24 **Abstract**

25

26 The Santa Barbara Basin naturally experiences transient deoxygenation due to its unique
27 geological setting in the Southern California Borderland and seasonal changes in ocean currents.
28 Long-term measurements of the basin showed that anoxic events and subsequent nitrate
29 exhaustion in the bottom waters have been occurring more frequently and lasting longer over the
30 past decade. One characteristic of the Santa Barbara Basin is the seasonal development of
31 extensive mats of benthic nitrate-reducing sulfur-oxidizing bacteria, which are found at the
32 sediment-water interface when the basin's bottom waters reach anoxia but still provide some
33 nitrate. To assess the mat's impact on the benthic and pelagic redox environment, we collected
34 biogeochemical sediment and benthic flux data in November 2019, after anoxia developed in the
35 deepest waters of the basin and dissolved nitrate was depleted (down to 9.9 μM). We found that
36 the presence of mats was associated with a shift from denitrification to dissimilatory nitrate
37 reduction to ammonium. The zone of sulfate reduction appeared near the sediment-water
38 interface in sediment hosting these ephemeral white mats, but that alone seems insufficient to
39 spur their growth. We found that a high sediment TOC content (>5%) and an exhaustion of iron
40 oxides in the surface sediment were additional prerequisites for mat proliferation. Our research
41 further suggests that cycles of deoxygenation and reoxygenation of the benthic environment
42 result in extremely high benthic fluxes of dissolved iron from the basin's sediment. This work
43 expands our understanding of nitrate-reducing sulfur-oxidizing mats and their role in sustaining
44 and potentially expanding marine anoxia.

45 **Introduction**

46

47 Naturally occurring low-oxygen waters in the ocean are commonly observed below the ocean's
48 mixed layer where respiration consumes oxygen faster than it is produced or ventilated. When
49 low oxygen conditions occur along the western continental shelf in regions susceptible to
50 upwelling events and/or undergoing eutrophication, organic matter remineralization can
51 frequently drive oxygen concentrations to hypoxic ($O_2 < 63 \mu\text{M}$) (Middelburg and Levin, 2009)
52 and/or anoxic levels ($O_2 < 3 \mu\text{M}$) (Fossing et al., 1995b; Canfield et al., 2010). These areas
53 usually referred to as Oxygen Minimum Zones (OMZs). In the water column of OMZs, nitrogen
54 transformation through canonical denitrification or dissimilatory nitrate reduction to ammonium
55 (DNRA) becomes the dominant organic matter remineralization mechanism (Ward et al., 2009).
56 OMZs within coastal basins that experience seasonal changes in upwelling can experience
57 anoxic and denitrifying conditions that extend to the benthic environment, especially when high
58 productivity (and associated organic matter export fluxes) coincide with seasonal patterns in
59 physical mixing. This fundamental change in the redox conditions at the sediment-water
60 interface encourages elevated rates of anaerobic microbial processes and promotes organic
61 matter preservation in the sediments (Middelburg and Levin, 2009; Treude, 2011). Persistent
62 anoxia in these coastal OMZ can lead to huge releases of sulfide (up to $13.7 \text{ mmol m}^{-2} \text{ d}^{-1}$) and
63 ammonium (up to $21.2 \text{ mmol m}^{-2} \text{ d}^{-1}$) into the water column (Sommer et al., 2016).

64

65 The Santa Barbara Basin (SBB) is a coastal basin in the California Borderland with an
66 approximate maximum depth of 600 m characterized by a seasonally anoxic water column
67 (Sverdrup and Allen, 1939; Sholkovitz and Gieskes, 1971). The transform boundary along the

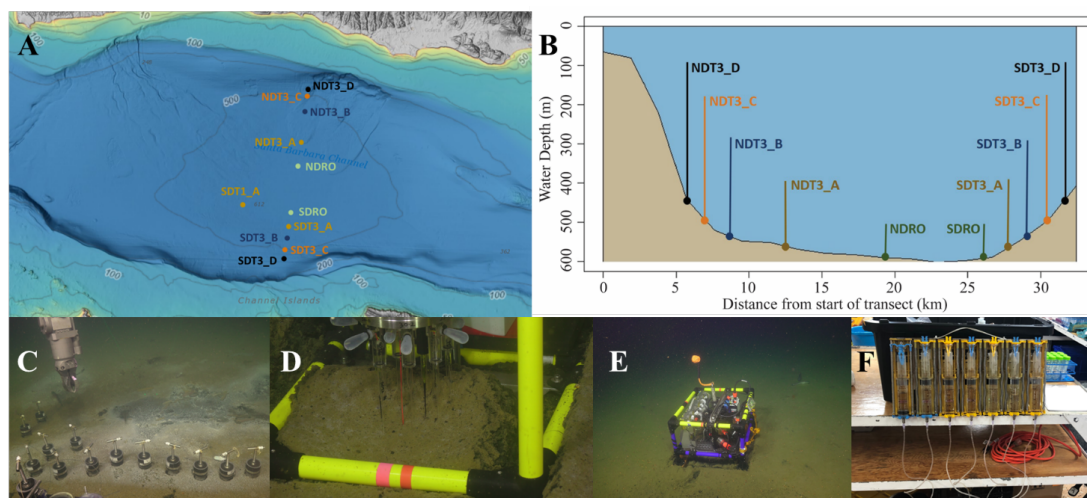

68 California Borderland heavily affects the geomorphology of basins in this region; these basins
69 become twisted as the plates rub against each other and form a series of “bathtubs” blocked by
70 sills and seamounts off the coast of California. The SBB is bordered by the California coast in
71 the north, the Channel Islands in the south, the Santa Monica basin to the east, and the Arguello
72 Canyon to the west. A sill to the west of the basin at around 475 m depth (Fig. 1) prohibits most
73 water transfer between the Santa Lucia Slope and the deeper waters of the SBB (Sholkovitz and
74 Gieskes, 1971). The highly productive surface waters in the basin provide ample organic matter
75 to the basin’s water column, encouraging strong remineralization processes below the euphotic
76 zone, which can induce anoxia below the sill depth, with typically less than $1 \mu\text{mol O}_2 \text{ L}^{-1}$
77 (Sholkovitz, 1973; Emery et al., 1962; Thunell, 1998; Emmer and Thunell, 2000). During
78 upwelling events (usually in Spring), oxygenated waters from the California Current spill over
79 the western sill and ventilate the SBB, increasing oxygen concentrations to approximately 20
80 $\mu\text{mol O}_2 \text{ L}^{-1}$ (Goericke et al., 2015). SBB water-column oxygen and nitrogen concentrations
81 have been evaluated through a longitudinal survey by the California Cooperative Oceanic
82 Fisheries Investigations (Calcofi) with data starting in the 1950’s . The data collected by this
83 survey shows increasingly ubiquitous anoxia and denitrification in the basin with the SBB
84 becoming completely nitrate-depleted below the sill at least three times between 2012 and 2017
85 (<https://calcofi.org/data/>).

