thus, understanding ice formation processes and determining
116 the climatological significance of mixed-phase clouds have proved difficult using
117 existing in-situ observations only.

118

119 Both observations and simulations reveal that ice-nucleating particles (INPs) impact
120 deep convective cloud properties including the persistence of deep convective
121 clouds and precipitation ([Twohy, 2015](#); [Fan et al., 2016](#)). However, the impact of
122 INPs on precipitation from deep convective clouds is still uncertain and may depend
123 on precipitation and cloud types ([van den Heever et al., 2006](#); [Min et al., 2009](#); [Fan
124 et al., 2010](#); [Li and Min, 2010](#)). Although the effects of INPs on convective
125 precipitation are not conclusive, it is certain that the interactions between convective
126 clouds and INPs affect cloud microphysical properties and hence cloud phase
127 distributions. In addition, previous numerical modeling studies on cloud-aerosols
128 interactions have focused on influences of aerosols acting as cloud condensation
129 nuclei (CCN) ([Fan et al., 2016](#)), which are linked to the ice phase e.g. through
130 impacts on the riming efficiency ([Barrett and Hoose, 2023](#)). Given the limited
131 knowledge on ice formation in deep convective clouds and significant uncertainties in
132 ice nucleation parameterizations, it is necessary to conduct sensitivity simulations to
133 investigate how ice formation processes are influenced by INP concentrations and
134 thermodynamic states in deep convective clouds.

135

136 In this study, with the help of realistic convection-permitting simulations using two-
137 moment microphysics, we address how and to what extent INP concentration and
138 thermodynamic state affect the in-cloud and cloud-top phase distributions in deep
139 convective clouds. In particular, cloud properties are retrieved using a satellite
140 forward operator and remote sensing retrieval algorithms with radiative transfer
141 simulations as input for a fair comparison to observations from SEVIRI. This method
142 allows us to compare model simulated cloud properties with remote sensing cloud
143 products directly, and is, to our knowledge, the first time this approach is used for the
144 cloud phase and related microphysical variables. We aim to evaluate the satellite
145 retrieval algorithms and investigate whether passive satellite cloud products can
146 detect cloud microphysical and thermodynamical perturbations.

147

148 This paper is structured as follows: In section 2, we introduce our model setups and
149 the experiment design, the satellite forward operator, remote sensing retrieval
150 algorithms, and datasets. Simulation results for the sensitivity experiments are
151 shown in section 3. Section 4 presents discussions; and we summarize the study
152 and draw conclusions in section 5.

153 **2. Data and Method**

154 **2.1. Model description**

155 The Icosahedral Nonhydrostatic (ICON) model ([Zängl et al., 2015](#)) is a state-of-the-
156 art unified modeling system offering three physics packages, which are dedicated to
157 numerical weather prediction (NWP), climate simulation, and large-eddy simulation.
158 ICON is a fully compressible model and has been developed collaboratively between
159 the German Weather Service (DWD), Max Planck Institute for Meteorology, German
160 Climate Computing Center (DKRZ), and Karlsruhe Institute of Technology (KIT). In
161 order to maximize the model performance and to remove the singularity at the poles,
162 ICON solves the prognostic variables suggested by [Gassmann and Herzog \(2008\)](#),
163 on an unstructured triangular grid with C-type staggering based on a successive
164 refinement of a spherical icosahedron ([Wan et al., 2013](#)). Governing equations are
165 described in [Wan et al. \(2013\)](#) and [Zängl et al. \(2015\)](#). The DWD has operated the
166 ICON model at a spatial resolution of about 13 km on the global scale since January
167 2015. In the global ICON, the higher-resolution ICON-EU (resolution 7 km) nesting

168 area for Europe has been embedded since July 2015. In this study, ICON-2.6.4 with
169 the NWP physics package is used and initial and lateral boundary conditions are
170 provided by the ICON-EU analyses.

171

172 For cloud microphysics, we use an updated version of the two-moment cloud
173 microphysics scheme developed by [Seifert and Beheng \(2006\)](#). The two-moment
174 scheme predicts the number and mass mixing ratios of two liquid (cloud and rain)
175 and four solid (ice, graupel, snow, and hail) hydrometers. The cloud condensation
176 nuclei (CCN) activation is described following the parameterization developed by
177 [Hande et al. \(2016\)](#). Homogeneous freezing, including freezing of liquid water
178 droplets and liquid aerosols, is parametrized according to [Kärcher et al. \(2006\)](#).
179 Heterogeneous ice nucleation, including the immersion and deposition modes, is
180 parameterized as a function of temperature- and ice supersaturation-dependent INP
181 concentration ([Hande et al., 2015](#)). The INP concentration due to immersion
182 nucleation is described as the following equation:

$$183 \quad C_{INP}(T_K) = A \times \exp[-B \times (T_K - T_{min})^C] \quad (1)$$

184 where T_k is the ambient temperature in Kelvin; A , B , and C are fitting constants with
185 different values to represent seasonally varying dust INP concentrations. The
186 parameterization for deposition INPs is simply scaled to the diagnosed relative
187 humidity with respect to ice (RH_{ice}):

$$188 \quad C_{INP}(T_K, RH_{ice}) \approx C_{INP}(T_K) \times DSF(RH_{ice}) \quad (2)$$

$$189 \quad DSF(RH_{ice}) = a \times \arctan(b \times (RH_{ice} - 100) + c) + d \quad (3)$$

190 where $C_{INP}(T_K)$ is given by Equation (1); a , b , c , and d are constants. More details
191 are found in [Hande et al. \(2015\)](#).

192 **2.2. Simulation setup and sensitivity experiments**

193 In this study, the setup consists of two different domains with one-way nesting
194 covering a major part of central Europe (Figure 1). The horizontal resolution for the
195 nested domains is halved from 2400 m to 1200 m in the innermost domain, and the
196 time steps for the two domains are 12 s and 6 s, respectively. 150 vertical levels are
197 used, with a grid stretching towards the model top at 21 km. The vertical resolution is
198 the same for all horizontal resolutions and the lowest 1000 m encompass 20 layers.

