25 **Abstract**

26

27 The Santa Barbara Basin naturally experiences transient deoxygenation due to its unique  
28 geological setting in the Southern California Borderland and seasonal changes in ocean currents.  
29 Long-term measurements of the basin showed that anoxic events and subsequent nitrate  
30 exhaustion in the bottom waters have been occurring more frequently and lasting longer over the  
31 past decade. One characteristic of the Santa Barbara Basin is the seasonal development of  
32 extensive mats of benthic nitrate-reducing sulfur-oxidizing bacteria, which are found at the  
33 sediment-water interface when the basin's bottom waters reach anoxia but still provide some  
34 nitrate. To assess the mat's impact on the benthic and pelagic redox environment, we collected  
35 biogeochemical sediment and benthic flux data in November 2019, after anoxia developed in the  
36 deepest waters of the basin and dissolved nitrate was depleted (down to 9.9  $\mu\text{M}$ ). We found that  
37 the development of mats was associated with a shift from denitrification to dissimilatory nitrate  
38 reduction to ammonium. The zone of sulfate reduction appeared near the sediment-water  
39 interface in sediment hosting these ephemeral white mats. We found that an exhaustion of iron  
40 oxides in the surface sediment was an additional prerequisite for mat proliferation. Our research  
41 further suggests that cycles of deoxygenation and reoxygenation of the benthic environment  
42 result in extremely high benthic fluxes of dissolved iron from the basin's sediment. This work  
43 expands our understanding of nitrate-reducing sulfur-oxidizing mats and their role in sustaining  
44 and potentially expanding marine anoxia.

45 **Introduction**

46

47 Naturally occurring low-oxygen waters in the ocean are commonly observed below the ocean's  
48 mixed layer where respiration consumes oxygen faster than it is produced or ventilated. When  
49 low oxygen conditions occur along the western continental shelf in regions susceptible to  
50 upwelling events and/or undergoing eutrophication, organic matter remineralization can  
51 frequently drive oxygen concentrations to hypoxic ( $O_2 < 63 \mu\text{M}$ ) (Middelburg and Levin, 2009)  
52 and/or anoxic levels ( $O_2 < 3 \mu\text{M}$ ) (Fossing et al., 1995; Canfield et al., 2010). These areas are  
53 usually referred to as Oxygen Minimum Zones (OMZs). In the water column of OMZs, nitrogen  
54 reduction becomes an important mechanism for organic matter remineralization (Ward et al.,  
55 2009). OMZs within coastal basins that experience seasonal changes in upwelling can experience  
56 anoxic and nitrate reducing conditions that extend to the benthic environment, especially when  
57 high productivity and associated organic matter export coincide with seasonal patterns of  
58 physical mixing. This fundamental change in the redox conditions at the sediment-water  
59 interface encourages elevated rates of anaerobic microbial processes and can promote organic  
60 matter preservation in the sediments (Middelburg and Levin, 2009; Treude, 2011), though a  
61 recent study suggests a thin reactive surface layer can provide high rates of organic matter  
62 degradation in anoxic environments (Van De Velde et al., 2023). Persistent anoxia in these  
63 coastal OMZ can lead to huge releases of sulfide (up to  $13.7 \text{ mmol m}^{-2} \text{ d}^{-1}$ ) and ammonium (up  
64 to  $21.2 \text{ mmol m}^{-2} \text{ d}^{-1}$ ) into the water column (Sommer et al., 2016).

65

66 The Santa Barbara Basin (SBB) is an example of one of these coastal OMZs that experiences  
67 seasonal deoxygenation. Drastic changes in water column oxygenation and seafloor redox

68 conditions drive complex changes in benthic biogeochemistry and microbiology, evidenced most  
69 clearly by the development of thick, expansive mats of giant sulfur-oxidizing bacteria (GSOB)  
70 on the SBB seafloor (Bernhard et al., 2003; Prokopenko et al., 2006; Valentine et al., 2016;  
71 Kuwabara et al., 1999). A 2016 survey of the basin identified a vast GSOB mat spread over 1.6  
72 contiguous km, confined between 487 and 523 km in the SBB depocenter where conditions were  
73 anoxic but not depleted of  $\text{NO}_3^-$  (Valentine et al., 2016). These GSOB mats have been noted  
74 previously in the SBB benthos, appearing at times of anoxia and disappearing when oxygen is  
75 present in the bottom water (Reimers et al., 1996; Kuwabara et al., 1999). Similar GSOB mats  
76 have been identified in other transiently deoxygenated OMZs such as the Peruvian/Chilean coast  
77 (Sommer et al., 2016; Schulz et al., 1996; Zopfi et al., 2001; Høglund et al., 2009). The  
78 chemoautotrophic bacteria that constitute the bulk of GSOB mats (typically *Thioploca* and/or  
79 *Beggiatoa*) utilize sulfide as an electron donor and  $\text{O}_2$  or  $\text{NO}_3^-$  as a terminal electron acceptor  
80 (Jørgensen and Nelson, 2004). Some GSOB can hyperaccumulate  $\text{NO}_3^-$  in cell vacuoles up to  
81 500 mM (Fossing et al., 1995) and use this  $\text{NO}_3^-$  reserve to oxidize sulfide that diffuses from the  
82 underlying sediment to perform their metabolism. (Huettel et al., 1996; Mußmann et al., 2003;  
83 Sayama, 2001).

**Figure 1. Maps of sampling locations in the Santa Barbara Basin and photographs of deployed equipment:** (A) bathymetric map of the Santa Barbara Basin with locations of all sampled stations; (B) cross-section of the Santa Barbara Basin with locations of all sampled station; (C) sediment push coring with ROV arm; (D) sediment microprofiler; (E) benthic flux chamber; (F) closeup of a syringe system from a benthic flux chamber. The map in (A) was generated using the Bathymetric Data Viewer provided by the National Centers for Environmental Information.

95 The activity of GSOB mats contribute significantly to element cycling in benthic marine  
 96 environments with large effects on biogeochemical conditions in the bottom water. Isotopic  
 97 measurements of  $^{15}\text{N}/^{14}\text{N}$  and  $^{18}\text{O}/^{16}\text{O}$  from  $\text{NO}_3^-$  in the SBB water column suggest that benthic  
 98 organisms are responsible for approximately 75% of the total  $\text{NO}_3^-$  reduction in the SBB  
 99 (Sigman et al., 2003). Other studies found that GSOB mats inhibit the diffusion of  $\text{NO}_3^-$  into  
 100 sediments via hyper-accumulation in vacuoles thereby creating conditions ideal for bacterial  
 101 heterotrophic sulfate reduction beneath them (Fossing et al., 1995; Zopfi et al., 2001). These  
 102 studies suggest that GSOB mats in the SBB may be responsible for the majority of  $\text{NO}_3^-$   
 103 consumption in the basin rather than water-column microbes. Additionally, GSOB mats have  
 104 been reported to deplete  $\text{NO}_3^-$  via dissimilatory nitrate reduction to ammonia (DNRA) in the  
 105 anoxic bottom water of the Peruvian OMZ (Dale et al., 2016) and in the hypoxic transition zone

106 in the Eastern Gotland Basin of the Baltic Sea (Noffke et al., 2016). By contrast, benthic  
107 microbial communities in the hypoxic (42  $\mu\text{M}$ ) Mauritanian OMZ perform canonical  
108 denitrification instead (Dale et al., 2014). The contrast between the Peruvian and Mauritanian  
109 OMZ suggests that bottom- water anoxia triggers the appearance of GSOB mats, and that DNRA  
110 is more prevalent where GSOB mats are present.

111

112 The rapid accumulation and consumption of  $\text{NO}_3^-$  by GSOB mats has ramifications for the redox  
113 conditions in the sediment underneath. The depletion of  $\text{NO}_3^-$  and shallowing of the nitracline  
114 could promote high rates of sulfate reduction in the sediment underneath the GSOB mat. In  
115 return, the sulfate reduction zone exists close to the sediment-water interface, providing the  
116 GSOB mat with readily accessible sulfide. If a metabolic feedback loop is then established  
117 between sulfur-oxidizing bacteria at the sediment-water interface and sulfate-reducing bacteria in  
118 the sediment, increased  $\text{NO}_3^-$  loss from the water column and spreading of sulfidic conditions in  
119 SBB sediment is expected. With these mats being potentially crucial to nitrogen and sulfur  
120 cycling in sediments underlying OMZs, their biogeochemical transformations and ergo effect  
121 upon basin redox conditions are critically important to understanding element cycling in the  
122 SBB. Such gained knowledge would have additional benefits for predicting biogeochemical  
123 feedbacks to the projected expansion of oceanic oxygen deficiency, in the SBB and in OMZs  
124 more general, as a result of global change (Stramma et al., 2008).

125

126 Utilizing in-situ technologies, sediment porewater extraction, solid phase analyses, and  
127 radiotracer techniques, this study aims to answer the following overarching questions: (1) Which  
128 environmental conditions initiate and sustain the proliferation of GSOB mats? (2) Which

129 biogeochemical transformations occur in the sediment underneath these mats? (3) What role do  
130 the mats play in the increasingly prevalent anoxic and nitrate-depleted condition found in the  
131 SBB? These investigations represent the first basin-wide geochemical characterization of the  
132 Santa Barbara Basin which hosts the largest as-of-yet mapped GSOB mat in the world's oceans.  
133 It is the first suite of in-situ flux measurements carried out in the SBB, which is unique to other  
134 heavily studied marine settings (e.g., Eastern Gotland Basin, Peruvian upwelling zone) in that it  
135 is an oceanic basin within an upwelling zone. The results presented here also provide  
136 geochemical context for a number of other related investigations in the SBB (Robinson et al.,  
137 2022; Xuefeng Peng et al., 2023; Peng et al., 2023) as well as the first measurements in a multi-  
138 year study of biogeochemical changes in response to warming waters and increased stratification  
139 on the California coast.

## 140 2. Materials and Methods

### 141 2.1 Study Site

142 The Santa Barbara Basin (SBB) is a coastal basin in the California Borderland with an  
143 approximate maximum depth of 600 m characterized by a seasonally anoxic water column  
144 (Sverdrup and Allen, 1939; Sholkovitz and Gieskes, 1971). The transform boundary along the  
145 California Borderland heavily affects the geomorphology of basins in this region; these basins  
146 become twisted as the plates rub against each other and form a series of “bathtubs” blocked by  
147 sills and seamounts off the coast of California. The SBB is bordered by the California coast in  
148 the north, the Channel Islands in the south, the Santa Monica basin to the east, and the Arguello  
149 Canyon to the west. A sill to the west of the basin at around 475 m depth (Fig. 1) prohibits most  
150 water transfer between the Santa Lucia Slope and the deeper waters of the SBB (Sholkovitz and  
151 Gieskes, 1971). The highly productive surface waters in the basin provide ample organic matter  
152 to the basin’s water column, encouraging strong remineralization processes below the euphotic  
153 zone, which can induce anoxia below the sill depth, with typically less than 1  $\mu\text{mol O}_2 \text{ L}^{-1}$   
154 (Sholkovitz, 1973; Emery et al., 1962; Thunell, 1998; Emmer and Thunell, 2000). Benthic faunal  
155 distribution within the basin is tightly correlated with this sill depth and related oxygen  
156 conditions; below the sill, the sea snail *Alia permodesta* is the most commonly found benthic  
157 fauna, while sea stars, sea urchins, and other echinoderms increase in density above the sill  
158 (Myhre et al., 2018). During upwelling events (usually in Spring), oxygenated waters from the  
159 California Current spill over the western sill and ventilate the SBB, reportedly increase bottom  
160 water oxygen concentrations to approximately 20  $\mu\text{mol O}_2 \text{ L}^{-1}$  (Goericke et al., 2015). SBB  
161 water-column oxygen and nitrogen concentrations have been evaluated through a longitudinal  
162 survey by the California Cooperative Oceanic Fisheries Investigations (Calcofi) with data

163 starting in the 1950's . The data collected by this survey shows increasing durations of anoxia  
164 and fixed nitrogen loss in the basin with the SBB becoming completely nitrate-depleted below  
165 the sill at least three times between 2012 and 2017 (<https://calcof.iorg/data/>).