86

87 These drastic changes in SBB oxygenation and seafloor redox conditions drive complex changes
88 in benthic biogeochemistry and microbiology, evidenced most clearly by the development of
89 thick, expansive mats of giant sulfur-oxidizing bacteria (GSOB) mats at the seafloor (Bernhard et
90 al., 2003; Prokopenko et al., 2006; Valentine et al., 2016; Kuwabara et al., 1999). A 2016 survey

91 of the basin seafloor identified a vast GSOB mat spread over 1.6 contiguous km, confined
92 between 487 and 523 km in the SBB depocenter where conditions were anoxic but not depleted
93 of NO_3^- (Valentine et al., 2016). Similar GSOB mats have been identified in several other
94 transiently deoxygenated OMZs including the Peruvian/Chilean coast (Sommer et al., 2016;
95 Schulz et al., 1996; Zopfi et al., 2001; Høglund et al., 2009). These chemoautotrophic bacteria
96 (typically *Thioploca* and/or *Beggiatoa*) utilize sulfide as an electron donor and O_2 or NO_3^- as a
97 terminal electron acceptor (Jørgensen and Nelson, 2004). Some GSOB can hyperaccumulate
98 NO_3^- in cell vacuoles up to 500 mM (Fossing et al., 1995a) and use this NO_3^- reserve to oxidize
99 sulfide that diffuses from the underlying sediment to perform their metabolism. (Huettel et al.,
100 1996; Mußmann et al., 2003; Sayama, 2001).

Figure 1. Maps of sampling locations in the Santa Barbara Basin and photographs of deployed equipment: (A) bathymetric map of the Santa Barbara Basin with locations of all sampled stations; (B) cross-section of the Santa Barbara Basin with locations of all sampled station; (C) sediment push coring with ROV arm; (D) sediment microprofiler; (E) benthic flux chamber; (F) closeup of a syringe system from a benthic flux chamber. The map in (A) was generated using the Bathymetric Data Viewer provided by the National Centers for Environmental Information.

111 These GSOB mats are ephemeral in the SBB, appearing to proliferate and potentially migrate
112 depending on bottom water oxidant concentrations (Kuwabara et al., 1999). The activity of
113 GSOB mats in turn contribute significantly to element cycling in the SBB with large effects on
114 biogeochemical conditions in the bottom water. Isotopic measurements of $^{15}\text{N}/^{14}\text{N}$ and $^{18}\text{O}/^{16}\text{O}$
115 from NO_3^- suggest that sedimentary organisms are responsible for approximately 75% of the total
116 NO_3^- uptake in the SBB (Sigman et al., 2003). Other studies found that GSOB mats inhibit the
117 diffusion of NO_3^- into sediments via hyper-accumulation in vacuoles thereby creating conditions
118 ideal for bacterial organoclastic sulfate reduction beneath them (Fossing et al., 1995b; Zopfi et
119 al., 2001). These studies suggest that GSOB mats in the SBB may be responsible for the majority
120 of NO_3^- consumption in the basin rather than water-column microbes. Additionally, GSOB mats
121 deplete NO_3^- via Dissimilatory Nitrate Reduction to Ammonium (DNRA) in the anoxic bottom
122 water of the Peruvian OMZ (Dale et al., 2016). By contrast, benthic microbial communities in
123 the hypoxic (42 μM) Mauritanian OMZ perform canonical denitrification instead (Dale et al.,
124 2014). The contrast between the Peruvian and Mauritanian OMZ suggests that anoxia triggers
125 the appearance of GSOB mats, and that DNRA is more prevalent where GSOB mats are present.
126
127 The rapid accumulation and consumption of NO_3^- by GSOB mats has ramifications for the redox
128 conditions in the sediment underneath. The depletion of NO_3^- and shallowing of the nitracline
129 could promote high rates of sulfate reduction in the sediment underneath the GSOB mat. In
130 return, the sulfate reduction zone exists close to the sediment-water interface, providing the
131 GSOB mat with readily accessible sulfide. If a metabolic feedback loop is then established
132 between sulfur-oxidizing bacteria at the sediment-water interface and sulfate-reducing bacteria in
133 the sediment, increased NO_3^- loss from the water column and spreading of sulfidic conditions in

134 SBB sediment is expected. With these mats being potentially crucial to nitrogen and sulfur
135 cycling in sediments underlying OMZ, their biogeochemical transformations and ergo effect
136 upon basin redox conditions are critically important to understanding element cycling in the
137 SBB. Such gained knowledge would have additional benefits for predicting biogeochemical
138 feedbacks to the projected expansion of oceanic oxygen deficiency, in the SBB and in OMZs
139 more general, as a result of global change (Stramma et al., 2008).

140

141 Utilizing in-situ technologies, sediment porewater extraction, solid phase analyses, and
142 radiotracer techniques, this study aims to answer the following overarching questions: (1) Which
143 environmental conditions initiate and sustain the proliferation of GSOB mats? (2) Which
144 biogeochemical transformations occur in the sediment underneath these mats? (3) What role do
145 the mats play in the increasingly prevalent anoxic and nitrate-depleted condition found in the
146 SBB?

147 **2. Materials and Methods**

148 **2.1 Benthic sediment sampling and instrument deployment**

149 Sediment samples were taken between 30 October and 11 November 2019 during an expedition
150 aboard the research vessel (*R/V Atlantis*) equipped with the remote operated vehicle (ROV)
151 Jason. Samples were taken at stations along a bimodal, north-south transect through the
152 depocenter of the SBB, as well as one station on a separate transect. Details of sampling stations
153 can be seen in Fig. 1A and 1B. Briefly, depocenter stations are labeled as NDRO and SDRO
154 (northern and southern depocenter radial origin, respectively). The remaining stations are named
155 for the cardinal direction (north vs. south) and the transect number (e.g., SDT1-A is on transect 1
156 while SDT3-A is on transect 3). As station depth decreases, the alpha suffix increases (e.g.,
157 NDT3-A is deeper than NDT3-B, etc.). ROV Jason conducted sediment push coring and
158 deployed automated benthic flux chambers (BFC) and microprofilers at each station. Station
159 depth, latitude, and longitude were automatically generated by the Jason data processor using
160 navigation data derived from the Doppler Velocity Log system and the ultrashort baseline
161 positioning system. Bottom water oxygen concentration was determined using an Aanderaa 4831
162 oxygen optode (Aanderaa Instruments, Bergen, Norway) installed on the ROV. Optical modems
163 (Luma 250LP, Hydromea, Renens, Switzerland) were used to transmit deployment settings and
164 initiate/terminate communications between ROV Jason and the BFC/microprofilers. Multiple
165 push cores (polycarbonate, 30.5 cm length, 6.35 cm inner diameter) per sampling station were
166 retrieved during ROV Jason deployments (Fig. 1C). These cores were inserted into the sediment
167 and retrieved using Jason's manipulator arm. Cores were then stored in a 6-core capacity basket
168 and transported to the surface using a free-ascending underwater elevator. Replicate cores from
169 each station were immediately transferred to a 6°C cold room (representing average in-situ