199 A 1-D vertical turbulence diffusion and transfer scheme is used for the 2400 m and
200 1200 m resolutions, referred to as numerical weather prediction (NWP) physics.
201 Deep convection is assumed to be explicitly resolved, while shallow convection is
202 parameterized for both domains. The simulations are initialized at 00:00 UTC on the
203 study day from ICON-EU analyses and integrated for 24 hours. Simulation results
204 were saved every 15 minutes. At the lateral boundaries of the outer domain, the
205 simulation of the model is updated with 3-hourly ICON-EU analyses. The nested
206 domains are coupled online, and the outer domain provides lateral boundary
207 conditions to the inner domain.

208

209 In nature, INP concentration varies across multiple orders of magnitude ([Hoose and](#)
210 [Möhler, 2012](#); [Kanji et al., 2017](#)). Thus, in our sensitivity experiments, heterogeneous
211 ice formation was scaled by multiplying the default INP concentration (Equation (1))
212 with a factor of 10^{-2} , 10^{-1} , 10^1 , 10^2 , 10^3 for both immersion freezing and deposition ice
213 nucleation. Together with a case with default INP concentration (case CTRL) and
214 one case switching off the secondary-ice production via rime-splintering process (the
215 so called Hallet-Mossop process), 7 cases were created in total to investigate the
216 impact of primary and secondary ice formation on cloud phase distribution in deep
217 convective clouds.

218

219 In order to assess the sensitivity of the cloud phase to thermodynamics, initial and
220 lateral boundary temperature fields are modified with increasing and decreasing
221 temperature increments, named experiments INC and DEC, respectively. The
222 temperature increment is linearly increased/decreased with height from 0 K at 3 km
223 to +/-3K and +/-5K at 12 km, creating 4 sensitivity experiments DEC03, DEC05,
224 INC03, and INC05. Above 12 km, the increment is constant up to the model top.
225 Initial temperature profiles are shown in Figure 2. The increasing or decreasing
226 environmental temperature leads to changes in the lapse rate and the stability of the
227 atmosphere, and hence results in decrease or increase in the convective available
228 potential energy (CAPE), respectively ([Barthlott and Hoose, 2018](#)). Thus, the CAPE
229 increases monotonically from case INC05 (spatial-averaged CAPE at 9:00 UTC: 413
230 J kg^{-1}) to case CTRL (724 J kg^{-1}) and finally to DEC05 (1235 J kg^{-1}). Note that the
231 relative humidity increases/decreases with decreasing/increasing temperature as the
232 specific humidity is unperturbed. The perturbations of INP concentration and

233 initial/lateral temperature profiles are motivated by [Hoose et al. \(2018\)](#) and [Barthlott](#)
234 [and Hoose \(2018\)](#), respectively. Complementary to these earlier studies, we now
235 investigate an ensemble of several deep convective clouds and focus on influences
236 of INP and thermodynamics on cloud phase distribution. Short descriptions of all
237 sensitivity experiments performed in this study are listed in Table 1.

238 **2.3. Satellite observations and retrieval algorithms**

239 The Spinning Enhanced Visible and Infrared Imager (SEVIRI) is a 12-channel imager
240 on board the geostationary Meteosat Second Generation (MSG) satellites. SEVIRI
241 has one high spatial resolution visible channel (HRV) and 11 spectral channels from
242 0.6 to 14 μm with a 15 min revisit cycle and a spatial resolution of 3 km at nadir
243 ([Schmetz et al., 2002](#)). Based on the spectral measurements of SEVIRI, a cloud
244 property data record, the CLAAS-2 dataset (CLOUD property dAtAset using SEVIRI,
245 Edition 2), has been generated in the framework of the EUMETSAT Satellite
246 Application Facility on Climate Monitoring (CM SAF) ([Benas et al., 2017](#)). CLAAS-2
247 is the successor of CLAAS-1 ([Stengel et al., 2014](#)), for which retrieval updates have
248 been implemented in the algorithm for the detection of clouds compared to CLAAS-1
249 ([Benas et al., 2017](#)) with the temporal coverage being extended to 2004-2015.
250 Retrieval algorithms for parameters that are important for this study are introduced
251 below. Detailed descriptions for the retrieval algorithms are found in [Stengel et al.](#)
252 [\(2014\)](#) and [Benas et al. \(2017\)](#) with the main features being summarized in the
253 following.

254

255 The MSGv2012 software package is employed to detect clouds and their vertical
256 placement ([Derrien and Le Gléau, 2005](#); [Benas et al., 2017](#)). Multi-spectral threshold
257 tests, which depend on illumination and surface types, among other factors, are
258 performed to detect cloud appearances. Each satellite pixel is assigned to categories
259 of cloud-filled, cloud-free, cloud water contaminated, or snow/ice contaminated.
260 Cloud top pressure (CTP) is retrieved with different approaches using input from
261 SEVIRI channels at 6.2, 7.3, 10.8, 12.0, and 13.4 μm ([Menzel et al., 1983](#); [Schmetz](#)
262 [et al., 1993](#); [Stengel et al., 2014](#); [Benas et al., 2017](#)). Cloud top height (CTH) and
263 cloud top temperature (CTT) are derived from CTP using ancillary data for
264 temperature and humidity profiles from ERA-Interim ([Dee et al., 2011](#)). The cloud top

265 phase (CPH) retrieval is based on a revised version of the multispectral algorithm
266 developed by [Pavolonis et al. \(2005\)](#). Clouds are categorized initially into six types,
267 that are liquid, supercooled, opaque ice, cirrus, overlap, and overshooting.
268 Subsequently, the binary cloud phase (liquid or ice) is generated based on the six
269 categories ([Benas et al., 2017](#)). Cloud optical and microphysical properties are
270 retrieved using the Cloud Physical Properties (CPP) algorithm ([Roebeling et al.,](#)
271 [2006](#)). SEVIRI visible (0.6 μm) and near-infrared (1.6 μm) measurements are used
272 to calculate cloud optical thickness (COT) and cloud particle effective radius (r_e) by
273 applying the [Nakajima and King \(1990\)](#) approach in the CPP algorithm ([Stengel et](#)
274 [al., 2014](#); [Benas et al., 2017](#)). Liquid water path (LWP) and ice water path (IWP) are
275 then computed as a function of liquid/ice water density, COT, and r_e of cloud water
276 and cloud ice following the scheme developed by [Stephens \(1978\)](#).

277

278 In this study we used instantaneous CLAAS-2 data with temporal resolution of 15
279 minutes and on native SEVIRI projection and resolution. In addition to the CLAAS-2
280 dataset, the recently developed software suite SEVIRI_ML (Philipp and Stengel
281 (2023) in preparation; code available on Github:

282 https://github.com/danielphilipp/seviri_ml) was applied to the SEVIRI measurements
283 to obtain cloud top phase and cloud top temperature for the selected case.