166

## 167 **2.2 Benthic sediment sampling and instrument deployment**

168 Sediment samples were taken between 30 October and 11 November 2019 during an expedition  
169 aboard the research vessel (*R/V*) *Atlantis* equipped with the remote operated vehicle (ROV)  
170 Jason. Samples were taken at stations along a bimodal, north-south transect through the  
171 depocenter of the SBB, as well as one station on a separate transect. Details of sampling stations  
172 can be seen in Fig. 1A and 1B. Briefly, depocenter stations are labeled as NDRO and SDRO  
173 (northern and southern depocenter radial origin, respectively). The remaining stations are named  
174 for the cardinal direction (north vs. south) and the transect number (e.g., SDT1-A is on transect 1  
175 while SDT3-A is on transect 3). As station depth decreases, the alpha suffix increases (e.g.,  
176 NDT3-A is deeper than NDT3-B, etc.).

177

178 ROV Jason conducted sediment push coring and deployed automated benthic flux chambers  
179 (BFC) and microprofilers at each station. Bottom water oxygen concentration was determined  
180 using an Aanderaa 4831 oxygen optode (Aanderaa Instruments, Bergen, Norway) installed on  
181 the ROV. Optical modems (Luma 250LP, Hydromea, Renens, Switzerland) installed on the ROV  
182 and the BFC and microprofilers were used to transmit deployment settings and start/terminate  
183 measurements of the instruments. Multiple push cores (polycarbonate, 30.5 cm length, 6.35 cm  
184 inner diameter) per sampling station were retrieved during ROV Jason deployments (Fig. 1C).  
185 Replicate cores from each station were transferred to an onboard 6°C cold room upon recovery

186 aboard the ship and subsampled for either solid phase analyses, porewater geochemistry, or  
187 radiotracer experiments.

188

### 189 **2.3 Sediment Core Sub-Sampling**

190 Two replicate ROV push cores that were collected near each other at each station were processed  
191 under a constant argon flow to protect redox-sensitive species. Cores were sectioned in 1-cm  
192 increments up to 10 cm followed by 2-cm increments. Note, sediments from the NDT3-B station  
193 were sliced in 2-cm increments. Sediment subsections were transferred into argon-filled 50-mL  
194 conical centrifuge tubes. Sediment samples were centrifuged at 2300 x g for 20 minutes. The  
195 centrifugate was subsampled unfiltered as fast as possible (to avoid contaminations with oxygen)  
196 for porewater analyses. Solid phase cores were sectioned similar to porewater cores and sub-  
197 sampled for sediment density, porosity, and organic matter content. A 10 mL cut-off plastic  
198 syringe was used to collect 6 mL of sediment into pre-weighed plastic vials (15 mL snap-cap  
199 vials) and stored in the dark at 4°C for sediment porosity and density analysis. Two-mL  
200 microcentrifuge tubes were filled with sediment from each depth interval and stored at -30°C for  
201 sediment organic matter analyses. One ROV push core per station was sub-sampled with a  
202 miniaturized push core (length 20 cm, inner diameter 2.6 cm) and taken immediately to the  
203 shipboard radioisotope van for radiotracer experiments (see section 2.5).

204

### 205 **2.4 Sediment Porewater Geochemistry**

206 Concentrations of porewater sulfide (Cline, 1969),  $\text{NH}_4^+$ ,  $\text{PO}_4^{3-}$ , and  $\text{Fe}^{2+}$  (Grasshoff et al., 1999)  
207 were determined shipboard with a Shimadzu UV-Spectrophotometer (UV-1800). Detection  
208 limits for sulfide,  $\text{NH}_4^+$ ,  $\text{PO}_4^{3-}$ , and  $\text{Fe}^{2+}$  were 1  $\mu\text{M}$ . Subsamples (2 mL) for porewater  $\text{NO}_3^-$  and

209  $\text{NO}_2^-$  concentrations were stored in 2-mL plastic vials with an O-ring, frozen shipboard at  $-30^\circ\text{C}$   
210 and analyzed back at the home laboratory on the same spectrophotometer using the method  
211 following (García-Robledo et al., 2014). The detection limit for  $\text{NO}_3^-$  and  $\text{NO}_2^-$  was  $0.5 \mu\text{M}$ .  
212 Samples for porewater DIC were preserved shipboard with  $5 \mu\text{L}$  saturated  $\text{HgCl}$  in headspace  
213 free glass vials and stored at  $4^\circ\text{C}$  for later analysis following (Hall and Aller, 1992). DIC  
214 detection limit was  $0.1 \text{ mM}$ . Total alkalinity was determined shipboard using direct titration of  
215  $500 \mu\text{L}$  of pore water with  $0.01\text{M}$  Titrisol<sup>®</sup>  $\text{HCl}$  (Pavlova et al., 2008). The analysis was  
216 calibrated using IAPSO seawater standard, with a precision and detection limit of  $0.05 \text{ meq L}^{-1}$ .  
217 Subsamples ( $1 \text{ mL}$ ) for sulfate and chlorinity were stored in 2-mL plastic vials with an O-ring,  
218 frozen shipboard at  $-30^\circ\text{C}$  and later measured in the lab using a Metrohm 761 ion chromatograph  
219 with a methodological detection limit of  $30 \mu\text{M}$  (Dale et al., 2015).

220

## 221 **2.5 Solid Phase Analyses**

222 Porosity/Density samples were collected in pre-weighed plastic vials and dried at  $50^\circ\text{C}$  for up to  
223  $96 \text{ hr}$  until the dry weight was stable. Sediment porosity was calculated by taking the difference  
224 between wet and dry sediment weight and divided by the volume of the wet sediment. Sediment  
225 density was calculated by dividing the wet sediment weight by its volume. Treatment of  
226 sediment subsamples for total organic carbon (TOC), total organic nitrogen (TON), and organic  
227 carbon isotope composition ( $\delta^{13}\text{C}$ ) were modified from (Harris et al., 2001) and sent to the  
228 University of California Davis Stable Isotope Facility for analysis using Elemental Analyzer –  
229 Isotope Ratio Mass Spectrometry. TOC and TON were calculated based on the sample peak area  
230 corrected against a reference material (alfalfa flour). Limit of quantification based on peak area  
231 was  $100 \mu\text{g C}$  with an uncertainty of  $\pm 0.2 \text{ ‰}$  for  $\delta^{13}\text{C}$ .

232

## 233 **2.6 Sulfate Reduction**

234 To determine ex-situ microbial sulfate reduction rates, whole round sub-cores were injected with  
235 10  $\mu\text{L}$  carrier-free  $^{35}\text{S}$ -Sulfate radiotracer (dissolved in water, 200 kBq, specific activity 37 TBq  
236  $\text{mmol}^{-1}$ ) into pre-drilled, silicon-filled holes at 1-cm increments according to (Jørgensen, 1978).  
237 These sub-cores were incubated at  $6^\circ\text{C}$  in the dark for 6-8 hours. Incubations were stopped by  
238 slicing sediment cores in 1-cm increments into 50-mL centrifuge tubes filled with 20-mL zinc  
239 acetate (20% w/w) and frozen at  $-20^\circ\text{C}$  until analysis at the land-based laboratory. Microbial  
240 activity in controls was terminated with zinc acetate (20 mL of 20% w/w) before the addition of  
241 radiotracer and subsequent freezing. Lab-based analysis of sulfate reduction rates were  
242 determined following the cold-chromium distillation procedure (Kallmeyer et al., 2004).

243

## 244 **2.7 Benthic In-Situ Investigations**

245 Per station, one to three microprofiler (Fig. 1D) and three BFC (Fig. 1E) deployments were  
246 carried out by the ROV Jason at the seafloor. Construction, deployment and operation of  
247 automated microprofilers and BFCs followed those described in (Treude et al., 2009). The  
248 microprofiler deployed in this study represents a modified, miniaturized version of the  
249 instrument described in (Gundersen and Jørgensen, 1990) that was constructed specifically for  
250 use by ROV. Microprofilers were outfitted with three  $\text{O}_2$ -microelectrodes (Glud et al., 2000),  
251 two pH-microelectrodes (Revsbech and Jørgensen, 1986), two  $\text{H}_2\text{S}$ -microelectrodes  
252 (Jeroschewsky et al., 1996), and one conductivity sensor to determine the position of the  
253 sediment-water interface relative to the tips of the microelectrodes. Concentrations of oxygen

254 and sulfide, as well as pH were each calculated from microelectrode readings and averaged for  
255 the respective sites where replicates existed.

256  
257 The BFC consisted of a frame equipped with a cylindrical polycarbonate chamber (inner  
258 diameter = 19 cm) with its lower portion sticking out of the frame. The upper side of the  
259 chamber was closed by a lid containing a stirrer (Type K/MT 11, K.U.M., Kiel, Germany),  
260 oxygen optodes (Type 4330, Aanderaa Data Instruments, Bergen Norway and Hydroflash,  
261 Contros/Kongsberg Maritime, Kongsberg, Norway), a conductivity sensor (type 5860, Aanderaa  
262 Data Instruments), and a valve. Prior to insertion into the sediments, the chambers were held  
263 upside down by the ROV manipulating arms within approximately 10 m of the seafloor and  
264 moved back and forth to make sure that water from shallower depth that may have been trapped  
265 was replaced by bottom water. Chamber incubations lasted between 240 and 390 minutes. Each  
266 BFC was outfitted with a custom-built syringe sampler containing seven syringes that were  
267 connected by tubes to sampling ports in the upper wall of the chambers (Fig. 1F): one injection  
268 syringe and six sampling syringes that were fired at regular time intervals over the time course of  
269 the deployment. The injection syringe contained de-ionized water and the reduction in salinity in  
270 the overlaying water after salinity readings stabilized (i.e., full mixing was achieved) 10-30 min  
271 after injection was used to determine BFC volumes (Kononets et al., 2021). Samples obtained  
272 from the overlaying water of the BFC were examined for the same geochemical constituents as  
273 described above (section 2.4). Benthic fluxes of  $\text{NO}_3^-$ ,  $\text{NH}_4^+$ ,  $\text{PO}_4^{3-}$ , and  $\text{Fe}^{2+}$  were calculated as  
274 follows:

275  
276 
$$J = \frac{\Delta c}{\Delta t} * \frac{V}{A} \quad (\text{EQ \# 2})$$

277

278 Where  $J$  is the flux in  $\text{mmol m}^{-2} \text{d}^{-1}$ ,  $\Delta C$  is the concentration change in  $\text{mmol m}^{-3}$ ,  $\Delta t$  is the time  
279 interval in d,  $V$  is the overlying water volume in  $\text{m}^3$ , and  $A$  is the surface area of the sediment  
280 covered by the benthic flux chamber in  $\text{m}^2$ . An average flux within BFC's was calculated for  
281 stations of similar depth. One chamber per site contained  $^{15}\text{N-NO}_3^-$  in the injection syringe for in-  
282 situ nitrogen cycling experiments. Results are reported from two of these chambers (SDRO and  
283 NDT3-D) and all  $^{15}\text{N-NO}_3^-$  chambers were excluded from benthic flux calculations (see next  
284 section).