170 temperature) and subsampled for either solid phase analyses, porewater geochemistry, or
171 radiotracer experiments.

172

173 **2.2 Sediment Core Sub-Sampling**

174 For sediment porewater geochemistry analyses, two replicate ROV push cores that were
175 collected near each other were processed under a constant argon flow to protect redox-sensitive
176 species. Cores were sectioned in 1-cm increments up to 10 cm followed by 2-cm increments
177 below 10 cm. Note, sediments from the NDT3-B station were sliced in 2-cm increments.
178 Sediment subsections were transferred into argon-filled 50-mL conical centrifuge tubes.
179 Porewater was retrieved after sediment samples were centrifuged at 4255 x g for 20 minutes.
180 Solid phase cores were sectioned similar to porewater cores and sub-sampled for sediment
181 density and porosity and organic matter analyses. A cut-off plastic syringe was used to collect 6
182 mL of sediment into pre-weighed plastic vials (15 mL snap-cap vials) and stored in the dark at
183 4°C for sediment porosity and density analysis. Two-mL microcentrifuge tubes were filled with
184 sediment from each depth interval and stored at -30°C for sediment organic matter analyses. One
185 ROV push core per station was sub-sampled with a miniaturized push core (length 20 cm, inner
186 diameter 2.6 cm) and taken to the shipboard radioisotope van for radiotracer experiments (see
187 section 2.5).

188

189 **2.3 Sediment Porewater Geochemistry**

190 Geochemical analyses were performed to provide context for electron donors and acceptors of
191 benthic microbial metabolisms, sediment redox states, and organic matter degradation.
192 Concentrations of sulfide (Cline, 1969), NH_4^+ , PO_4^{3-} , and Fe^{2+} (Grasshoff et al., 1999) were

193 determined shipboard with a Shimadzu UV-Spectrophotometer (UV-1800). Detection limits for
194 sulfide, NH_4^+ , PO_4^{3-} , and Fe^{2+} were $1 \mu\text{M}$. Subsamples (2 mL) for porewater NO_3^- and NO_2^-
195 concentrations were stored in 2-mL plastic vials with an O-ring, frozen shipboard at -30°C and
196 analyzed in the lab on the same spectrophotometer using the method following (García-Robledo
197 et al., 2014). The detection limit for NO_3^- and NO_2^- was $0.5 \mu\text{M}$. Samples for porewater DIC
198 were preserved shipboard with $5 \mu\text{L}$ saturated HgCl_2 in headspace free glass vials and stored at
199 4°C for later analysis following (Hall and Aller, 1992). DIC detection limit was 0.5 mM . Total
200 alkalinity was determined shipboard using direct titration of $500 \mu\text{L}$ of pore water with 0.01 M
201 Titrisol[®] HCl (Pavlova et al., 2008). The analysis was calibrated using IAPSO seawater standard,
202 with a precision and detection limit of 0.05 meq L^{-1} . Subsamples (1 mL) for sulfate and
203 chlorinity were stored in 2-mL plastic vials with an o-ring, frozen shipboard at -30°C and later
204 measured in the lab using a Metrohm 761 ion chromatograph with a methodological detection
205 limit of $30 \mu\text{M}$ (Dale et al., 2015).

206

207 **2.4 Solid Phase Analyses**

208 Plastic vials for sediment porosity and density measurements were weighed prior to the
209 expedition. Samples collected in the vials were dried at 50°C for up to 96 hr until the dry weight
210 was stable. Sediment porosity was determined by calculating the difference between wet and dry
211 sediment weight divided by the volume of the wet sediment. Sediment density was determined
212 by dividing the wet sediment weight by its volume. Analyses for sediment total organic carbon
213 (TOC), total organic nitrogen (TON), and organic carbon isotope composition ($\delta^{13}\text{C}$) were
214 modified from (Harris et al., 2001). Briefly, samples were dried up to 48 hours at 50°C until the
215 dry weight was stable and then treated with direct addition of 1 mL of 6N HCl to dissolve

216 carbonate minerals. These samples were then washed in triplicate with 1-mL of ultrapure water
217 or until a neutral pH was re-established. Samples were centrifuged at 4255 x g for 20 minutes,
218 the supernatant was decanted, and vials were re-dried at 50°C. A subsample (approximately 10-
219 15 mg of sediment) was then packed into individual 8x5 mm pressed tin capsules and sent to the
220 University of California Davis Stable Isotope Facility for analysis using Elemental Analyzer –
221 Isotope Ratio Mass Spectrometry. TOC and TON were calculated based on the sample peak area
222 corrected against a reference material (alfalfa flour). Limit of quantification based on peak area
223 was 100 µg C with an uncertainty of ± 0.2 ‰ for δ¹³C.

224

225 **2.5 Sulfate Reduction**

226 To determine ex-situ microbial sulfate reduction rates, whole round sub-cores were injected with
227 10 µL carrier-free ³⁵S-Sulfate radiotracer (dissolved in water, 200 kBq, specific activity 37 TBq
228 mmol⁻¹) into pre-drilled, silicon-filled holes at 1-cm increments according to (Jørgensen, 1978).
229 These sub-cores were incubated at 6°C in the dark for 6-8 hours. Incubations were stopped by
230 slicing sediment cores in 1-cm increments into 50-mL centrifuge tubes filled with 20-mL zinc
231 acetate (20% w/w) and frozen at -20°C until analysis at the land-based laboratory. Triplicate
232 “killed” controls were produced using homogenized sediment from the same ROV push core.
233 Microbial activity in controls was terminated with zinc acetate (20 mL of 20% w/w) before the
234 addition of radiotracer and subsequent freezing. Lab-based analysis of sulfate reduction rates
235 were determined following the cold-chromium distillation procedure (Kallmeyer et al., 2004).
236 Sulfate reduction rates were calculated per volume of wet sediment (cm³) following equation:

237

$$238 \quad SRR = [SO_4] * P_{SED} * \frac{a_{TRIS}}{a_{TOT}} * \frac{1}{t} * 1.06 * 1000 \quad (\text{EQ \# 1})$$

239

240 Where SRR is sulfate reduction rate ($\text{nmol cm}^{-3} \text{ d}^{-1}$); $[\text{SO}_4]$ is porewater sulfate concentration;
241 P_{sed} is sediment porosity; a_{TRIS} is radioactivity of the total reducible inorganic sulfur (counts per
242 minute); a_{TOT} is total radioactivity used in incubation (counts per minute); t is incubation time in
243 days; 1.06 is the correction factor for expected isotope fractionation; and 1000 is the factor to
244 convert from mmol to nmol.