284 SEVIRI_ML uses a machine learning approach calibrated against Cloud-Aerosol
285 Lidar with Orthogonal Polarization (CALIOP) data. One feature of the SEVIRI_ML is
286 that it also provides pixel-based uncertainties such that values with low reliability can
287 be filtered out. We applied the retrieval algorithms to the model simulations in this
288 study and compared the results to satellite observations. A similar strategy was used
289 by [Kay et al. \(2018\)](#) for the evaluation of precipitation in a climate model with
290 CloudSat observations and termed “scale-aware and definition-aware evaluation”.

291 **2.4. Satellite forward operators**

292 In order to compare simulation results and satellite observations directly, SEVIRI-like
293 spectral reflectance and brightness temperatures are calculated using the radiative
294 transfer model for TOVS (RTTOV, v12.3)([Saunders et al., 2018](#)). RTTOV is a fast
295 radiative transfer model for simulating top-of-atmosphere radiances from passive
296 visible, infrared, and microwave downward-viewing satellite radiometers. It has been

297 widely used in simulating synthetic satellite images and assimilating radiances in
298 numerical models ([Saunders et al., 2018](#); [Pscheidt et al., 2019](#); [Senf et al., 2020](#);
299 [Geiss et al., 2021](#); [Rybka et al., 2021](#)).

300

301 In this work, ICON simulated surface skin temperature, near-surface pressure,
302 temperature, specific humidity, wind velocity, total liquid water content, total ice water
303 content, and effective radius of cloud liquid and cloud ice are used as input to drive
304 the RTTOV model. Before inputting to the RTTOV model, ICON simulations are
305 remapped onto SEVIRI's full disc coordinate. Brightness temperatures from 8
306 channels (at 3.9, 6.2, 7.3, 8.7, 9.7, 10.8, 12.0, and 13.4 μm) and reflectance from 3
307 channels (at 0.6, 0.8, and 1.6 μm) simulated by the RTTOV model are used as input
308 to run the remote sensing retrieval algorithms to derive CLAAS-2-like and
309 SEVIRI_ML-like retrievals, named ICON_RTTOV_CLAAS-2 and
310 ICON_RTTOV_SEVIRI_ML products, respectively.

311 **2.5. Synoptic overview**

312 The day 06 June 2016 was selected to analyze, which was dominated by
313 summertime deep convection located in central Europe. The synoptic forcing was
314 weak on the day, and convection was triggered mainly by local thermal instabilities.
315 The day has been discussed frequently in previous studies in terms of convection
316 triggering, cloud microphysics, and its parameterizations ([Keil et al., 2019](#); [Geiss et](#)
317 [al., 2021](#)).

318 **3. Results and discussion**

319 Perturbing INP concentration and temperature profiles directly affects microphysical
320 and thermodynamic processes of the developing deep convective clouds, and hence
321 impact in-cloud and cloud-top phase distributions. The following section shows
322 results and discussions on the sensitivities of cloud phase and cloud microphysics to
323 INP concentration and thermodynamic perturbations.

324 **3.1. Spatial distribution of cloud properties**

325 Before analyzing the results of sensitivity experiments, retrieved cloud properties via
326 RTTOV and the CLAAS-2 retrieval scheme for the CTRL case are compared to

327 CLAAS-2 products. Spatial distributions of derived LWP, IWP, and COT at 13:00
328 UTC of the CTRL case and CLAAS-2 satellite observation are shown in Figure 3.
329 Discrepancies are found between ICON simulation and CLAAS-2 satellite
330 observations in terms of spatial coverage and intensity. The ICON simulation
331 overestimates the cloud coverage of low-level liquid clouds compared to CLAAS-2
332 satellite observations, while LWP derived from the ICON simulation (case CTRL) is
333 smaller and more homogeneously distributed than that from the CLAAS-2
334 observation (Figure 3a and 3b). The spatial distributions of IWP and COT represent
335 the approximate location and spatial extension of deep convective clouds in this
336 study. The ICON simulation could reproduce cores of deep convective clouds of a
337 number and spacing comparable to observations, while the spatial extension and
338 intensity of individual deep convective clouds are not simulated very well by the
339 ICON model. The ICON simulation underestimates the spatial extension of deep
340 convective clouds but overestimates IWP and COT outside the convective cores
341 compared to the CLAAS-2 observation (Figure 3c-f).

342

343 Overall, the simulated clouds appear to be too homogeneous without sufficient
344 internal structure. [Geiss et al. \(2021\)](#) also reported significant deviations between
345 model simulations and satellite observations. The error sources are manifold and
346 may originate from the model physics as well as from the forward operator and the
347 retrieval algorithm. [Geiss et al. \(2021\)](#) investigated the sensitivity of derived visible
348 and infrared observation equivalents to model physics and operator settings. They
349 found that the uncertainty of the visible forward operator is sufficiently low while
350 infrared channels could bring errors in cloud-top variables. [Geiss et al. \(2021\)](#)
351 concluded that the primary source of deviations is mainly from model physics,
352 especially model assumptions on subgrid-scale clouds. In addition to the subgrid-
353 scale cloud scheme, multiple critical cloud microphysical processes missing from the
354 model, introducing significant uncertainties into the simulation results. For example,
355 entrainment mixing process is not resolved or parameterized in the model, which has
356 essential influences on processes at cloud boundaries and hence the cloud
357 properties ([Mellado, 2017](#)). Moreover, secondary ice processes including droplet
358 shattering and collisional breakup due to ice particles collisions are missing, which
359 have significant impacts on the cloud ice microphysics ([Sullivan et al., 2018](#);
360 [Sotiropoulou et al., 2021](#)).

361 **3.2. Sensitivity of microphysical properties to INP perturbation**

362 Perturbing INP concentration results in a direct influence on the heterogeneous
363 freezing processes and hence impacts on cloud microphysical properties.
364 Systematic variations have been found in the spatial- and time-averaged profiles of
365 mass mixing ratios of cloud hydrometeors as shown in Figure 4. All profiles
366 discussed here are averaged over cloudy pixels (defined as having a condensed
367 mass of cloud water plus total cloud ice greater than a threshold of $1.0 \times 10^{-5} \text{ kg kg}^{-1}$)
368 and over the time period from 9:00 to 19:00 UTC, when convection was well
369 developed. The mass concentration of ice crystals decreases with increasing INP
370 concentration (Figure 4a). However, the mass concentration of snow, graupel, and
371 rainwater increase with increasing INP concentration, especially in the high INP
372 concentration cases (cases $A \times 10^2$ and $A \times 10^3$).