285

## 286 **2.8 In Situ $^{15}\text{N}$ Incubations**

287 Two hundred  $\mu\text{mol}$  of  $^{15}\text{N}$ -labeled potassium nitrate (99%  $^{15}\text{N}$ ; Cambridge Isotopes) was injected  
288 into the  $^{15}\text{N}$  incubation chamber at each site to obtain a final concentration of  $\sim 50 - 100 \mu\text{M}$   $^{15}\text{N}$ -  
289 labeled nitrate. Nitrate was amended at this level to prevent its depletion before the last sampling  
290 time point (Valentine et al., 2016). Samples for  $\delta^{15}\text{N}$  analysis were preserved by filling a pre-  
291 vacuumed 12-ml exetainer vial with 0.1 ml 7M zinc chloride as a preservative. Another aliquot  
292 ( $\sim 12$  ml) of seawater for ammonium isotope analysis (see section 2.7.2) was filtered through 0.2  
293  $\mu\text{m}$  syringe filters and stored frozen. Prior to analyzing the samples in 12-ml exetainer vials, 5  
294 mL of sample was replaced with ultra-high purity helium to create a headspace. The  
295 concentration and  $\delta^{15}\text{N}$  of dissolved  $\text{N}_2$  and  $\text{N}_2\text{O}$  was determined using a Sercon CryoPrep gas  
296 concentration system interfaced to a Sercon 20-20 isotope-ratio mass spectrometer (IRMS) at the  
297 University of California Davis Stable Isotope Facility.

298

## 299 **2.9 Ammonium Isotope Analyses**

300 The production of  $^{15}\text{NH}_4^+$  in seawater samples was measured using a method adapted from  
301 (Zhang et al., 2007) and described previously by (Peng et al., 2016). In brief,  $\text{NH}_4^+$  was first  
302 oxidized to  $\text{NO}_2^-$  using hypobromite ( $\text{BrO}^-$ ) and then reduced to  $\text{N}_2\text{O}$  using an acetic acid-azide  
303 working solution (Zhang et al., 2007). The  $\delta^{15}\text{N}$  of the produced  $\text{N}_2\text{O}$  was determined using an  
304 Elementar Americas PrecisiON continuous flow, multicollector, isotope-ratio mass spectrometer  
305 coupled to an automated gas extraction system as described in (Charoenpong et al., 2014).  
306 Calibration and correction were performed as described in (Bourbonnais et al., 2017). The  
307 measurement precision was  $\pm 0.2$  ‰ for  $\delta^{15}\text{N}$ . Depending on the in-situ ammonium  
308 concentration, the detection limit for total  $\text{NH}_4^+$  production rates ranged between 0.006 and  
309 0.0685  $\text{mmol m}^{-2} \text{d}^{-1}$ .

310

### 311 3. Results

#### 312 3.1 Bottom water conditions

313 O<sub>2</sub> and NO<sub>3</sub><sup>-</sup> concentrations in the bottom water along the transects can be seen in Table 1. O<sub>2</sub>  
314 concentrations below detection as determined by the ROV sensor could in some cases be  
315 considered to represent anoxia (0 μM O<sub>2</sub>) based on a set of different analytical methods (see  
316 discussion section 4.1). Bottom water solute concentrations (as defined by the average T<sub>0</sub>  
317 concentration in BFC at each site) can be seen in Suppl. Figs. 1-4. Bottom water NO<sub>3</sub><sup>-</sup>  
318 concentrations roughly decreased with station depth (e.g., 28 μM at NDT3-D vs. 19 μM at  
319 NDRO). Bottom water NO<sub>2</sub><sup>-</sup> concentrations were below detection at all stations. Bottom water  
320 NH<sub>4</sub><sup>+</sup> concentrations were 9 μM at NDRO and 13 μM at SDRO and below detection in shallower  
321 stations. Bottom water PO<sub>4</sub><sup>3-</sup> concentrations roughly increased with increasing basin depth (e.g.,  
322 2 μM at SDT3-D vs. 7 μM at SDRO). Finally, Fe<sup>2+</sup> was 2 and 5 μM at the NDRO and SDRO  
323 stations, respectively and below detection at all shallower stations.

324

#### 325 3.2 Sediment characteristics

326 Photographs of sediment cores with a depth scale are shown below Table 1. Sediment colors  
327 were classified according to (Hossain et al., 2014). Cores from the shallowest (D) stations were  
328 uniformly reddish in color with small pockets of black. The sediment color changed with station  
329 depth, transitioning from a reddish color in the shallowest stations to predominantly black with  
330 reddish laminations at the depocenter stations. The band of black sediment appeared at approx. 8  
331 cm sediment depth in the C-station cores and became progressively more ubiquitous with station  
332 depth. Notably, NDT3-C sediment (Table 1B) contained black bands from approx. 6-14 cm  
333 sediment depth, while SDT3-C sediment (Table 1J) had a much narrower band around 8-10 cm.

334 Sediment cores from shallower stations (D and C stations) contained signs of bioturbation (e.g.,  
 335 u-shaped burrows) and, in some cases, contained visible macrofauna, such as polychaetas and  
 336 mollusks. Deeper in the basin (A and depocenter stations) no signs of bioturbation were detected,  
 337

338 **Table 1.** Station details and photos of representative ROV push cores taken at each station. Mat presence (Y =  
 339 yes, N = no) was determined visually. Station water depth and oxygen concentration were determined by sensors  
 340 attached to ROV Jason (bdl = below detection limit (<3  $\mu\text{M O}_2$ ). Anoxia was confirmed by additional methods  
 341 (see discussion section 4.1). Latitude and longitude were determined by triangulation between the ROV and the  
 342 ship. Bottom water nitrate concentration was derived from an average of benthic flux chamber nitrate  
 343 measurements at time 0 for each station (chambers with no calculatable flux and  $^{15}\text{N}$ -nitrate addition excluded).  
 344 Note, benthic flux chambers were not deployed at SDT1-A. Photographs show the sediment-water interface  
 345 (SWI; top part) and each sediment core in full length (lower part).  
 346

 348  
 349 and the sediment-water interface was colonized by patches of white GSOB mats. Spherical cells  
 350 (given the moniker ‘ghost balls’) were found mixed amongst giant sulfur bacteria filaments  
 351 within the top 0-1 cm of sediment at NDRO (Suppl. Fig. 7). These unknown species had similar  
 352 morphological characteristics to the species *Thiomargarita namibiensis* (Schulz et al., 1999;  
 353 Schulz and Schulz, 2005) containing a translucent cell with sulfur granules giving them a ghostly

354 white appearance. A small sample of cells ( $n = 8$ ) were measured, featuring diameters between  
 355 48.0 and 99.6  $\mu\text{m}$ , amounting to an average biovolume of  $2.5 \times 10^5 \mu\text{m}^3$ , compared to *T.*  
 356 *namibiensis* with a cell diameter usually between 100-300  $\mu\text{m}$  (Schulz et al., 1999).

357  
 358 **Table 2.** Sediment solid phase data: porosity, density, total organic carbon (TOC), total organic nitrogen (TON),  
 359 C:N ratio, and  $\delta^{13}\text{C}$ . All data were averaged for the top 0-19 cm sediment, except NDT3-C (17 cm), NDT3-A  
 360 (11 cm) and SDRO (7 cm), where the core length was shorter. Integrated sulfate reduction rates (iSRR) were  
 361 integrated over 0-14 cm sediment depth. No sulfate reduction rates are available for NDT3-B, SDT3-A, and  
 362 SDT3-B; rates were not integrated for SDRO due to missing surface samples.

364  
 365  
 366  
 367 B station cores contained sporadic GSOB filaments slightly deeper in the sediment (approx. 2-4  
 368 cm sediment depth). Sediment solid phase parameters (averaged over the entire sediment core  
 369 depth) can be seen in Table 2. Average sediment porosity increased with basin depth (e.g., from  
 370 0.79 at NDT3-D to 0.88 at NDRO). TOC, TON, the C/N ratio, and the  $\delta^{13}\text{C}$  isotopic signature of  
 371 organic carbon remained relatively constant (2.5 – 4.5%, 0.1 – 0.4%, 8.0 – 8.7 and 21.3 –  
 372 22.4 ‰, respectively) over all stations.

373  
 374 **3.3 Sediment porewater geochemistry**

375 Total alkalinity (Figs. 2 A-E & 3 A-F) increased steadily with sediment depth at all stations  
 376 starting with, on average, 2.4 mM in the core supernatant reaching a maximum at the respective  
 377 deepest sediment sample (20 cm). Porewater alkalinity and DIC also increased with basin depth

378 (Figs. 2 A-E & 3 A-F) indicating that total alkalinity was dominated by the carbonate system.  
379 Porewater DIC was, on average, 2.2 mM in the core supernatant and reached maximum  
380 concentrations at the deepest sediment depth (20 cm) at most stations.  
381  
382 Porewater  $\text{PO}_4^{3-}$  profiles (Figs. 2 A-E & 3 A-F) were markedly different between the depocenter  
383 and shallower C and D stations. Porewater  $\text{PO}_4^{3-}$  concentrations in the depocenter and A stations  
384 generally increased with sediment depth but several profiles (NDT3-C, NDT3-A, SDRO, SDT1-  
385 A) remained unchanged or decreased deeper in the sediment (starting at approx. 10 cm). The  
386 profiles in C and D stations showed a peak in  $\text{PO}_4^{3-}$  concentrations near the sediment-water  
387 interface, particularly in the northern basin. Below 2 cm,  $\text{PO}_4^{3-}$  decreased with sediment depth,  
388 but sometimes showed a second small peak deeper in the sediment (12-14 cm at NDT3-D and  
389 10-12 cm at SDT3-D).  
390  
391 Porewater  $\text{NH}_4^+$  concentrations (Figs 2 & 3 A-E) showed trends often similar to alkalinity and  
392 DIC;  $\text{NH}_4^+$  concentrations increased downcore and were higher at depocenter than at D stations  
393 (e.g., 370 and 91  $\mu\text{M}$  at 20 cm for SDRO and SDT3-D, respectively). Porewater  $\text{NO}_2^-$  (Suppl.  
394 Table 1) and  $\text{NO}_3^-$  (Figs. 2 F-J & F G-L) concentrations were at or near zero below 2 cm at every  
395 station, except at SDRO and NDT3-A where large peaks in  $\text{NO}_3^-$  (376 and 81  $\mu\text{M}$ , respectively)  
396 and  $\text{NO}_2^-$  (37 and 5  $\mu\text{M}$ , respectively) occurred in the top 1 cm.  
397  
398 Porewater  $\text{Fe}^{2+}$  concentrations (Figs. 2 F-J & 3 G-L) were several orders of magnitude higher at  
399 shallower D-stations (max. 722 and 395  $\mu\text{M}$  at NDT3-D and SDT3-D, respectively) compared to  
400 depocenter stations (max. 13 and 51  $\mu\text{M}$  at NDRO and SDRO, respectively). NDT3-C porewater

401  $\text{Fe}^{2+}$  concentration (Fig. 2G) peaked in the top 1 cm of sediment (similar to deeper stations)  
402 while SDT3-C porewater  $\text{Fe}^{2+}$  concentration (Fig. 3H) peaked around 5-cm sediment depth.  $\text{Fe}^{2+}$   
403 concentrations reached a max. at 0-2 cm and declined sharply with depth in depocenter and A-  
404 station sediment. Northern basin sediment was similar, but the decline in  $\text{Fe}^{2+}$  below 0-2 cm was  
405 less pronounced.