245

246 **2.6 Benthic In-Situ Investigations**

247 Per station, one to three microprofiler (Fig. 1D) and three BFC (Fig. 1E) deployments were
248 carried out by the ROV Jason at the seafloor. Construction, deployment and operation of
249 automated microprofilers and BFCs followed those described in (Treude et al., 2009). The
250 microprofiler deployed in this study represents a modified, miniaturized version of the
251 instrument described in (Gundersen and Jørgensen, 1990) that was constructed specifically for
252 use by ROV. Microprofilers were outfitted with three O_2 -microelectrodes (Glud et al., 2000),
253 two pH-microelectrodes (Revsbech and Jørgensen, 1986), two H_2S -microelectrodes
254 (Jeroschewsky et al., 1996), and one conductivity sensor to determine the position of the
255 sediment-water interface relative to the tips of the microelectrodes. Concentrations of oxygen
256 and sulfide, as well as pH were each calculated from microelectrode readings as an average per
257 site where replicates existed. Microprofiler frames (and benthic flux chamber frames) were
258 outfitted with syntactic foam to reduce the negative buoyancy of the instruments in water and
259 prevent them from sinking into the extremely soft sediments in the SBB.

260

261 The BFC consisted of a frame equipped with a cylindrical polycarbonate chamber (inner
262 diameter = 19 cm) with its lower portion sticking out of the frame. The upper side of the
263 chamber was closed by a lid containing a stirrer (Type K/MT 11, K.U.M., Kiel, Germany),
264 oxygen optodes (Type 4330, Aanderaa Data Instruments, Bergen Norway and Hydroflash,
265 Contros/Kongsberg Maritime, Kongsberg, Norway), a conductivity sensor (type 5860, Aanderaa
266 Data Instruments), and a valve. Prior to insertion into the sediments, the chambers were held
267 upside down by the ROV manipulating arms within approximately 10 m of the seafloor and
268 moved back and forth to make sure that water from shallower depth that may have been trapped
269 was replaced by bottom water. Chamber incubations lasted between 240 and 390 minutes. Each
270 BFC was outfitted with a custom-built syringe sampler containing seven syringes that were
271 connected by tubes to sampling ports in the upper wall of the chambers (Fig. 1F): one injection
272 syringe and six sampling syringes that were fired at regular time intervals over the time course of
273 the deployment. The injection syringe contained de-ionized water and the reduction in salinity in
274 the overlaying water after salinity readings stabilized (i.e., full mixing was achieved) 10-30 min
275 after injection was used to determine BFC volumes (Kononets et al., 2021). Samples obtained
276 from the overlaying water of the BFC were examined for the same geochemical constituents as
277 described above (section 2.4). Benthic fluxes of NO_3^- , NH_4^+ , PO_4^{3-} , and Fe^{2+} were calculated as
278 follows:

279

$$280 \quad J = \frac{\Delta c}{\Delta t} * \frac{V}{A} \quad (\text{EQ \# 2})$$

281

282 Where J is the diffusive flux in $\text{mmol m}^{-2} \text{d}^{-1}$, ΔC is the concentration change in mmol m^{-3} , Δt is
283 the time interval in d, V is the overlying water volume in m^3 , and A is the surface area of the

284 sediment covered by the benthic flux chamber in m^2 . Final diffusive flux in BFC was averaged
285 for stations of similar depth (e.g., we averaged calculated diffusive flux from NDT3-A and
286 SDT3-A and report as “A stations”). One chamber per site contained $^{15}\text{N-NO}_3^-$ in the injection
287 syringe for in-situ nitrogen cycling experiments. Results are reported from two of these chambers
288 (SDRO and NDT3-D) and all $^{15}\text{N-NO}_3^-$ chambers were excluded from benthic flux calculations
289 (see next section).

290

291 **2.7.1 In Situ ^{15}N Incubations**

292 Two hundred μmol of ^{15}N -labeled potassium nitrate (99% ^{15}N ; Cambridge Isotopes) was injected
293 into the ^{15}N incubation chamber at each site to obtain a final concentration of $\sim 50 - 100 \mu\text{M}$ ^{15}N -
294 labeled nitrate. Nitrate was amended at this level to prevent its depletion before the last sampling
295 time point (Valentine et al., 2016). Samples for $\delta^{15}\text{N}$ analysis were preserved by filling a pre-
296 vacuumed 12-ml exetainer vial with 0.1 ml 7M zinc chloride as a preservative. Another aliquot
297 (~ 12 ml) of seawater for ammonium isotope analysis (see section 2.7.2) was filtered through 0.2
298 μm syringe filters and stored frozen. Prior to analyzing the samples in 12-ml exetainer vials, 5
299 mL of sample was replaced with ultra-high purity helium to create a headspace. The
300 concentration and $\delta^{15}\text{N}$ of dissolved N_2 and N_2O was determined using a Sercon CryoPrep gas
301 concentration system interfaced to a Sercon 20-20 isotope-ratio mass spectrometer (IRMS) at the
302 University of California Davis Stable Isotope Facility.