373

374 In order to further reveal why ice crystal mass concentration decreases with
375 increasing INP concentration, we investigate process rates related to ice particle
376 nucleation and growth. Figure 5 shows spatial- and time-averaged (from 9:00 to
377 19:00 UTC) profiles of process rates for homogeneous freezing, heterogeneous
378 freezing, secondary ice production via the rime-splintering process, cloud droplets
379 rimed with ice crystals, rain droplets rimed with ice crystals, and collection between
380 ice and ice crystals. Heterogeneous freezing (Figure 5a) includes processes of
381 immersion freezing, deposition ice nucleation, and immersion freezing of liquid
382 aerosols ([Kärcher et al., 2006](#); [Hande et al., 2015](#)), see also equations (1) and (2).
383 Process rates of heterogeneous freezing increase significantly with increasing INP
384 concentration compared to the CTRL (Figure 5a). Compensating the change in
385 heterogeneous freezing, process rates of homogeneous freezing decrease
386 significantly with increasing INP concentration (Figure 5b). However, a decrease in
387 INP concentration (compared to the CTRL) does not have a strong influence on the
388 heterogeneous freezing mass rate, which is already low compared to the other
389 processes in CTRL. Riming processes of cloud droplets and rain droplets onto ice
390 crystals are greatly invigorated due to enhanced INP concentration (Figure 5d and
391 5e). Moreover, process rates of secondary ice production due to rime-splintering are
392 strengthened as well due to the increase in rimed ice, albeit much lower values.
393 Figure 5f shows process rates of collection between ice and ice crystals. Process

394 rates of collection between ice and ice particles increase with increasing INP
395 concentration, especially in high INP concentration cases (cases $A \times 10^2$ and $A \times 10^3$).
396 Process rates of collection of other ice particles all increase with increasing INP
397 concentration, similar to the collection between ice and ice crystals (not shown). The
398 increase in the riming of clouds and rain droplets onto ice crystals and collections
399 between ice particles leads to the increase in the mass concentration of snow,
400 graupel, and hail (Figure 4b and 4c). However, the total mass increase in snow,
401 graupel, and hail do not outbalance the decrease in the mass concentration of ice
402 crystals (Figure 4). The weakened homogeneous freezing is most likely the dominant
403 factor leading to the decrease in ice mass concentration in high INP cases,
404 considering the magnitude of the process rate of homogeneous freezing (Figure 5b).
405 Supercooled liquid and cloud droplets have been converted into ice crystals before
406 reaching the homogeneous freezing layer, leading to fewer supercooled droplets
407 remaining for homogeneous freezing. Even though homogeneous freezing is
408 weakened in high INP cases, the process rate of homogeneous freezing is still larger
409 than heterogeneous freezing, which means homogeneous freezing is the dominant
410 ice formation process in the convective clouds discussed in this study. Moreover, the
411 enhanced production of large ice particles (snow, graupel, and hail) in the highest
412 INP case, which sediment more rapidly to lower levels, leads to increased surface
413 precipitation by about 10% in the $A \times 10^3$ case (not shown). Interestingly, ice crystal
414 effective radius (r_e^{ice}) increases monotonically with increasing INP concentration,
415 especially in the mixed-phase layer (Figure 4e). [Zhao et al. \(2019\)](#) also reported an
416 increased r_e^{ice} with polluted continental aerosols in their simulated moderate
417 convection cases, and they attributed it to enhanced heterogeneous freezing and
418 prolonged ice crystal growth at higher INP loading.

419

420 This competition between homogeneous and heterogeneous freezing has been
421 discussed in previous studies ([Heymsfield et al., 2005](#); [Deng et al., 2018](#); [Takeishi
422 and Storelmo, 2018](#)). In contrast, simulations of mixed-phase moderately deep
423 convective clouds by [Miltnerberger and Field \(2021\)](#) indicate that cloud ice mass
424 concentration increases with increasing INP concentration, which is in opposition to
425 the findings in this work. The main reason is that the CTT is about -18°C in
426 [Miltnerberger and Field \(2021\)](#)'s study, and heterogeneous freezing does not

427 compete with homogeneous freezing. Thus, results on INPs effects on glaciation
428 processes in convective clouds can be opposite under different conditions.

429 **3.3. Cloud liquid mass fraction**

430 Varying the INP concentration has a direct impact on the primary ice formation.
431 Thus, it affects cloud liquid mass fraction within the clouds (directly for all cloudy
432 layers where heterogeneous freezing is active and indirectly for warmer and colder
433 temperatures) and at the cloud top. Cloud liquid mass fraction is defined as the ratio
434 of mass mixing ratio between cloud droplets (q_c) and the sum of cloud droplets and
435 cloud ice crystals (q_i). In-cloud liquid mass fraction, sampled at a time interval of 15
436 minutes between 9:00 to 19:00 from all cloudy pixels, is shown as scatterplots
437 versus temperature in Figure 6a-d. The corresponding frequencies of the occurrence
438 of the temperature/liquid fraction bins are shown in Figure 6e-h. Similar analyses
439 were made by [Hoose et al. \(2018\)](#), but for idealized simulations of deep convective
440 clouds. In-cloud liquid mass fractions smaller than 0.5 are quite common already at
441 temperature just below $-3\text{ }^\circ\text{C}$ except for the case without rime-splintering process
442 ($A \times 10^0$ _NSIP). The decrease in INP concentrations has limited effects on the in-
443 cloud liquid mass fraction (Figure 6c and 6g), while a stronger influence has been
444 found in the case with enhanced INP concentration (Figure 6d and 6h). The number
445 of pixels having high liquid mass fraction values at temperatures lower than $-30\text{ }^\circ\text{C}$
446 decreases with increasing INP concentration. In addition, more and more pixels
447 having liquid mass fraction smaller than 0.5 appear with increasing INP
448 concentration and the number of pure ice pixels increases with increasing INP
449 concentration as well. This is because higher INP concentration intensifies the
450 heterogeneous freezing processes (immersion freezing and deposition ice
451 nucleation) and invigorates the rime-splintering process as well (will be discussed in
452 section 3.4). Interestingly, at the lower end of the mixed-phase temperature range ($-$
453 $38 \sim -28\text{ }^\circ\text{C}$), there are fewer pixels having high liquid mass fraction in the high INP
454 case, and those remaining are mainly the ones at high vertical velocities (above ~ 10
455 m/s). This is probably because supercooled droplets are more easily frozen in high
456 INP cases and stronger updrafts are needed to offset the Wegener-Begeron-
457 Findeisen (WBF) process to maintain the supersaturation with respect to water.
458 Switching off the secondary ice production via rime-splintering process, pixels having

459 a liquid mass fraction smaller than 0.9 are reduced significantly at temperatures
460 between -10 °C and 0 °C (Figure 6b and 6f).