406

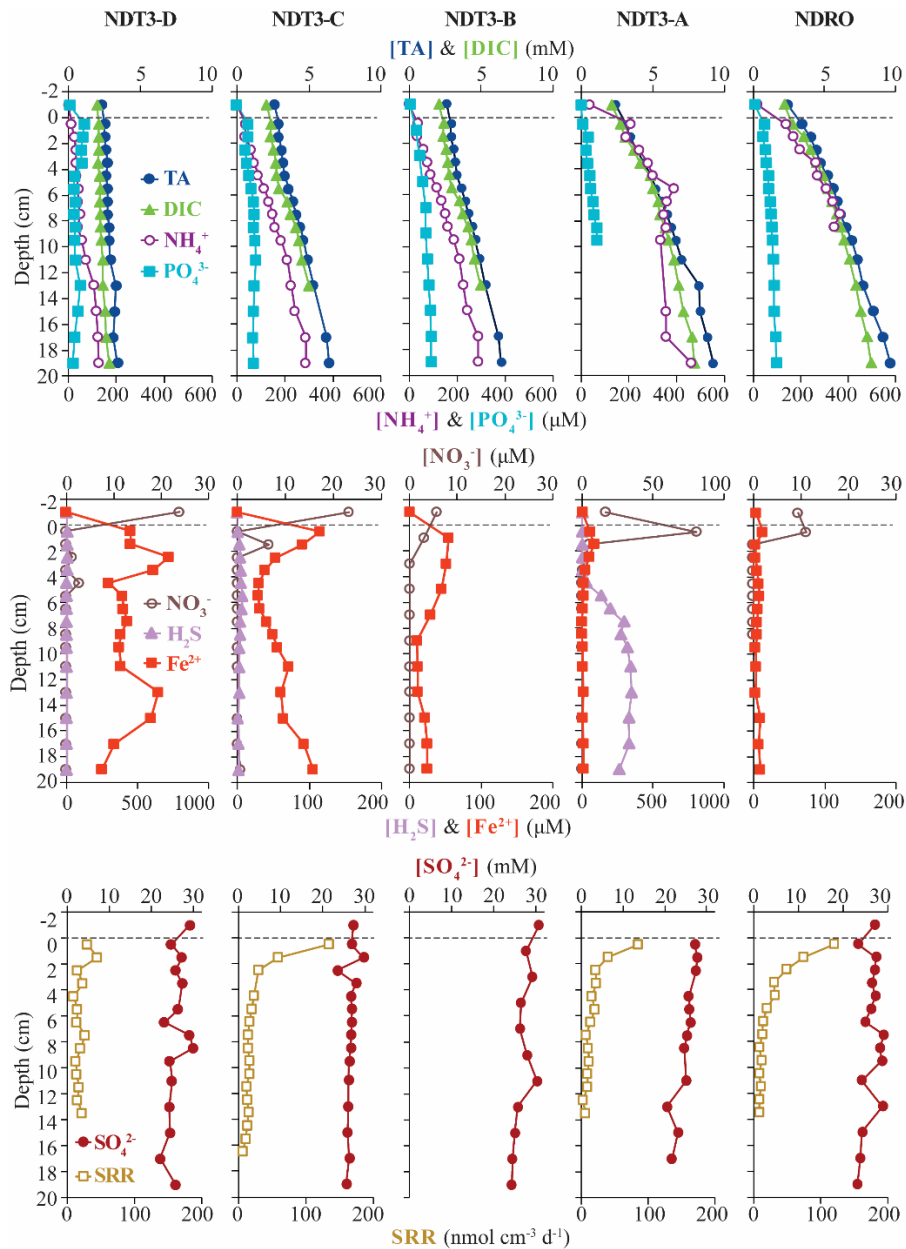

407 Maximum porewater sulfide concentrations (Figs. 2 F-J & 3 G-L) were several orders of  
408 magnitude lower at the shallower D-stations (5 and 4  $\mu\text{M}$  at NDT3-D and SDT3-D, respectively)  
409 compared to A stations (350 and 148  $\mu\text{M}$  at NDT3-A and SDT1-A, respectively). Unlike  $\text{Fe}^{2+}$ ,  
410 peaks in sulfide concentration occurred deeper in the sediment (e.g., below 5 cm depth at A  
411 stations). Porewater sulfate concentrations (Figs. 2 K-O & 3 M-R) decreased slightly with depth,  
412 but never reached values below 20 mM at any station.

413

### 414 **3.4 In-situ microprofiling**

415 Microprofiler  $\text{O}_2$  and sulfide measurements are shown in Fig. 4. Oxygen was rapidly consumed  
416 within the first 0-1 cm of sediment at every station where  $\text{O}_2$  was detected in the bottom water  
417 (i.e., at all stations except NDRO, which showed no positive signal of oxygen in the water  
418 compared to the sediment; note that no oxygen profile is available for SDRO). Sulfide  
419 concentrations from microsensors showed similar trends to spectrophotometric measurements,  
420 albeit with different absolute values (below detection in shallower B-, C- and D-stations that  
421 lacked mats and  $>1,000 \mu\text{M}$  at A- and depocenter stations). Microprofiler pH (Fig. 4) was near  
422 7.5 in the bottom water at all stations, and slowly decreased to near 7.0 in the lower parts (3-5

423 cm) sediment at most stations except NDT3-C and SDT3-B. pH at 2.5 cm at SDT3-B reached  
 424 6.77, which was the lowest observed during this expedition.  
 425

426  
 427 **Figure 2.** Biogeochemical data from ROV sediment push cores collected at stations on the northern transect  
 428 (NDT3) and in the northern depocenter (NDRO): total alkalinity (TA), dissolved inorganic carbon (DIC),  
 429 ammonium ( $\text{NH}_4^+$ ), phosphate ( $\text{PO}_4^{3-}$ ) in the first row; nitrate ( $\text{NO}_3^-$ ), total sulfide (sulfide), and iron (II) ( $\text{Fe}^{2+}$ )  
 430 in the second row; sulfate ( $\text{SO}_4^{2-}$ ) and bacterial sulfate reduction rate (SRR) in the third row. Data analyzed from  
 431 sediment core supernatant are plotted at -1 cm sediment depth; the dotted line connotes the sediment-water  
 432 interface. Note the change in scale on the primary x-axis in panel I and the change in scale of the secondary x-  
 433 axis in panels F and I. No spectrophotometric sulfide data is available for NDRO and NDT3-B and no SRR data  
 434 is available for NDT3-B. For station details see Fig. 1 and Table 1.

Note the change in scale on the secondary x-axis for NDRO sulfide. Values determined in the overlying water are plotted at negative sediment depths; the dotted line connotes the sediment-water interface.

### 455 3.5 In-situ fluxes of benthic solutes

456 NO<sub>3</sub><sup>-</sup>, NH<sub>4</sub><sup>+</sup>, PO<sub>4</sub><sup>3-</sup>, and Fe<sup>2+</sup> flux measured in the BFC revealed different patterns of uptake and  
457 release from the sediment throughout the basin (Fig. 5 and Suppl. Figs. 1-4). BFC O<sub>2</sub>  
458 concentrations were compromised by O<sub>2</sub> release from the chamber's polycarbonate walls, which  
459 prevented an accurate calculation of O<sub>2</sub> fluxes from BFC sensor data. NO<sub>3</sub><sup>-</sup> was consumed at all  
460 stations as indicated by a negative flux (i.e., a flux into the sediment). On the contrary, benthic  
461 release (i.e., a flux out of the sediment) was observed for all other analyzed solutes (NH<sub>4</sub><sup>+</sup>, PO<sub>4</sub><sup>3-</sup>,  
462 and Fe<sup>2+</sup>), with the lowest fluxes in the shallow D and C-stations and highest fluxes in the  
463 depocenter. Ammonium fluxes were the highest of all the determined solutes and showed the  
464 largest difference between deep and shallow stations, with a flux of 1.6 mmol m<sup>-2</sup> d<sup>-1</sup> at NDT3-C

465 (there were no measurable  $\text{NH}_4^+$  fluxes in D-station chambers) and reaching  $11.1 \pm 3.1 \text{ mmol m}^{-2}$   
466  $\text{d}^{-1}$  ( $n = 3$ ) at the two depocenter stations. The depocenter ammonium flux far-outpaced the  
467 concomitant flux of nitrate into depocenter sediments ( $-3.2 \pm 0.7 \text{ mmol m}^{-2} \text{ d}^{-1}$ ,  $n = 3$ ). Iron and  
468 phosphate fluxes were similar at depocenter stations ( $4.1 \pm 0.7$ ,  $n = 3$ , and  $3.2 \pm 0.7$ ,  $n = 3$ ,  $\text{mmol}$   
469  $\text{m}^{-2} \text{ d}^{-1}$ , respectively). Alkalinity and DIC concentrations from flux chambers (Suppl. Figs. 5 and  
470 6) remained constant at all stations and thus no DIC flux was calculated. Results from BFCs  
471 injected with  $^{15}\text{N-NO}_3^-$  at the SDRO and NDT3-D station are shown in Fig. 6. The rates of  
472 denitrification, anammox, and  $\text{N}_2\text{O}$  production were higher at SDRO compared to NDT3-D.  
473  $^{15}\text{NH}_4^+$  production (DNRA) was one order of magnitude higher at the SDRO station ( $2.67 \text{ mmol}$   
474  $\text{m}^{-2} \text{ d}^{-1}$ ) compared to the NDT3-D station ( $0.14 \text{ mmol m}^{-2} \text{ d}^{-1}$ ). DNRA accounted for a much  
475 higher percentage of  $\text{NO}_3^-$  reduction at SDRO (54.1%) than NDT3-D (13.3%).