303

304 **2.7.2 Ammonium Isotope Analyses**

305 The production of $^{15}\text{NH}_4^+$ in seawater samples was measured using a method adapted from
306 (Zhang et al., 2007) and described previously by (Peng et al., 2016). In brief, NH_4^+ was first

307 oxidized to NO_2^- using hypobromite (BrO^-) and then reduced to N_2O using an acetic acid-azide
308 working solution (Zhang et al., 2007). The $\delta^{15}\text{N}$ of the produced N_2O was determined using an
309 Elementar Americas PreciSION continuous flow, multicollector, isotope-ratio mass spectrometer
310 coupled to an automated gas extraction system as described in (Charoenpong et al., 2014).
311 Calibration and correction were performed as described in (Bourbonnais et al., 2017). The
312 measurement precision was $\pm 0.2\%$ for $\delta^{15}\text{N}$. Depending on the in-situ ammonium
313 concentration, the detection limit for total NH_4^+ production rates ranged between 0.006 and
314 $0.0685 \text{ mmol m}^{-2} \text{ d}^{-1}$.
315

316 **3. Results**

317 **3.1 Bottom water conditions**

318 Oxygen and nitrate concentrations in the bottom water, i.e., in the water surrounding the ROV
319 during its operations at the seafloor and in the benthic flux chambers at T_0 , respectively, along
320 the transects can be seen in Table 1. O_2 concentration decreased with basin depth, with average
321 concentrations of 9 and 10 μM at the shallowest stations (NDT3-D and SDT3-D, respectively)
322 and concentrations below detection ($<3 \mu\text{M}$) at the deepest stations (NDRO and SDRO), which
323 were confirmed to represent anoxia by different methods (see discussion section 4.1). Bottom
324 water solute concentrations (as defined by the average time 0 concentration in BFC at each site)
325 can be seen in Suppl. Figs. 1-4. Bottom water NO_3^- concentrations decreased with station depth;
326 NO_3^- was 27 and 28 μM at NDT3-D and SDT3-D, respectively, and decreased to 19 and 10 μM
327 at NDRO and SDRO, respectively. Bottom water NO_2^- concentrations were below detection at
328 all stations. Bottom water NH_4^+ concentrations were 9 μM at NDRO and 13 μM at SDRO and
329 below detection in shallower stations. Bottom water PO_4^{3-} concentrations showed similar trends
330 to NH_4^+ , with an average concentration of 1 and 2 μM at NDT3-D and SDT3-D stations,
331 respectively, and 5 and 7 μM at NDRO and SDRO stations, respectively. Finally, Fe^{2+} was 2 and
332 5 μM at the NDRO and SDRO stations, respectively. Bottom water Fe^{2+} was below detection at
333 all shallower stations.

334

335 **3.2 Sediment characteristics**

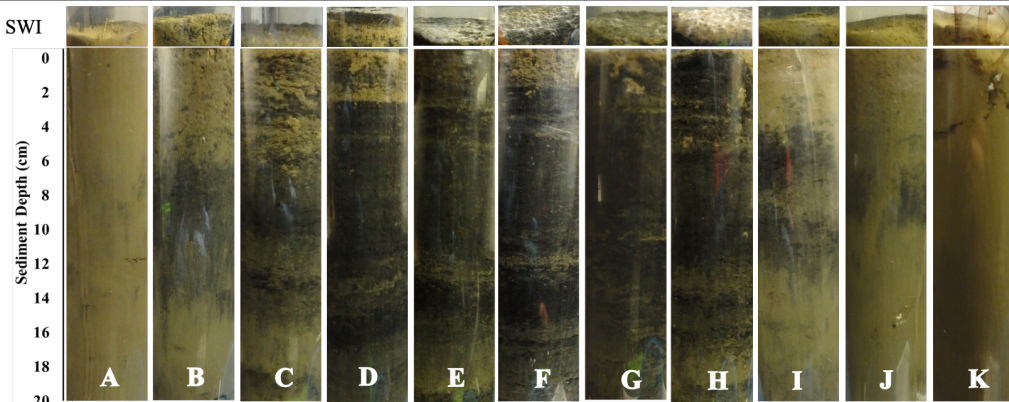

336 Photographs of sediment cores with a depth scale are shown below Table 1. Sediment colors
337 were classified according to (Hossain et al., 2014). Cores from the shallowest (D) stations were
338 uniformly reddish in color with small pockets of black. The sediment color changed with station

339 depth, transitioning from a reddish color in the shallowest stations to predominantly black with
 340 reddish laminations at the depocenter stations. The band of black sediment appeared at approx. 8
 341 cm sediment depth in the C-station cores and became progressively more ubiquitous with station
 342 depth. Sediment cores from shallower stations (D and C stations) contained signs of bioturbation
 343 and, in some cases, contained visible macrofauna, such as polychaetas and mollusks. Deeper in
 344

345 **Table 1.** Station details and photos of representative ROV push cores taken at each station. Mat presence (Y =
 346 yes, N = no) was determined visually. Station water depth and oxygen concentration were determined by sensors
 347 attached to ROV Jason. Anoxia was confirmed by additional methods (see discussion section 4.1). Latitude and
 348 longitude were determined by triangulation between the ROV and the ship. Bottom water nitrate concentration
 349 was derived from an average of benthic flux chamber nitrate measurements at time 0 for each station (chambers
 350 with no calculatable flux and ¹⁵N-nitrate addition excluded). Note, benthic flux chambers were not deployed at
 351 SDT1-A. Photographs show the sediment-water interface (SWI; top part) and each sediment core in full length
 352 (lower part).
 353

 355

356

357 the basin (A and depocenter stations) no signs of bioturbation were detected, and the sediment-
 358 water interface was colonized by patches of white GSOB mats. Spherical cells (given the

359 moniker ‘ghost balls’) were found mixed amongst giant sulfur bacteria filaments within the top
 360 0-1 cm of sediment at NDRO (Suppl. Fig. 5). These unknown species had similar morphological
 361 characteristics to the species *Thiomargarita namibiensis* (Schulz et al., 1999; Schulz and Schulz,
 362 2005) containing a translucent cell with sulfur granules giving them a ghostly white appearance.
 363 A small sample of cells were measured, with a diameter that ranged from 48.0 – 99.6 μm ($n = 8$),
 364 amounting to an average biovolume of $2.5 \times 10^5 \mu\text{m}^3$, compared to *T. namibiensis* with a cell
 365 diameter up to 700 μm (Schulz et al., 1999).