461

462 At the cloud top (Figure 7), the number of pixels having a liquid mass fraction smaller
463 than 0.5 increases with increasing INP concentration, which is the same as within
464 the clouds. “Cloud top” is defined as the height of the uppermost cloud layer (which
465 has a condensed mass of cloud water plus cloud total cloud ice greater than a
466 threshold of 1.0×10^{-5} kg kg⁻¹) in a pixel column. At the cloud top, the liquid mass
467 fraction has a more polarized distribution, with either large values or small values,
468 and intermediate values are less common than within the clouds. This is because the
469 vertical velocities at the cloud top are significantly smaller compared to that within
470 the cloud, which leads to a more efficient WBF process at the cloud top.

471 **3.4. Liquid cloud pixel fraction**

472 Liquid cloud pixel fractions are calculated differently for model simulations and
473 retrieved cloud products. For simulation results, a cloudy pixel having a cloud liquid
474 mass fraction larger than 0.5 is counted as a liquid pixel, otherwise, it is an ice pixel.
475 Both CLAAS-2 and SEVIRI_ML products and the corresponding retrievals derived
476 from ICON simulations by the satellite forward operators (see section 2.4) provide
477 binary cloud phase information (liquid or ice) only. For these data, the liquid cloud
478 pixel fraction is calculated as the ratio between the number of liquid cloud pixels and
479 the sum of all cloudy pixels.

480

481 Liquid cloud pixel fractions within clouds and at the cloud top are shown in Figure 8.
482 Decrease in INP concentration has limited impacts on the liquid cloud pixel fraction
483 for in-cloud layers. Increase in INP concentration leads to a decrease in liquid cloud
484 pixel fraction but not monotonically (Figure 8a). The decrease in liquid cloud pixel
485 fraction is significant in the highest INP concentration case (case $A \times 10^3$), while
486 decreases in intermediate INP concentration cases (cases $A \times 10^1$ and $A \times 10^2$) are
487 only obvious in temperature ranges from -30 °C to -20 °C and from -15 °C to -5 °C.
488 Moreover, liquid mass fraction decreases monotonically with increasing INP
489 concentration in the temperature range from about -15 to -35 °C both within the cloud
490 and at the cloud top (except for the lowest INP concentrations), and the decreasing

491 trend is more significant at the cloud top compared to within the cloud (not shown).
492 Switching off the rime-splintering process results in an increase in liquid cloud pixel
493 fraction in the temperature range between -10 °C and -3 °C, which is consistent with
494 the strong decrease in pixels of cloud liquid mass fraction lower than 0.9 in the same
495 temperature range (Figure 7b). The temperature at which the liquid cloud pixel
496 fraction equals 0.5 is often termed “glaciation temperature”. The glaciation
497 temperature shifts slightly to a warmer temperature by ~2 °C at the highest INP
498 concentration case (case $A \times 10^3$, Figure 8a).

499

500 Sensitivities of the cloud phase to INP concentration are more complex at the cloud
501 top than inside the cloud. Liquid cloud pixel fractions at the cloud top calculated
502 directly from ICON simulations on its native grid (~1200 m) are shown in Figure 8b.
503 Cloud-top liquid pixel fraction decreases significantly with increasing INP
504 concentration. In the temperature range between -35 °C and -15 °C, where
505 heterogeneous freezing processes (immersion freezing and deposition nucleation)
506 are dominant, the impact of INP is most pronounced. Above -15 °C, the impact of
507 INP does not disappear, especially in the highest INP concentration case (case
508 $A \times 10^3$). This is mostly likely due to the sedimentation of ice crystals from upper
509 layers and the secondary ice production invigorated by the WBF process. Switching
510 off the rime-splintering process increases cloud-top liquid pixel fraction only slightly
511 in the temperature range from -10 °C to -3 °C and is almost identical to the control
512 run (case CTRL) outside this temperature range. Interestingly, the shift of glaciation
513 temperature with increasing INP concentration is about 8 °C (Figure 8b) at the cloud
514 top, which is stronger than that inside the clouds (~2 °C, Figure 8a). A possible
515 explanation is that, typically, the vertical velocity at the cloud top is smaller than
516 within the cloud and the ice formation through the WBF process is expected to be
517 more efficient. Thus, the WBF process is more sensitive to INP perturbation at the
518 cloud top than within clouds, and leads to the glaciation temperature shifting to be
519 more significant at the cloud top.

520

521 Liquid cloud pixel fractions at the cloud top calculated directly from ICON simulations
522 on SEVIRI's grid (~ 5000 m) are shown in Figure 8c. They are noisier and do not
523 exhibit the small minimum between -10 °C and -3 °C related to rime-splintering, but

524 are otherwise very similar to Figure 8b. In contrast, the scale-aware and definition-
525 aware ICON_RTTOV_CLAAS-2 cloud-top liquid pixel fractions shown in Figure 8d
526 differ markedly from the direct or regridded model output. Above $-23\text{ }^{\circ}\text{C}$, increase
527 and decrease in INP concentration both lead to a decrease in cloud-top liquid pixel
528 fraction at certain temperature, but the high INP concentration cases (cases $A \times 10^2$
529 and $A \times 10^3$), still exhibit the lowest liquid fractions, and case $A \times 10^0$ _NSIP the highest.
530 Thus, the fingerprints of primary and secondary ice formation are retained in the
531 ICON_RTTOV_CLAAS-2 liquid fraction in this temperature range only for very strong
532 perturbations. At the same time, it must be noted that the decrease of the liquid pixel
533 fraction to values around 0.8 above $-15\text{ }^{\circ}\text{C}$ is not related to the rime-splintering
534 process, but to the application of the CLAAS-2 satellite simulator. Below $-23\text{ }^{\circ}\text{C}$, in
535 the high INP cases $A \times 10^2$ and $A \times 10^3$, cloud-top liquid pixel fractions even increase
536 with increasing INP concentration. In moderate and low INP cases, the impacts of
537 INP perturbation are not pronounced. Moreover, the shape of cloud-top liquid pixel
538 fraction decreasing with cloud-top temperature is different from that in Figure 8b.
539 Here, the fingerprints of the ice formation processes are completely lost. As
540 demonstrated in Figure 8c, remapping of simulation data onto SEVIRI's coarser grid
541 is not the cause of liquid pixel fraction difference between direct ICON output and the
542 ICON_RTTOV_CLAAS-2 diagnostics, but the CLAAS-2 retrieval algorithm itself is
543 responsible.