476

### 477 **3.6 Sulfate reduction rates**

478 Vertical profiles of bacterial sulfate reduction as determined by the radioisotope technique  
479 differed throughout the basin (Figs. 2 & 3). Peaks in sulfate reduction were seen in the top 0-1  
480 cm of sediment at stations with a visible GSOB mat on the surface ( $120.2$ ,  $151.0$ , and  $85.3 \text{ nmol}$   
481  $\text{cm}^{-3} \text{ d}^{-1}$  at NDRO, SDT1-A, and NDT3-A, respectively). Sediments at most shallower basin  
482 depths exhibited peaks slightly deeper in the sediment and of lower magnitude ( $25.5$ ,  $44.5$ ,  $22.5$   
483  $\text{nmol cm}^{-3} \text{ d}^{-1}$  at SDT3-C, NDT3-D, and SDT3-D respectively). NDT3-C had no visible GSOB  
484 mats but exhibited a peak ( $133.7 \text{ nmol cm}^{-3} \text{ d}^{-1}$ ) in sulfate reduction at 0-1 cm depth, similar to  
485 deeper stations (e.g., NDRO in Fig. 2O), which differed from other shallow stations (e.g., SDT3-  
486 C in Fig. 3N). The integrated sulfate reduction rate (0-14 cm depth) at NDRO ( $4.1 \text{ mmol m}^{-2} \text{ d}^{-1}$ )  
487 was noticeably higher than most other stations with the exception of NDT3-C ( $3.8 \text{ mmol m}^{-2} \text{ d}^{-1}$ )

488 (Table 2). NDT3-D and NDT3-C exhibited higher integrated rates ( $2.9$  and  $3.8$   $\text{mmol m}^{-2} \text{d}^{-1}$ )  
 489 than their southern station counterparts SDT3-D and SDT3-C ( $1.9$  and  $1.7$   $\text{mmol m}^{-2} \text{d}^{-1}$ ).  
 490

## 504 4. Discussion

### 505 4.1 Giant sulfur-oxidizing bacterial mats proliferated in response to deoxygenation in the 506 Santa Barbara Basin

507 The SBB is an ideal environment to study the effect of transient deoxygenation on benthic  
508 biogeochemistry. In Fall 2019, when this expedition took place, the SBB was undergoing a  
509 transition from oxygenated to virtually anoxic conditions (Qin et al., 2022). When the AT42-19  
510 cruise occurred, most of the bottom water in the basin was hypoxic (A-, B-, C-, and D-stations),  
511 except for the depositional center. Separate O<sub>2</sub> measurements from the ROV sensor (O<sub>2</sub> below  
512 detection limit, Table 1), microprofilers (no signal change between water column and sediment,  
513 Fig. 4), and Winkler titration from CTD/rosette casts (uniform non-zero value below 500 m (Qin  
514 et al., 2022)) indicated full anoxia in the bottom water at the deeper stations (NDRO and SDRO).  
515 Notably, bottom water conditions revealed a slight asymmetry between the basin transects (Fig.  
516 1); bottom water along the northern transect generally had more O<sub>2</sub> and NO<sub>3</sub><sup>-</sup> than the southern  
517 transect (e.g., 9 μM O<sub>2</sub> at NDT3-A and 0 μM O<sub>2</sub> at SDT3-A). This asymmetry indicated  
518 differences in the circulation and/or microbial communities between the northern and southern  
519 portions of the basin. Whether this asymmetry is a permanent feature of the basin or  
520 symptomatic of the specific conditions in November 2019 is unclear; previous studies in the SBB  
521 have been restricted to the depocenter or one side of the basin (Sholkovitz, 1973; Reimers et al.,  
522 1996; Kuwabara et al., 1999). Regardless of bottom water oxidant concentration, the  
523 energetically most favorable terminal electron acceptors (O<sub>2</sub> and NO<sub>3</sub><sup>-</sup>) disappeared in a very  
524 narrow zone below the sediment-water interface (Fig. 4 and Figs. 2 and 3, respectively),  
525 consistent with their expected rapid consumption by the benthic microbial community.

526

527 In the present study, benthic GSOB mats were primarily limited to the anoxic depocenter of the  
528 SBB. Similarly, such mats were replete in the core of the anoxic Peruvian OMZ (Levin et al.,  
529 2002; Sommer et al., 2016; Mosch et al., 2012), but absent from the seafloor below the hypoxic,  
530 i.e., slightly oxygenated, Mauritanian OMZ (Schroller-Lomnitz et al., 2019). GSOB mats in  
531 November 2019 were observed deeper in the basin than in October 2013 (Valentine et al., 2016)  
532 but in a similar location to June 1988 (Reimers et al., 1996) and April 1997 (Kuwabara et al.,  
533 1999). During the 2013 sampling, dense GSOB mats were confined to depths between approx.  
534 500-570 m (equivalent to the B-stations from this expedition), corresponding with anoxic  
535 conditions in the bottom water. This habitat was sandwiched between an anoxic, anitric (i.e.,  
536 nitrate-free) deep and a hypoxic, nitrogenated (i.e., nitrate-rich) shallower water layer (Valentine  
537 et al., 2016). The difference in depth distribution of GSOB mats between the 2013 and 2019  
538 expedition provides evidence that GSOB mats in the SBB are ephemeral and proliferate where  
539 the bottom water is anoxic but not anitric.

540

541 As our study represents only a snapshot of an oxygen- and nitrate-driven mat dynamic, we can  
542 only speculate how areas of the basin that did not contain GSOB mats in November 2019 fit into  
543 this dynamic. For example, mat-forming sulfur bacteria found slightly deeper in the sediment at  
544 B-stations (see section 3.2) could be progenitors to surface sediment colonization of thick GSOB  
545 mats, as has been recorded in other transiently deoxygenated environments (Jørgensen, 1977).  
546 Alternatively, these subsurface colonies could also be remnants of a former surface GSOB mat  
547 that retreated under changing redox conditions. Oxygenated conditions in the water preceding  
548 the 2019 expedition would, in this context, suggest the mats migrated following a previous  
549 anoxic event (Qin et al., 2022). If deoxygenation persisted in the SBB after the AT42-19 cruise,

550 then anitria (i.e., anitric conditions – similar to anoxia) would likely follow in the deepest basin  
551 water. These conditions would be similar to those seen in 2013 (Valentine et al., 2016), where  
552 GSOB mats formed a contiguous “donut ring” at shallower basin depths. Interestingly, GSOB  
553 mats in the Eastern Gotland Basin of the Baltic Sea were confined to a hypoxic transition zone,  
554 where  $O_2$  was  $< 30 \mu\text{M}$  but did not reach anoxia, while no mats were observed at deeper anoxic  
555 locations (Noffke et al., 2016). This difference in distribution compared to the SBB suggests that  
556 GSOB mats proliferate under different conditions (anoxic or hypoxic), potentially depending on  
557 the species of mat-forming bacteria present and whether they specialize in aerobic or anaerobic  
558 chemosynthesis.

559

#### 560 **4.2 Shift from benthic denitrification to dissimilatory nitrate reduction to ammonium in** 561 **response to complete deoxygenation in the Santa Barbara Basin**

562

563 Benthic uptake and release of nitrogen species by SBB sediment appeared to be affected by the  
564 presence of GSOB mats. While total benthic nitrate uptake was similar between D- and  
565 depocenter stations based on in-situ  $\text{NO}_3^-$  flux measurements (Fig. 4),  $\text{NH}_4^+$  release from the  
566 sediment into the water column increased where GSOB mats were present (Fig. 5). This trend is  
567 supported by the porewater profiles of  $\text{NH}_4^+$ , which showed a steeper increase over sediment  
568 depth at deeper stations (Figs. 2 & 3). Incubations with  $^{15}\text{N}\text{-NO}_3^-$  revealed that  $\text{N}_2$  production  
569 (denitrification and anammox) accounted for 86% of  $\text{NO}_3^-/\text{NO}_2^-$  reduction in the shallow basin,  
570 while  $\text{NH}_4^+$  production (DNRA) accounted for 13% and  $\text{N}_2\text{O}$  production accounted for 1%  
571 (NDT3-D, Fig. 6;(Peng et al., 2023)). In contrast, most (54%) of  $\text{NO}_3^-$  reduction at the  
572 depositional center occurred via DNRA;  $\text{N}_2$  production accounted for 45% and  $\text{N}_2\text{O}$  production

573 accounted for 1% of  $\text{NO}_3^-$  reduction at the SDRO (Fig. 6; Peng et al. 2023). It is important to  
574 note that these results only describe patterns of  $\text{NO}_3^-$  reduction in the basin, while other  
575 mechanisms of nitrate uptake by sediment (e.g., hyper-accumulation of nitrate into vacuoles) are  
576 more difficult to calculate accurately.

577  
578 It is likely important to SBB benthic nitrogen cycling that some eukaryotic organisms can hyper-  
579 accumulate  $\text{NO}_3^-$  in benthic, anoxic environments including diatoms (Kamp et al., 2011) and  
580 foraminifera (Risgaard-Petersen et al., 2006). Additionally, meiofauna (e.g., nematodes) can  
581 enhance rates of denitrification (Bonaglia et al., 2014). Both foraminifera and meiofauna were  
582 observed in SBB depocenter and A-station sediments in November 2019, and diatoms were  
583 observed in shallower sediments in the basin (data not shown). Other studies found that benthic  
584 foraminifera in the SBB depocenter can hyperaccumulate  $\text{NO}_3^-$  intracellularly up to  $375 \pm 174$   
585 mM (Bernhard et al., 2012) and host symbionts capable of performing denitrification (Bernhard  
586 et al., 2000). These foraminifera were found to be responsible for approx.  $3 \text{ mM N m}^{-2} \text{ d}^{-1}$ , or  
587 67% of the total denitrification occurring in the SBB depocenter (Bernhard et al., 2012).  
588 Additionally, fungi could reduce  $\text{NO}_3^-$  or  $\text{NO}_2^-$  to nitrous oxide in marine sediments and may  
589 contribute to denitrification in SBB sediments (Kamp et al., 2015; Lazo-Murphy et al., 2022).  
590 This opens up the possibility that the majority of denitrification we observed in the SBB  
591 depocenter is performed by eukaryotes, while prokaryotes (especially GSOB) are responsible for  
592 most of the DNRA. Elevated  $\text{NO}_3^-$  and  $\text{NO}_2^-$  concentrations that were observed in our 0-1 cm  
593 samples from NDT3-A and SDRO have been reported from SBB depocenter sediments in the  
594 past (Reimers et al., 1996; Bernhard et al., 2003), and have been attributed to both GSOB and benthic  
595 eukaryotes. The impact of eukaryotes on SBB benthic nitrogen transformation remains to be disentangled  
596 from the mats themselves.