366
 367 **Table 2.** Sediment solid phase data: porosity, density, total organic carbon (TOC), total organic nitrogen (TON),
 368 C:N ratio, and $\delta^{13}\text{C}$. All data were averaged for the top 0-19 cm sediment, except NDT3-C (17 cm), NDT3-A
 369 (11 cm) and SDRO (7 cm), where the core length was shorter. Integrated sulfate reduction rates (iSRR) were
 370 integrated over 0-14 cm sediment depth. No sulfate reduction rates are available for NDT3-B, SDT3-A, and
 371 SDT3-B; rates were not integrated for SDRO due to missing surface samples.
 372

373
 374
 375
 376 B station cores contained sporadic filaments slightly deeper in the sediment (approx.. 2-4 cm
 377 sediment depth). Depocenter and A-station sediment was laminated throughout the entire core
 378 length, B-station sediment showed some lamination below the first 4 cm, but sediment from
 379 shallower stations had little (C station) to no signs of lamination (D station). Sediment solid
 380 phase parameters (averaged over the entire sediment core depth) can be seen in Table 2. Average
 381 sediment porosity increased with basin depth (e.g., from 0.79 at NDT3-D to 0.88 at NDRO).
 382 TOC and TON increased slightly with station depth (from 3.67% TOC and 0.41 TON at NDT3-
 383 D to 5.34% and 0.66% TON at SDRO) while the C/N ratio and the $\delta^{13}\text{C}$ isotopic signature of

384 organic carbon remained relatively constant (8.0 – 8.7 and 21.3 – 22.4 ‰, respectively) over all
385 stations.

386

387 **3.3 Sediment porewater geochemistry**

388 Geochemical parameters of sediment porewater are shown in Fig. 2 (northern stations) and 3
389 (southern stations). Total alkalinity (Figs. 2 A-E & 3 A-F) increased steadily with sediment depth
390 at all stations starting with, on average, 2.4 mM in the core supernatant reaching a maximum at
391 the respective deepest sediment sample (20 cm). Total alkalinity also increased with basin depth;
392 cores in the depocenter exhibited higher total alkalinity (max. 9.6 mM at NDRO) than D-stations
393 (max. 3.4 mM at NDT3-D). Porewater DIC (Figs. 2 A-E & 3 A-F) showed patterns very similar
394 to total alkalinity, indicating that total alkalinity was dominated by the carbonate system.
395 Porewater DIC was, on average, 2.2 mM in the core supernatant and reached maximum
396 concentrations at the deepest sediment depth (20 cm) at most stations. Porewater DIC also
397 increased with basin depth; depocenter sediment had higher DIC concentrations (max. 8.3 mM at
398 NDRO) than D-station (max. 2.8 mM at NDT3-D).

399

400 Porewater PO_4^{3-} profiles (Figs. 2 A-E & 3 A-F) were markedly different between the depocenter
401 and shallower C and D stations. PO_4^{3-} concentration increased by approx. one order of magnitude
402 between the core supernatant and the 0-1 cm section at most stations (e.g., 7 and 48 μM at
403 NDRO, respectively). Porewater PO_4^{3-} concentrations in the depocenter and A stations generally
404 increased with sediment depth but several profiles (NDT3-C, NDT3-A, SDRO, SDT1-A)
405 remained unchanged or decreased deeper in the sediment (starting at approx. 10 cm). The
406 profiles in C and D stations showed a peak in PO_4^{3-} concentrations near the sediment-water

407 interface, particularly in the northern basin. Below 2 cm, PO_4^{3-} decreased with sediment depth,
408 but sometimes showed a second small peak deeper in the sediment (12-14 cm at NDT3-D and
409 10-12 cm at SDT3-D).
410
411 Porewater NH_4^+ concentrations (Figs 2 & 3 A-E) showed trends often similar to alkalinity and
412 DIC; NH_4^+ concentrations increased downcore and were higher at depocenter than at D stations
413 (e.g., 370 and 91 μM at 20 cm for SDRO and SDT3-D, respectively). NH_4^+ concentration
414 increased by approx. one order of magnitude between the core supernatant and the 0-1 cm
415 section at most stations (e.g., 16 μM and 139 μM at NDRO, respectively). Supernatant NH_4^+ was
416 below detection at D and C stations (and SDT3-B) and above 10 μM at the deeper A (except
417 SDT1-A) and depocenter stations. NO_2^- and NO_3^- were at or near zero concentration below 2 cm
418 at every station. NO_3^- concentration decreased substantially in the transition from core
419 supernatant to the 0-1 cm section at most stations (e.g., 24 μM and 0 μM at NDT3-D,
420 respectively). Sediment cores from SDRO and NDT3-A stations exhibited strong peaks in NO_3^-
421 (376 and 81 μM , respectively) and NO_2^- (37 and 5 μM , respectively) in the top 1 cm.
422
423 Porewater Fe^{2+} concentrations (Figs. 2 F-J & 3 G-L) were several orders of magnitude higher at
424 shallow D stations (max. 722 and 395 μM at NDT3-D and SDT3-D, respectively) compared to
425 depocenter stations (max. 13 and 51 μM at NDRO and SDRO, respectively). Fe^{2+} concentration
426 increased by approx. one order of magnitude between the core supernatant and the 0-1 cm
427 section at all stations (e.g., 16 μM and 139 μM at NDRO, respectively). Concentrations reached
428 a max. at 0-2 cm and declined sharply with depth in depocenter and A-station sediment.
429 Northern basin sediment was similar, but the decline in Fe^{2+} below 0-2 cm was less pronounced.