544

545 The satellite observed cloud-top liquid pixel fraction from CLAAS-2 is plotted as a
546 grey dashed line in Figure 8d. It does not reach 1.0 for all cases even as the cloud-
547 top temperature is approaching $0\text{ }^{\circ}\text{C}$, and shows a different temperature dependency
548 than the simulated curves. No matter how strong the INP concentration and rime-
549 splintering are perturbed, the retrieved cloud-top liquid pixel fractions from simulation
550 data deviate strongly from the CLAAS-2 products. In this context one should note
551 that in particular cloud edges have been found to be problematic situations for the
552 cloud retrievals, being to some extent responsible for biasing the liquid-pixel fraction
553 towards smaller values, in particular for the CLAAS-2 data.

554

555 Finally, the comparison to observations is repeated with the SEVIRI_ML retrieval
556 scheme applied to both simulated radiances (ICON_RTTOV_SEVIRI_ML) and the

557 SEVIRI observations themselves (Figure 8e). As SEVIRI_ML provides uncertainty
558 estimates, pixels for which either the cloud mask uncertainty or the cloud phase
559 uncertainty is larger than 10% are filtered out. While this ensures that only very
560 certain values are kept, it has a significant impact on the number of remaining values
561 as more than 90% of the pixels are filtered out. The filtering affects pixels rather
562 randomly, thus we could not identify any patterns of pixels, such as cloud edges, that
563 are primarily affected by the filtering. The resulting liquid pixel fractions
564 ICON_RTTOV_SEVIRI_ML bear a much stronger similarity to the regridded model
565 output in Figure 8c. Remaining differences are a noisier behavior, a plateau of non-
566 zero liquid pixel fractions even below $-40\text{ }^{\circ}\text{C}$, and a general shift to lower
567 temperatures. SEVIRI_ML applied to observations (dashed black line in Figure 8e),
568 with the same uncertainty criterion, exhibits the expected behavior with a liquid
569 fraction of approximately 1 above $-10\text{ }^{\circ}\text{C}$ and 0 below approximately $-30\text{ }^{\circ}\text{C}$, and
570 results in a very good agreement to the $A \times 10^3$ case. Generally, the SEVIRI_ML
571 retrieval algorithm is assumed to perform better than the CLAAS-2 scheme for both
572 cloud top temperature and cloud phase. This is because SEVIRI_ML employs state-
573 of-the-art neural networks to emulate CALIOP v4 data. Moreover, SEVIRI_ML
574 provides uncertainty estimates which facilitates filtering out pixels with high
575 uncertainties. Nevertheless, retrieval inaccuracies are unavoidable for passive
576 satellite retrievals which holds true for CLAAS-2 but also for SEVIRI_ML.

577 **3.5. Sensitivity of cloud phase to atmospheric stability perturbations**

578 In addition to the reference run (case CTRL), four cases with perturbations in initial
579 temperatures are analyzed. Mean updraft velocities increase gradually from the low
580 CAPE case INC05 to high CAPE case DEC05 (Figure 9) and cause differences in
581 cloud microphysics and cloud phase distributions.

582

583 In-cloud and cloud-top liquid cloud pixel fractions for the five cases are shown in
584 Figure 10. Systematic shifting of liquid cloud pixel fractions is detected both inside
585 clouds and at the cloud top. Liquid cloud pixel fraction decreases with increasing
586 CAPE from INC05 to DEC05. Both in-cloud and cloud-top glaciation temperatures
587 shift toward warmer temperatures as the CAPE increases from case INC05 to
588 DEC05. This is different from the results reported by [Hoose et al. \(2018\)](#) that cloud-

589 top glaciation temperatures hardly changed with increasing temperature in the
590 boundary-layer by 2 °C, and appears to be contradictory to the expectation that
591 stronger vertical velocities result in a lower glaciation temperature due to
592 suppression of the WBF process ([Korolev, 2007](#)). Further analysis (not shown)
593 revealed that the mass concentration of cloud ice particle increases while the mass
594 concentration of cloud droplet decreases with the increase in CAPE from case
595 INC05 to DEC05. Moreover, homogeneous and heterogeneous freezing are both
596 enhanced in the high CAPE cases (Figure 11), possibly due to more transport of
597 moisture to upper levels in the stronger updrafts (Figure 9). With more ice generated,
598 the WBF process can be stimulated despite the higher updrafts. Interestingly, cloud-
599 top liquid pixel fractions from the two high CAPE cases (cases DEC03 and DEC05)
600 are closer to SEVIRI observations, both using the CLAAS-2 retrieval (Figure 10c)
601 and the SEVIRI_ML retrieval (Figure 10d), especially in the temperature range
602 between -10 and -28 °C.

603

604 Compared to the INP perturbation, the impact of thermodynamical perturbation on
605 cloud phase distribution is significantly stronger within the cloud (Figure 8a and
606 Figure 10a). At the cloud top, the effect of perturbation in thermodynamics on the
607 cloud phase distribution is as large as the largest INP perturbation (case $A \times 10^3$).
608 Moreover, the impacts of thermodynamical perturbation on domain-averaged profiles
609 of cloud hydrometeors and process rates related to the ice cloud process are also
610 significantly stronger than the INP perturbation. Thus, the thermodynamical
611 perturbation is stronger than the INP perturbation when the entire depth of the cloud
612 is considered. Overall, perturbing initial thermodynamic states or CAPE of convective
613 clouds is as important as and may even stronger than the modifications to cloud
614 heterogeneous freezing parameterizations.