597

598

599 Our data suggests a transition from denitrification-dominated sediment in the oxygenated basin  
600 to an increasing influence of DNRA on N cycling in the deeper, anoxic basin. Placed in the  
601 context of other OMZs, Mauritanian shelf sediment was dominated by denitrification (Dale et al.,  
602 2014), similar to SBB shallow sediment (below hypoxic water) while core Peruvian OMZ  
603 sediment was dominated by DNRA, similar to sediment of the deeper SBB (below anoxic water)  
604 (Sommer et al., 2016). Nitrate reduction in sediment below the seasonally hypoxic Eckernförde  
605 Bay (Dale et al., 2011) and below the hypoxic transition zone of the Eastern Gotland Basin  
606 (Noffke et al., 2016) also showed increased DNRA where GSOB mats were present, though with  
607 an order of magnitude lower  $\text{NH}_4^+$  flux (avg.  $1.74 \text{ mmol m}^{-2} \text{ d}^{-1}$  and max.  $1.10 \text{ mmol m}^{-2} \text{ d}^{-1}$ ,  
608 respectively) than the SBB depocenter.

609

610 While our study suggests a shift from denitrification to DNRA during deoxygenation of SBB  
611 bottom water, other studies examined changes in benthic nitrogen cycling under reverse  
612 conditions, i.e., the reoxidation of the environment following anoxia (Hylén et al., 2022; De  
613 Brabandere et al., 2015). After a decadal oxygenation event in the Eastern Gotland Basin (Baltic  
614 Sea) in 2015-2016, sediment exhibited a slight increase in denitrification, but remained  
615 dominated by DNRA and  $\text{N}_2\text{O}$  production (Hylén et al., 2022). The lack of  $\text{N}_2$  production via  
616 denitrification following this oxygenation event was attributed to the reoxygenation event being  
617 too weak to substantially oxidize sediments, which would favor denitrification (Hylén et al.,  
618 2022). In an engineered reoxygenation event of the By Fjord on Sweden's western coast, where  
619 dissolved  $\text{O}_2$  and  $\text{NO}_3^-$  content of anoxic and anoxic bottom water was artificially increased to

620 approx. 130  $\mu\text{M}$   $\text{O}_2$  and 20  $\mu\text{M}$   $\text{NO}_3^-$  over a period of roughly 2 years, denitrification rates were  
 621 increased by an order of magnitude and DNRA rates were also stimulated (De Brabandere et al.,  
 622 2015). Comparing our results to these two studies suggests that DNRA bacteria are more  
 623 resilient to weak reoxygenation events and thrive in transiently deoxygenated systems that  
 624 remain hypoxic ( $\text{O}_2 < 63 \mu\text{M}$ ). The frequency and magnitude of reoxygenation and  
 625 deoxygenation of SBB bottom waters, and the effect of these processes on the benthic microbial  
 626 community, could be a major factor supporting some of the highest recorded total nitrate  
 627 reduction rates in a natural benthic marine setting (Peng et al., 2023).

628 **Table 3.** Example reactions of nitrate reduction pathways with associated energy yield in respect to the electron  
 629 donor ( $\text{H}_2$  or  $\text{HS}^-$ ) and electron acceptor ( $\text{NO}_3^-$ ) and electron accepting capacity. Modified from Table 2 in (Tiedje  
 630 et al., 1983).

Reaction	$\Delta\text{G}^\circ$ (kcal mol <sup>-1</sup> )		Electrons per $\text{NO}_3^-$
	$\text{H}_2 / \text{HS}^-$	$\text{NO}_3^-$	
<u>Chemoheterotrophic Denitrification</u>			
$2\text{NO}_3^- + 5\text{H}_2 + 2\text{H}^+ \rightarrow \text{N}_2 + 6\text{H}_2\text{O}$	-53.6	-133.9	5
<u>Chemoautotrophic Denitrification</u>			
$8\text{NO}_3^- + 5\text{HS}^- + 3\text{H}^+ \rightarrow 5\text{SO}_4^{2-} + 4\text{N}_2 + 4\text{H}_2\text{O}$	-177.9	-111.2	5
<u>Chemoheterotrophic DNRA</u>			
$\text{NO}_3^- + 4\text{H}_2 + 2\text{H}^+ \rightarrow \text{NH}_4^+ + 3\text{H}_2\text{O}$	-35.8	-143.3	8
<u>Chemoautotrophic DNRA</u>			
$\text{NO}_3^- + \text{HS}^- + \text{H}^+ + \text{H}_2\text{O} \rightarrow \text{NH}_4^+ + \text{SO}_4^{2-}$	-107.0	-107.0	8

631  
 632  
 633 A high ratio of electron donor to electron acceptor favors DNRA over denitrification (Marchant  
 634 et al., 2014; Hardison et al., 2015; Tiedje et al., 1983) and this ratio appears to be critical in  
 635 determining the dominant nitrate reduction pathway in SBB sediments, similar to the Eastern  
 636 Gotland Basin (Hylén et al., 2022) and the By Fjord (De Brabandere et al., 2015). Example  
 637 energy yields for denitrification and DNRA are shown in Table 3. As discussed in (Tiedje et al.,  
 638 1983), heterotrophic denitrification yields more energy per mol of electron donor than DNRA.  
 639 However, the reverse is true when considering energy yield per mol of electron acceptor ( $\text{NO}_3^-$ ).

640 DNRA also yields 3 more electrons per molecule of  $\text{NO}_3^-$  than denitrification. Tiedje et al.  
641 argued that in environments that are starved of powerful terminal electron acceptors, such as  
642 anoxic, organic-rich sediment, the energy yield per electron acceptor and additional electrons  
643 available for transfer could push nitrate reduction towards DNRA. Multiple laboratory and  
644 model studies have converged on an electron donor to acceptor ratio of approximately 3 to  
645 encourage DNRA over denitrification (Hardison et al., 2015; Algar and Vallino, 2014) though  
646 other studies have found higher values (Porubsky et al., 2009; Kraft et al., 2014). Sulfide  
647 concentrations near the sediment-water interface at the SBB depocenter (approx.  $200 \mu\text{M}$  at 0.5  
648 cm depth; Fig. 3, NDRO) would favor chemoautotrophic DNRA over denitrification at ambient  
649 marine nitrate concentrations (approx.  $28 \mu\text{M}$ ). Additionally, DNRA appears to be the preferred  
650 nitrate reduction pathway for chemoautotrophs that utilize iron or sulfide as an electron donor  
651 (Caffrey et al., 2019; Kessler et al., 2019; An and Gardner, 2002). As GSOB mats hyper-  
652 accumulate nitrate from the bottom water into their intracellular vacuoles, the resulting decline in  
653 electron acceptors at the sediment-water interface coupled with an elevation of the sulfate  
654 reduction zone would create an electron donor to acceptor ratio that favors DNRA. Since GSOB  
655 mats in the SBB seem to prefer DNRA, starving the bottom water of electron acceptors coupled  
656 with the high sulfate reduction rates could give them a competitive advantage and allow them to  
657 proliferate into the largest-yet mapped GSOB mat in Earth's oceans, as seen in other expeditions  
658 (Valentine et al., 2016; Reimers et al., 1996; Kuwabara et al., 1999).

659

660 **4.3 Microbial mat proliferation and benthic phosphate remineralization dependent on high**  
661 **rates of organic matter degradation in the Santa Barbara Basin**

662

663 Organic carbon content of the benthic environment appears to be a key control on sulfate  
664 reduction rates near the sediment-water interface as well as microbial mat proliferation. Sulfate  
665 reduction rates in the SBB depocenter are most similar in magnitude and profile (i.e., highest  
666 rates found at the sediment-water interface and decline drastically thereafter) to those found in  
667 sediments below the transiently deoxygenated portion of the Peruvian shelf (e.g., 4.1 mmol m<sup>-2</sup>  
668 d<sup>-1</sup> at the SBB NDRO station vs. 2.5-3.8 mmol m<sup>-2</sup> d<sup>-1</sup> at 128-144 m water depth on the Peruvian  
669 margin (Gier et al., 2016; Treude et al., 2021)). The TOC content of surface sediments in these  
670 two regions are both high and within the same order of magnitude (maximum recorded TOC of  
671 5.2% at the 0-1 cm margin at the SDT1-A station compared with 7.6% in the Peruvian margin  
672 145 m depth (Noffke et al., 2012)). In comparison, sulfate reduction rates in the SBB were at  
673 least one order of magnitude lower than found in sediment below the OMZ on the Namibian  
674 Shelf, which has much higher TOC contents of >10% (Brüchert et al., 2003; Bremner, 1981).  
675 Sulfate reduction rates in the shelf sediments below the Eastern Arabian OMZ were much lower  
676 (0.18 – 1.27 mmol m<sup>-2</sup> d<sup>-1</sup>) than rates in the SBB depocenter (Naik et al., 2017) despite similar  
677 hypoxic to anoxic bottom water conditions. These lower sulfate reduction rates were attributed to  
678 the relatively low amount of pelagic primary productivity and ergo benthic organic matter  
679 delivery in the Eastern Arabian OMZ compared to other upwelling systems (Naik et al., 2017).  
680 The organic matter content of the sediment appears to be important in the proliferation of GSOB  
681 mats; too much TOC could result in toxic levels of sulfide at the sediment-water interface  
682 (*Beggiatoa* exhibit an aversion to sulfidic sediments but toxicity has not been quantified)  
683 (Preisler et al., 2007), whereas too little sulfide would not provide enough electron donor for the  
684 GSOB's chemoautotrophic metabolism.  
685

686 The profiles of several indicators for benthic anaerobic organic matter remineralization (total  
687 alkalinity, DIC,  $\text{PO}_4^{3-}$ ,  $\text{NH}_4^+$ ) increased in steepness with increasing water depth (Figs. 2 A-E &  
688 3A-F). One divergence from this trend can be seen in  $\text{PO}_4^{3-}$  profiles from the shallow C- and D-  
689 stations, which also featured low rates of sulfate reduction.  $\text{PO}_4^{3-}$  profiles in these sediments  
690 track closely to  $\text{Fe}^{2+}$  profiles; both solutes dip in concentration in areas with visible iron sulfide  
691 formation (e.g., 5-11 cm in NDT3-D as seen in Fig. 2A). Additionally, several stations that  
692 exhibited high sulfate reduction rates in surface sediment (e.g., SDT1-A) showed almost no  
693 change in  $\text{PO}_4^{3-}$  at depths below 5 cm (e.g., Fig. 2 K-O compared to Fig. 2 A-E). This  
694 phenomenon has been previously documented in SBB sediment and is attributed to the  
695 precipitation of carbonate fluorapatite (Reimers et al., 1996). The confinement of these flat  $\text{PO}_4^{3-}$   
696 profiles to stations with  $>100 \text{ nmol cm}^{-3} \text{ d}^{-1}$  sulfate reduction in surface sediment suggests that  
697 this mineralogical sink of  $\text{PO}_4^{3-}$  in SBB sediment may be dependent on high sulfate reduction  
698 rates, owing to the bicarbonate produced by sulfate reduction (Reimers et al., 1996), and is not  
699 found throughout the basin. Flat  $\text{PO}_4^{3-}$  profiles were also reported from the transiently  
700 deoxygenated portion of the Peruvian OMZ, where phosphate mineral precipitation has been  
701 documented (Noffke et al., 2012). Similar to the shallow margins of the SBB,  $\text{PO}_4^{3-}$  in  
702 Mauritanian OMZ porewater tracks closely with changes in porewater  $\text{Fe}^{2+}$  (Schroller-Lomnitz  
703 et al., 2019), indicating that iron mineralization/dissolution mechanisms hold a greater influence  
704 on  $\text{PO}_4^{3-}$  concentrations under hypoxic bottom waters.