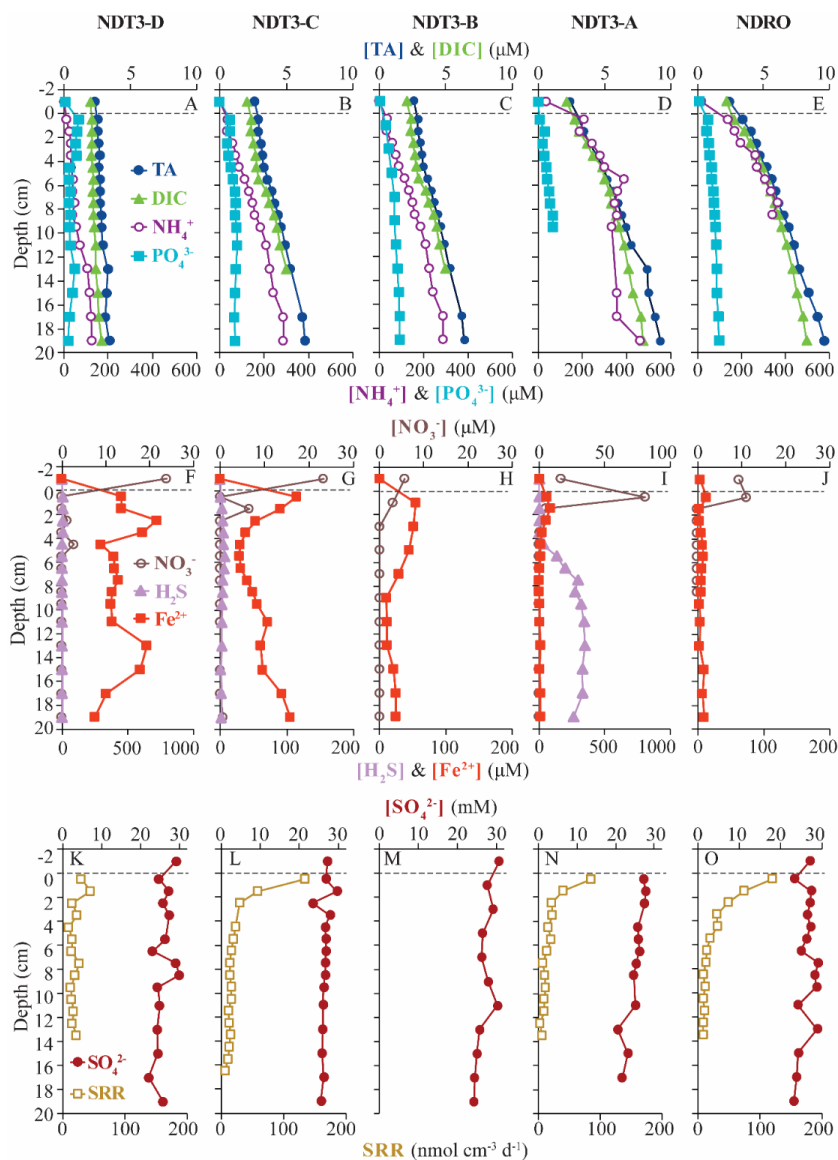

430

431 Max. porewater sulfide concentrations (Figs. 2 F-J & 3 G-L) were several orders of magnitude
432 lower at shallow D stations (5 and 4 μM at NDT3-D and SDT3-D, respectively) compared to A
433 stations (350 and 148 μM at NDT3-A and SDT1-A, respectively). Unlike Fe^{2+} , peaks in sulfide
434 concentration occurred deeper in the sediment (e.g., below 5 cm depth at A stations). Porewater
435 sulfate concentrations (Figs. 2 K-O & 3 M-R) decreased slightly with depth, but never reached
436 values below 20 mM at any station.

437

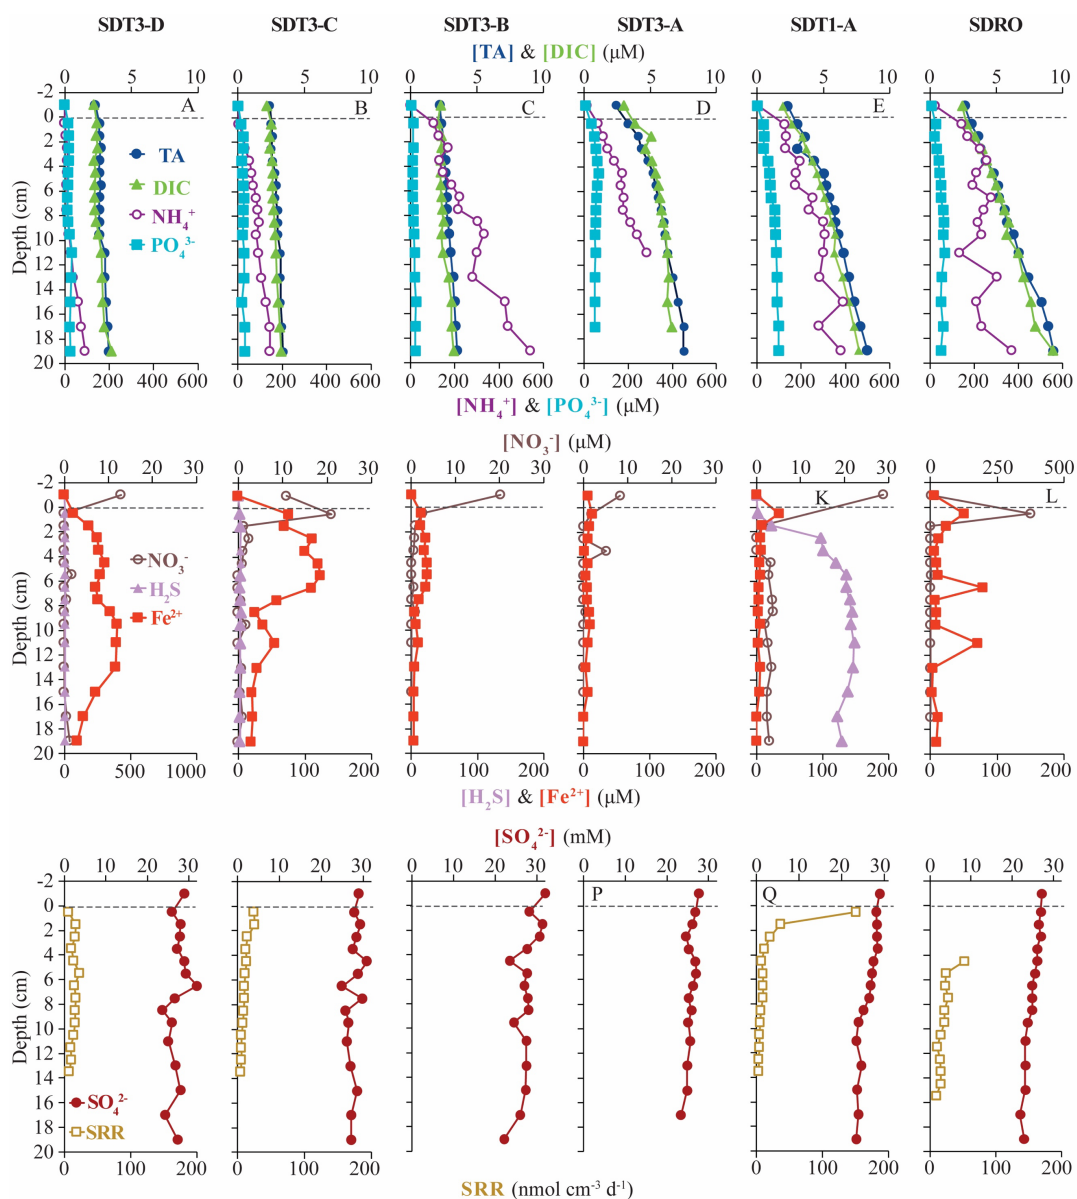

438 **3.4 In-situ microprofiling**

439 Microprofiler O_2 and sulfide measurements are shown in Fig. 4. Oxygen was rapidly consumed
440 within the first 0-1 cm of sediment at every station where O_2 was detected in the bottom water
441 (i.e., at all stations except NDRO, SDRO, and SDT3-A, which were anoxic). Sulfide
442 concentrations from microsensors showed similar trends to spectrophotometric measurements,
443 albeit with different absolute values (e.g., 196 and 808 μM sulfide at the 7 cm depth at NDT3-A
444 using the cline method and microprofilers, respectively). Sulfide was below detection of the
445 microprofilers in shallower stations (B, C, and D), all of which lacked GSOB mats. The A and
446 depocenter stations had high sulfide concentrations ($>1,000 \mu\text{M}$) in the sediment underlying
447 GSOB mats, which rapidly decreased towards zero near the sediment-water interface.
448 Microprofiler pH (Fig. 4) was near 7.5 in the bottom water at all stations, and slowly decreased