615 **4. Conclusions**

616 Remote sensing products, which cover the entire globe, provide a unique opportunity
617 to constrain the representation of cloud microphysics in global and regional
618 numerical models. In this study, instead of comparing simulation results to satellite
619 observations directly, we derived cloud properties using a radiative transfer model
620 and two different satellite remote sensing retrieval algorithms and then performed the

621 comparison. This enables us to make apples-to-apples comparisons between model
622 simulations and satellite observations. A series of numerical experiments were
623 performed applying convection-permitting simulations with perturbations in INP
624 concentrations and initial thermodynamic states to investigate their impacts on cloud
625 phase distributions in deep convective clouds. Moreover, cloud properties were
626 derived using a satellite forward operator and retrieval algorithms with ICON
627 simulations as input, and compared with CLAAS-2 and SEVIRI_ML satellite cloud
628 products to evaluate whether satellite retrievals could detect perturbations in cloud
629 microphysics and thermodynamics. Uncertainties in the forward operator were
630 however not assessed in this study, which may influence the validity of
631 corresponding results in some extent.

632

633 INP concentration was found to have a significant role in shaping cloud phase
634 distributions both within clouds and at the cloud top. Cloud liquid pixel fraction
635 decreased with increasing INP concentration both within the cloud and at the cloud
636 top, indicating a higher glaciation temperature and more intense heterogeneous
637 freezing processes in enhanced INP concentration cases. Interestingly, the
638 influences of INP did not increase linearly but are more pronounced in the high INP
639 concentration cases. In addition, the shifting of glaciation temperature was more
640 significant at the cloud top than within the cloud, which means the impact of INP
641 concentration on cloud phase distribution is more pronounced at the cloud top. It
642 turned out that with the CLAAS-2 retrieval scheme, the INP sensitivity of the cloud-
643 top phase distribution was not detectable, while the SEVIRI_ML retrieval scheme, for
644 which the most uncertain pixels could be excluded, resulted in a better agreement
645 and retained the sensitivity to INP. In contrast, secondary ice production via rime-
646 splintering did not have a detectable impact on the cloud-top phase distribution.
647 Therefore, in future studies, we recommend using the SEVIRI_ML retrieval scheme
648 and SEVIRI_ML satellite-based cloud products.

649

650 Ice crystal mass concentration did not increase but decreases with increasing INP
651 concentrations in the simulated deep convective clouds. Process rate analyses
652 revealed that heterogeneous freezing process rates increased with increasing INP
653 concentration, while homogeneous freezing process rates decreased with increasing
654 INP concentration. The competition between heterogeneous freezing and

655 homogeneous freezing for water vapor suppressed ice formation via homogeneous
656 freezing, which was the dominant nucleation process in the simulated deep
657 convective clouds, and hence reduced the cloud ice mass concentration. The
658 increase in heterogeneous nucleation in high INP cases invigorated riming and
659 collection processes of ice particles, making it easier for small ice crystals to grow
660 into large ice aggregates and sediment to lower levels. This was the reason why
661 precipitation increases in enhanced INP cases.

662

663 Perturbations in initial thermodynamic states had a strong impact on the cloud phase
664 distribution both within the cloud and at the cloud top, although the used
665 perturbations might be rather large compared to initial condition uncertainty in a
666 weather forecasting context. Moreover, cloud thermodynamics can perturb the cloud
667 phase distribution even stronger than microphysics. To completely distinguish
668 microphysical impacts from thermodynamic impacts, applying a piggybacking
669 approach ([Grabowski, 2015](#); [Thomas et al., 2023](#)) in future simulations is necessary.

670

671 Utilizing satellite forward operator (the RTTOV radiative model) and remote sensing
672 retrieval algorithms enabled us to derive cloud-top microphysical properties and
673 compare simulation results to satellite products more consistently. However, there
674 were significant differences in retrieved cloud-top liquid fractions between model
675 simulations and satellite products. The sources of errors were very complicated and
676 may come from simulation results, satellite operators, and retrieval algorithms, which
677 will be investigated in the future. Moreover, the cloud-top property analysis
678 presented in this study was based on domain-wide statistics, including clouds of
679 varying types. Statistical results could differ if individual clouds are tracked, as clouds
680 differ in different experiments in terms of locations and extensions. Although there
681 are significant uncertainties in satellite forward operators and retrieval algorithms,
682 passively remote-sensed cloud products provide potential opportunities to constrain
683 microphysical processes in numerical models.

684

685 Simulation results of this study revealed a close dependence of heterogeneous
686 freezing and cloud phase distribution on INP concentrations. Despite this finding, the
687 ice formation processes in deep convective clouds remain poorly understood. It is
688 necessary to investigate how and in which conditions the competition of

689 heterogeneous with homogeneous freezing for water vapor and cloud water depends
690 on INP availability and vertical velocities in different types of deep convective clouds.
691 Moreover, the importance of other secondary ice production processes than rime-
692 splintering (droplet shattering and collisional breakup) in deep convective clouds
693 need to be quantified in the future.

987 **Tables:**

988

989 Table 1: Setups of simulations performed in this study.

| Num | Experiment | Description |
|-----|------------------------|------------------------------------------------------------------------------------------------------------------------------------------|
| 1 | $A \times 10^0$ (CTRL) | Without any perturbations, the CTRL run, used as a reference. |
| 2 | $A \times 10^{-2}$ | INP concentrations for both immersion and deposition mode are scaled by multiplying parameter A in Equation (1) by 10^{-2} . |
| 3 | $A \times 10^{-1}$ | Same as num. 2, but multiplying by 10^{-1} . |
| 4 | $A \times 10^1$ | Same as num. 2, but multiplying by 10^1 . |
| 5 | $A \times 10^2$ | Same as num. 2, but multiplying by 10^2 . |
| 6 | $A \times 10^3$ | Same as num. 2, but multiplying by 10^3 . |
| 7 | $A \times 10^0$ _NSIP | INP concentration as in CTRL. The secondary ice production (rime-splintering process) is switched off. |
| 8 | DEC05 | Initial and lateral temperature decreases from 3 to 12 km with a maximum increment of 5 K. No perturbations in INPs ($A \times 10^0$). |
| 9 | DEC03 | Same as num. 8, but with a maximum increment of 3 K. |
| 10 | INC03 | Initial and lateral temperature increases from 3 to 12 km with a maximum increment of 3 K. No perturbations in INPs ($A \times 10^0$). |
| 11 | INC05 | Same as num. 10, but with a maximum increment of 5 K. |

Figure 4: Spatial- and time-averaged (9:00~19:00) profiles of cloud mass mixing ratios of (a) ice crystals, (b) snow, (c) graupel, (d) rainwater, and (e) ice crystal effective radius. Mass mixing ratio unit is g kg^{-1} and the unit of ice crystal effective radius is μm . Shaded area indicates the spatial- and time-averaged mixed-phase region.