705

706 **4.4 Iron oxide exhaustion is critical for raising the sulfate reduction zone close to the**  
707 **sediment-water interface in Santa Barbara Basin sediment.**

708

709 The hyper-accumulation of  $\text{NO}_3^-$  by GSOB mats potentially facilitates sulfate reduction close to  
710 the sediment-water interface in the SBB (e.g., NDRO and NDT3-A as seen in fig. 2N and 2O) by  
711 starving the sediment of this more powerful electron acceptor. The rise of the sulfate reduction  
712 zone at NDT3-C (fig. 2L) further suggests that the exhaustion of iron oxides and the formation of  
713 iron sulfide below the sediment-water interface may play a crucial role in controlling the  
714 distribution of sulfate reduction as well. SBB sediments showed a wide vertical and horizontal  
715 heterogeneity of redox states based on visual appearance (Fig. 1A-K). Sediment beneath the  
716 hypoxic bottom water at the shallowest D-stations was reddish, consistent with a high content of  
717 iron oxides. Interestingly, porewater  $\text{Fe}^{2+}$  concentrations in shallower parts of the basin (e.g.,  
718 NDT3-D, max.  $\sim 700 \mu\text{M Fe}^{2+}$ ) were an order of magnitude larger than those found in both the  
719 Peruvian (max  $\sim 60$  and  $\sim 30 \mu\text{M Fe}^{2+}$ , respectively; (Noffke et al., 2012; Plass et al., 2020) and  
720 Mauritanian (max.  $\sim 50 \mu\text{M Fe}^{2+}$ ; Schroller-Lomnitz et al 2019) OMZ. It should be noted that  
721 porewater samples for geochemical analyses were unfiltered and hence reported iron  
722 concentrations include aqueous, colloidal, and nanoparticulate species. Regardless, all these  
723 components represent bioavailable sources of iron. Further, since filtering through 0.45 or 0.2  
724  $\mu\text{m}$  filters only removes a fraction of colloidal particles and no nanoparticles (Raiswell and  
725 Canfield, 2012), potential surplus porewater iron in SBB samples in comparison to studies that  
726 applied filtering was likely minimal.

727

728 Deeper in the basin, bands of black sediment that appear mid-core at NDT3-C (6-14 cm) and  
729 SDT3-C (6-10 cm) indicate the formation of iron sulfides as a result of sulfide produced by  
730 sulfate reduction (Canfield, 1989). Both D-stations had similar bottom water conditions (Table  
731 1), sulfate reduction rates (Fig. 3W-AG), porewater concentrations of solutes (Figs. 2 and 3), and

732 visual sediment characteristics (Section 3.1). On the contrary, there are some noticeable  
733 differences in the porewater geochemistry between the two C-stations. At the C-stations, peaks  
734 in sulfate reduction were in the surface sediment, above the iron sulfide layers, and declined  
735 below approximately 4 cm, indicating a discrepancy between observed peak sulfate reduction  
736 activity and the mineralogical clues left behind by the process. Comparing NDT3-C and SDT3-  
737 C, iron sulfide formation (Table 1B compared to 1J), porewater  $\text{Fe}^{2+}$  profiles (Fig. 2G compared  
738 to Fig. 3H), and sulfate reduction rates (Fig. 2L compared to Fig. 3N) show that NDT3-C  
739 sediment appears to be in transition towards a more sulfidic state, while SDT3-C sediments still  
740 mimic the shallow D-station ferruginous state. While sulfate reduction rates for B-stations are  
741 not available due to technical issues during sample processing, porewater  $\text{Fe}^{2+}$  profiles show a  
742 similar difference between the north and south basin (Fig. 2H compared to Fig. 3I) as did visual  
743 sediment characteristics (Table 1C compared to 1I). This difference in biogeochemical profiles  
744 and apparent mineralogy between the north and south C- and B-stations could be a result of  
745 hydrographic and/or bathymetric differences in the basin (Sholkovitz and Gieskes, 1971; Bograd  
746 et al., 2002), but a discernable link between the differences in sediment biogeochemistry and the  
747 differences in bottom water oxygen (Table 1) need to be further explored.

748

749 Deeper in the basin (depocenter and A-stations), porewater  $\text{Fe}^{2+}$  concentrations in sediment  
750 beneath anoxic bottom water (max.  $84 \mu\text{M Fe}^{2+}$ ) were similar to concentrations found below the  
751 Peruvian OMZ in 2008 under anoxic bottom water conditions (78 m water depth, max.  $80 \mu\text{M}$   
752  $\text{Fe}^{2+}$ ) (Noffke et al., 2012). These deep basin porewater  $\text{Fe}^{2+}$  concentrations were, however, an  
753 order of magnitude larger than those found at a similar site on the Peruvian shelf (75 m water  
754 depth, max.  $1 \mu\text{M Fe}^{2+}$ ) in 2017 during a kelvin-wave-associated “Coastal El Niño” event that

755 created oxygenated bottom waters during the sampling and the disappearance of previously  
756 observed dense GSOB mats (Plass et al., 2020). As the SBB water column was undergoing rapid  
757 deoxygenation in the weeks preceding this study (Qin et al., 2022), the sediments below the sill  
758 appeared to be actively shifting from a ferruginous state to a sulfidic state, with this change  
759 starting around the C-stations and being complete in the depocenter. Comparing apparent iron  
760 sulfide formation with dips in porewater  $\text{Fe}^{2+}$  concentrations in C-station profiles (Fig. 1B  
761 compared to Fig. 2G and Fig. 1J compared to Fig. 3H) signals a shift away from a ferruginous  
762 state occurring just below the SBB sill.

763

764 C-station porewater  $\text{Fe}^{2+}$  concentrations and sulfate reduction rates indicate that migration of the  
765 sulfate reduction zone towards the sediment-water interface is associated with iron sulfide  
766 formation deeper in the sediment. The activity (or lack thereof) of cable bacteria, which are able  
767 to bridge the gap between the oxidized sediment-water interface and reduced sediment below  
768 using a biofilament (Pfeffer et al., 2012), could explain the interplay between sulfate reduction  
769 and iron cycling in SBB sediments. Cable bacteria, such as *Ca. Electronema* sp., contain genes  
770 involved in DNRA (Kjeldsen et al., 2019) and can perform nitrate reduction in incubation  
771 experiments (Marzocchi et al., 2014), but their direct transformation of  $\text{NO}_3^-$  in the environment  
772 appears limited (Kessler et al., 2019) and they appear to be inactive in anoxic aquatic  
773 environments (Seitaj et al., 2015; Marzocchi et al., 2018; Hermans et al., 2019). Cable bacteria  
774 primarily conduct aerobic sulfide oxidation (Pfeffer et al., 2012), though they can also utilize  
775  $\text{Fe}^{2+}$  as an electron donor (Seitaj et al., 2015). The maximum recorded filament length of cable  
776 bacteria is 7 cm (Van De Velde et al., 2016), though typically they are not stretched completely  
777 vertically through the sediment. The appearance of black sediment in the SBB C-station

778 sediments, starting at approx. 5 cm depth, could be an indication that cable bacteria are oxidizing  
779 iron sulfides at that sediment depth and prevent their formation at shallower depths. Further,  
780 cable bacteria have been found to directly compete with GSOB in transiently deoxygenated  
781 systems, with cable bacteria active under oxygenated conditions and GSOB active in anoxic  
782 conditions (Seitaj et al., 2015). Cable bacteria can also prevent the benthic release of sulfide,  
783 which is toxic to many pelagic animals, via the creation of an iron-oxide buffer (formed through  
784  $\text{Fe}^{2+}$  oxidation) in near-surface sediments (Seitaj et al., 2015). Therefore, if cable bacteria activity  
785 in the SBB decreased with declining oxygen concentrations below the sill, the iron oxide buffer  
786 they create could have been reduced, encouraging the sulfate reduction zone to migrate towards  
787 the sediment surface (as seen at NDT3-C). Cable bacteria can sometimes be detected in  
788 sediments via a slight pH increase (typically  $\text{pH} > 8$ ) (Schauer et al., 2014) which was not  
789 reflected in our pH results, but this phenomenon is more typically seen in the laboratory and not  
790 the field (Hermans et al., 2019).

791

#### 792 **4.5 Iron and phosphate flux into SBB bottom water is a feature of transient deoxygenation.**

793

794 Release of dissolved iron and phosphate from sediment below anoxic waters is a well-  
795 documented phenomenon (e.g., (Mortimer, 1941; Van Cappellen and Ingall, 1994; Van De  
796 Velde et al., 2020; Noffke et al., 2012)) and this phenomenon is seen in the SBB as well. As  
797 postulated previously (Kuwabara et al., 1999), basin flushing oxidizes iron sulfides at the  
798 sediment-water interface, providing ample substrate for microbial iron reduction once anoxia  
799 returns. This iron reduction initiates high rates of  $\text{Fe}^{2+}$  release from SBB depocenter sediment  
800 (Fig. 5). Iron reduction further releases iron-bound  $\text{PO}_4^{3-}$  (Mortimer, 1941) as seen by high

801 benthic fluxes of  $\text{PO}_4^{3-}$  at the depocenter (Fig. 5), although notably some of this  $\text{PO}_4^{3-}$  release is  
802 likely attributed to organic matter degradation (Van Cappellen and Ingall, 1994). High benthic  
803  $\text{Fe}^{2+}$  and  $\text{PO}_4^{3-}$  fluxes were also seen on the Peruvian shelf during transient anoxia (Noffke et al.,  
804 2012). The release of these solutes was interpreted to be sourced from a layer of reactive iron  
805 hydroxides existing near the sediment surface, likely established during a recent oxygenation  
806 event. Similar conditions, i.e., visibly oxidized (reddish) sediment laminae and a thin zone of  
807 iron reduction apparent from a peak in  $\text{Fe}^{2+}$  at the sediment-water interface, were found in  
808 sediment from the SBB depocenter. Deeper in the persistently anoxic core of the Peruvian OMZ,  
809 sediment appears to have little to no flux of  $\text{Fe}^{2+}$  and  $\text{PO}_4^{3-}$  into the bottom water (Noffke et al.,  
810 2012). Here, iron at the sediment-water interface is hypothesized to be locked up in iron sulfides,  
811 which are rarely re-oxidized due to persistent anoxia.

812

813 In a different study from the Eastern Gotland Basin in the Baltic Sea, enhanced elemental fluxes  
814 were observed during a decadal oxygen flushing event (Van De Velde et al., 2020), which was  
815 attributed to enhanced elemental recycling, or cycles of mineral precipitation in the water column  
816 followed by mineral dissolution once those minerals sink to the sediment. Notably, the iron flux  
817 observed in the Eastern Gotland Basin (max.  $0.08 \text{ mmol m}^{-2} \text{ d}^{-1}$ ) (Van De Velde et al., 2020) was  
818 two orders of magnitude lower than the flux observed in the anoxic depocenter of the Santa  
819 Barbara Basin (max.  $4.9 \text{ mmol m}^{-2} \text{ d}^{-1}$ ). It is further notable that benthic fluxes of  $\text{PO}_4^{3-}$  in the  
820 SBB depocenter were also an order of magnitude higher than fluxes in the Eastern Gotland  
821 Basin's hypoxic transition zone ( $3.6$  vs.  $0.23 \text{ mmol PO}_4^{3-} \text{ m}^{-2} \text{ d}^{-1}$ ) - both of which contained  
822 GSOB mats, but while the SBB was anoxic and the Eastern Gotland Basin was hypoxic (Noffke  
823 et al., 2016). These differences in  $\text{Fe}^{2+}$  and  $\text{PO}_4^{3-}$  flux between the SBB and the Eastern Gotland

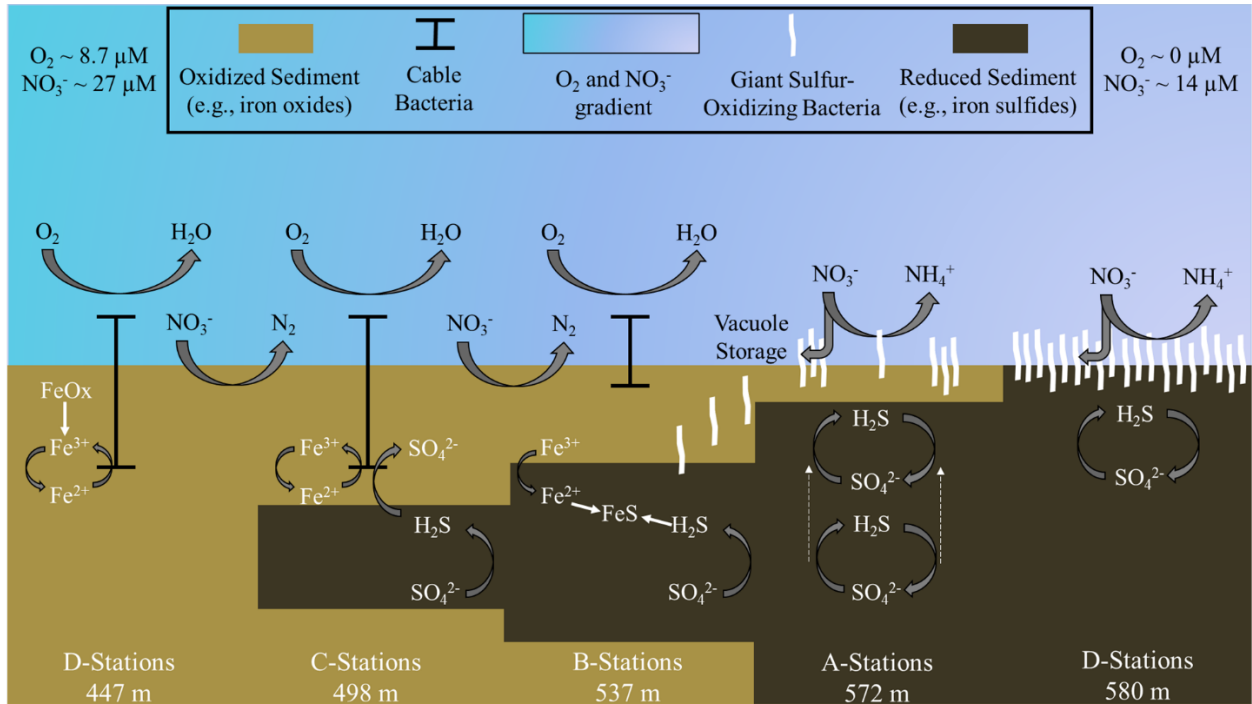

824 Basin suggest that reoxidation of the sediment-water interface during basin flushing, as opposed  
825 to water-column-associated reoxidation, appears to encourage higher benthic iron fluxes.  
826  
827  $\text{Fe}^{2+}$  and  $\text{PO}_4^{3-}$  flux from the SBB depocenter were also approximately five times higher (Fig. 5)  
828 compared to the anoxic Peruvian shelf (4.9 vs. 0.9  $\text{mmol Fe}^{2+} \text{ m}^{-2} \text{ d}^{-1}$  and 3.6 vs. 0.8  $\text{mmol PO}_4^{3-}$   
829  $\text{m}^{-2} \text{ d}^{-1}$ , respectively) (Noffke et al., 2012). Based on  $\text{Fe}^{2+}$  profiles, the zone of iron reduction in  
830 Peruvian shelf sediments extended down to approx. 10 cm, while the zone appeared to be much  
831 shallower and narrower (less than the top 5 cm) in the SBB depocenter. These differences in  
832 magnitude of  $\text{Fe}^{2+}$  concentration and  $\text{Fe}^{2+}$  and  $\text{PO}_4^{3-}$  flux between the SBB depocenter and the  
833 Peruvian shelf could be attributed to differences in the recency and magnitude of reoxygenation  
834 events. The release of  $\text{Fe}^{2+}$  from sediment into the bottom water could create a buffer against  
835 reoxygenation in transiently deoxygenated systems, giving a competitive advantage to anaerobic  
836 benthic metabolisms (Dale et al., 2013; Wallmann et al., 2022). Additionally, both  $\text{Fe}^{2+}$  and  
837  $\text{PO}_4^{3-}$  release from the SBB sediment could allow for higher rates of primary productivity if  
838 those constituents diffused into the photic zone (Robinson et al., 2022). The fate of  $\text{Fe}^{2+}$  and  
839  $\text{PO}_4^{3-}$  diffusing into SBB waters from the sediment-water interface is a focus of ongoing work  
840 within the basin.

841  
842 **5 Conclusions**  
843

844 This research expands upon the wealth of science already conducted in the SBB and other  
845 transiently deoxygenated environments by examining changes in benthic biogeochemistry  
846 promoted by the onset of anoxia. Our main interpretations are summarized in Fig. 7. We found  
847 that GSOB mats proliferate in the SBB where the bottom water is anoxic and nitrate

848 concentrations are declining (Fig. 7, A- and depocenter stations). Nitrate uptake by SBB  
849 sediment is similar regardless of GSOB mat presence, but these mats appear to initiate a shift  
850 from denitrification to DNRA as the primary nitrate reduction pathway (Fig. 7, beginning at B-  
851 stations). The zone of sulfate reduction rises to the sediment-water interface where GSOB mats  
852 are present (Fig. 7, A-stations), possibly because the hyper-accumulation of nitrate into their  
853 intracellular vacuoles starves the environment of this more powerful electron acceptor. However,  
854 following the natural order of electron acceptor utilization (Boudreau and Jorgensen, 2001), iron  
855 oxides near the sediment-water interface must be exhausted before sulfate reduction can  
856 dominate surface sediments and GSOB mats can proliferate in the SBB (Fig. 7, depocenter  
857 stations). If anoxic events become longer and more frequent in the SBB because of global  
858 warming (see, e.g., (Qin et al., 2022; Stramma et al., 2008)), the iron oxide buffer built up in  
859 shallower basin depths could be exhausted, allowing for surface sulfate reduction and the  
860 proliferation of GSOB mats in shallower margins of the basin than currently seen. Further, the  
861 same transient deoxygenation that allows for these mats to re-establish themselves also allows for  
862 a high  $\text{Fe}^{2+}$  and  $\text{PO}_4^{3-}$  flux into the SBB water column. In order to fully understand the complex  
863 changes in the benthic environment in response to deoxygenation, genomic and molecular work  
864 of the upper sediment community needs to be characterized. Overall, the insights gleaned from  
865 this research will aid in the understanding of fundamental biogeochemical changes that occur  
866 when marine environments become anoxic.

**Figure 7:** Schematic of biogeochemical processes in the Santa Barbara Basin along the depth gradients studied in October/November 2019. Teal to lavender gradient represents a decline in  $O_2$  and  $NO_3^-$  concentrations with basin depth. In the shallower, hypoxic basin (D-stations), denitrification and iron reduction are dominant and reduced iron is rapidly re-oxidized in near-surface sediment by cable bacteria. Deeper in the basin (A-stations and depocenter), nitrogen cycling shifts towards dissimilatory nitrate reduction to ammonia (DNRA). Reduced iron combines with sulfide, produced by sulfate reduction, diffusing from deeper sediment layers to form iron sulfides. As oxygen concentration approaches zero between the A-stations and the basin's depocenter, giant sulfur-oxidizing bacteria hyper-accumulate nitrate in their intracellular vacuoles. Nitrate removal combined with the exhaustion of available iron oxides in the near-surface sediments allows the zone of sulfate reduction to migrate towards the surface (see dashed arrows at A-stations), providing the giant sulfur-oxidizing bacteria with sufficient reduced sulfur to proliferate into thick, contiguous mats. Note: Figure is not to scale, and processes are simplified to illustrate main concepts.

881 **Acknowledgements**

882 We thank the captain, crew, and scientific party of the R/V Atlantis, and the crew of the ROV  
883 Jason for their technical and logistical support during the research expedition AT42-19. We also  
884 thank Q. Qin, E. Arrington, M. O’Beirne, A. Mazariegos, X. Moreno, A. Eastman, and K.  
885 Gosselin for assisting with shipboard analyses. We thank J. Liu for assistance in reviewing the  
886 data processing for this manuscript. We further thank M. Alisch from the Max-Planck-Institute  
887 in Bremen, Germany for DIC analyses. We thank G. Eickert-Gröttschel, V. Hübner, A. Niclas, I.  
888 Schröder, and C. Wigand from the Max-Planck-Institute in Bremen, Germany for constructing  
889 the microsensors. We acknowledge J. Matthews from the UC Davis Stable Isotope facility for  
890 assisting with solid phase analyses. Funding for this work was provided by the US National  
891 Science Foundation, NSF OCE-1756947 and OCE-1830033 (to DLV) and OCE-1829981 (to  
892 TT), and a Simons Foundation Postdoctoral Fellowship in Marine Microbial Ecology (No.  
893 547606 to XP). Further support was provided by the Max Planck Society and the Alfred  
894 Wegener Institute for Polar and Marine Research.

896 **Data availability.**

897 Biogeochemical data presented in this manuscript are accessible through the Biological &  
898 Chemical Oceanography Data Management Office (BCO-DMO) at the following landing pages:  
899 <https://www.bco-dmo.org/dataset/867007>; <https://www.bco-dmo.org/dataset/867113>;  
900 <https://www.bco-dmo.org/dataset/867221>; <https://www.bco-dmo.org/dataset/896706>

901 **Author contributions.**

902 TT, DV, FK, NL, and JT designed the project. DJY, SK, JT, DR, and TT processed sediment  
903 cores at sea. DJY conducted geochemical analyses of sediment porewater and benthic flux  
904 chamber water. DJY prepared TOC and TON samples. DR and SK analyzed sediment porosity  
905 and density. TT and SK performed shipboard sulfate reduction incubations. DJY and DR  
906 conducted sulfate reduction analyses. DJY, NL, and JT transformed and interpreted ROV Jason  
907 data. FJ and FW operated BFC and microprofilers and analyzed associated data. XP conducted  
908 <sup>15</sup>N experiments and analyses. All authors reviewed and edited the manuscript.