1024

Figure 5: Spatial- and time-averaged (9:00~19:00) profiles of process rates of (a) heterogeneous freezing (immersion and deposition nucleation), (b) homogeneous freezing, (c) secondary-ice production (rime-splintering), (d) cloud droplets rimed with ice crystals, (e) rain droplets rimed with ice crystals, (f) collection between ice and ice. Unit is $\text{g kg}^{-1} \text{s}^{-1}$. The average mixed-phase layer ($0 \sim -38^\circ \text{C}$) is roughly in between 3.2 and 8.6 km. Shaded area indicates the spatial- and time-averaged mixed-phase region. Unit is $\text{g kg}^{-1} \text{s}^{-1}$.

1025

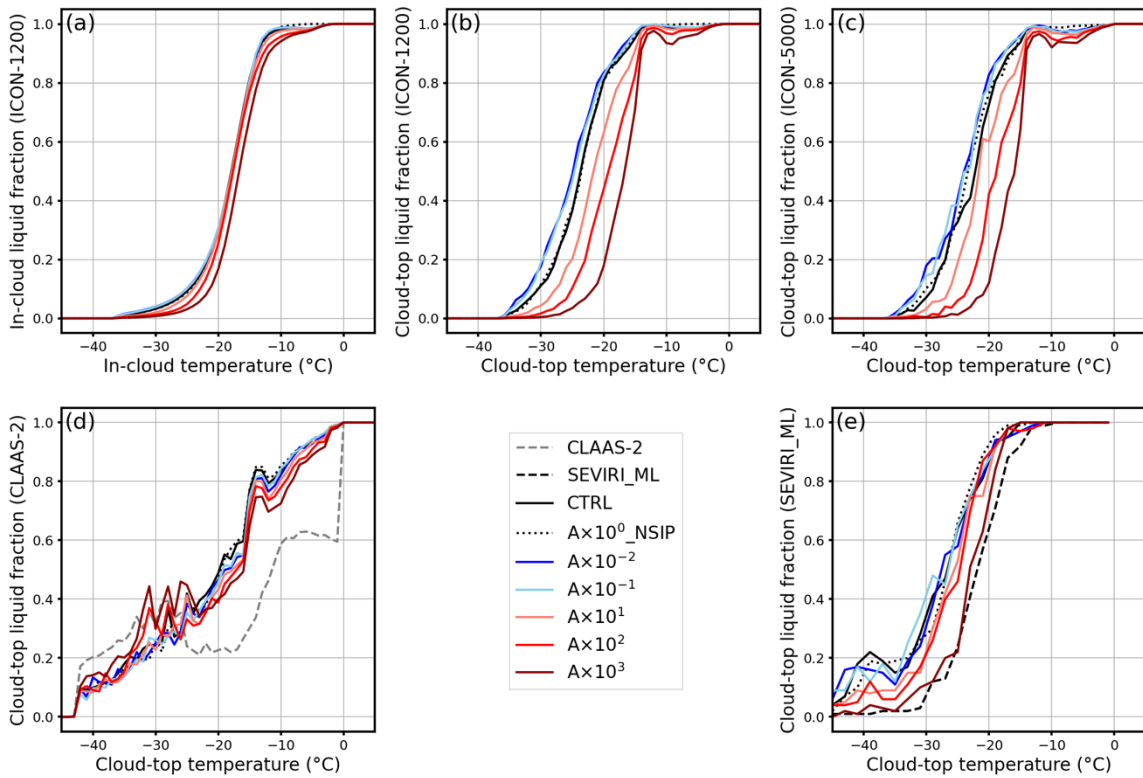

1027 Figure 6: In-cloud supercooled liquid mass fraction distribution as a function of
1028 temperature (binned by 1°C) between 9:00 and 19:00 (a-d) for the 4 cases ($A \times 10^0$,
1029 $A \times 10^0_{\text{NSIP}}$, $A \times 10^{-2}$, $A \times 10^3$), the colour of points indicates the vertical wind velocity
1030 (unit, m s^{-1}). 2-D histogram of in-cloud liquid mass fraction versus temperature (e-f).

1032 Figure 7: Cloud-top supercooled liquid mass fraction distribution as a function of
1033 temperature (binned by 1°C) between 9:00 and 19:00 (a-d) for the 4 cases ($A \times 10^0$,
1034 $A \times 10^0$ _NSIP, $A \times 10^{-2}$, $A \times 10^3$), the colour of points indicates the vertical wind velocity
1035 (unit, m s^{-1}). 2-D histogram of cloud-top liquid mass fraction versus temperature (e-f).

1051

1052

Figure 9: Spatial- and time-averaged (9:00~19:00) profiles of vertical velocities (w values $\leq 0 \text{ m s}^{-1}$ are excluded). The dashed grey line indicates the clout top height which is about 11.7 km.

1054

1055 Figure 10: Liquid cloud pixel fraction as a function of temperature from 9:00 to 19:00
 1056 for the thermodynamic sensitivity experiments, (a) in-cloud fraction calculated
 1057 directly from simulations, (b) cloud-top fraction calculated from directly simulations,
 1058 (c) cloud-top fraction calculated by remote-sensing retrieval algorithms to produce
 1059 CLAAS-2 dataset, and (d) cloud-top fraction calculated by remote-sensing retrieval
 1060 software suite SEVIRI_ML. The temperature is binned by 1°C in (a), (b), and (c), and
 1061 by 2°C in (d).

1062

1063

1064

1065 Figure 11: Spatial- and time-averaged (9:00~19:00) profiles of process rates of (a)
1066 homogeneous freezing, (b) heterogeneous freezing (immersion and deposition
1067 nucleation) for cases with perturbed initial thermodynamic states. Shaded area
1068 indicates the spatial and time-averaged mixed-phase region. Unit is $\text{g kg}^{-1}\text{s}^{-1}$.