Figure 3. Biogeochemical data from ROV sediment push cores collected at stations on the two southern transects (SDT1 and SDT3) and the southern depocenter (SDRO): total alkalinity (TA), dissolved inorganic carbon (DIC), ammonium (NH_4^+), phosphate (PO_4^{3-}) in the first row; nitrate (NO_3^-), total sulfide (sulfide), and iron (II) (Fe^{2+}) in the second row; sulfate (SO_4^{2-}) and bacterial sulfate reduction rate (SRR) in the third row. Data analyzed from sediment core supernatant are plotted at -1 cm sediment depth; the dotted line connotes the sediment-water interface. Note the change in scale on the primary x-axis in panel L and the change in scale of the secondary x-axis in panel G. No sulfide and SRR data are available for SDT3-B and -A; at SDRO, the top 0-4 cm of sulfate reduction data are not available. For station details see Fig. 1 and Table 1.

468 to near 7.0 within the top 20 cm of sediment at most stations. At NDT3-C and SDT3-D, pH
 469 exhibited no discernable trend over depth with values remaining around pH 7.5.
 470

471
 472
 473 **Figure 4.** In-situ sediment microprofiler results for all stations (except SDT1-A): oxygen (O₂) and total sulfide
 474 (sulfide) concentration in the first row; pH profiles in the second row. Note the change in scale on the secondary
 475 x-axis for NDRO sulfide. Values determined in the overlying water are plotted at negative sediment depths; the
 476 dotted line connotes the sediment-water interface.
 477

478 3.5 In-situ fluxes of benthic solutes

479 NO₃⁻, NH₄⁺, PO₄³⁻, and Fe²⁺ flux measured in the BFC revealed different patterns of uptake and
 480 release from the sediment throughout the basin (Fig. 5 and Suppl. Figs. 1-4). BFC O₂
 481 concentrations were compromised by O₂ release from the chamber's polycarbonate walls, which
 482 prevented an accurate calculation of O₂ fluxes from sensor data. NO₃⁻ was consumed at all
 483 stations as indicated by a negative flux (i.e., a flux into the sediment). On the contrary, benthic
 484 release (i.e., a flux out of the sediment) was observed for all other analyzed solutes (NH₄⁺, PO₄³⁻,

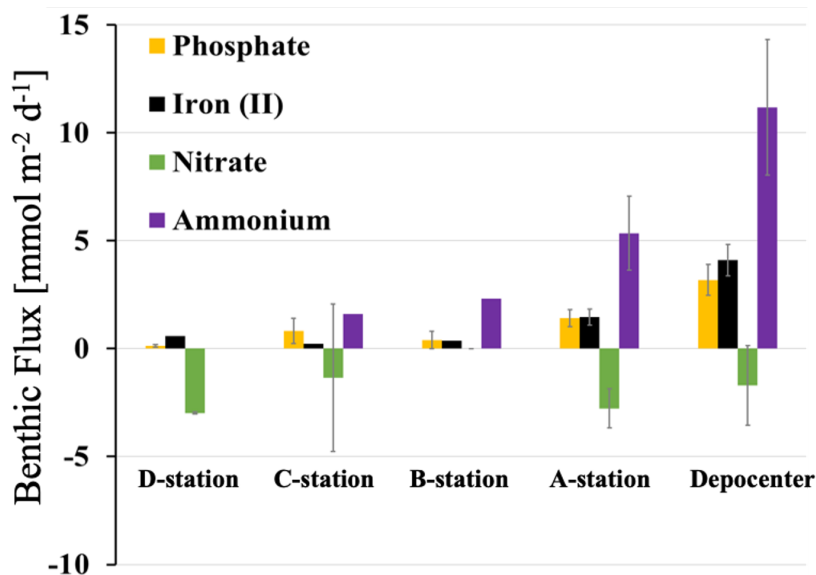

485 and Fe^{2+}), with the lowest fluxes in the shallow D and C-stations and highest fluxes in the
486 depocenter. Ammonium fluxes were the highest of all the determined solutes and showed the
487 largest difference between deep and shallow stations, with a flux of $1.6 \text{ mmol m}^{-2} \text{ d}^{-1}$ at NDT3-C
488 (there were no measurable NH_4^+ fluxes in D-station chambers) and reaching $11.1 \pm 3.1 \text{ mmol m}^{-2}$
489 d^{-1} ($n = 3$) at the two depocenter stations. The depocenter ammonium flux far-outpaced the
490 concomitant flux of nitrate into depocenter sediments ($-3.2 \pm 0.7 \text{ mmol m}^{-2} \text{ d}^{-1}$, $n = 3$). Iron and
491 phosphate fluxes were similar at depocenter stations (4.1 ± 0.7 , $n = 3$, and 3.2 ± 0.7 , $n = 3$, mmol
492 $\text{m}^{-2} \text{ d}^{-1}$, respectively) but there was no discernable trend between the two solutes at shallower
493 stations. Results from BFCs injected with $^{15}\text{N-NO}_3^-$ at the SDRO and NDT3-D station are shown
494 in Fig. 6. The rates of denitrification, anammox, and N_2O production were higher at SDRO
495 compared to NDT3-D. $^{15}\text{NH}_4^+$ production (DNRA) was one order of magnitude higher at the
496 SDRO station ($2.674 \text{ mmol m}^{-2} \text{ d}^{-1}$) compared to the NDT3-D station ($0.140 \text{ mmol m}^{-2} \text{ d}^{-1}$).
497 DNRA accounted for a much higher percentage of NO_3^- reduction at SDRO (54.1%) than NDT3-
498 D (13.3%).

499

500 **3.6 Sulfate reduction rates**

501 Vertical profiles of bacterial sulfate reduction as determined by the radioisotope technique
502 differed throughout the basin (Figs. 2 & 3). Peaks in sulfate reduction (120.2 , 151.0 , 85.3 nmol
503 $\text{cm}^{-3} \text{ d}^{-1}$) were seen in the top 0-1 cm of sediment at stations with a visible GSOB mat on the
504 surface (NDRO, SDT1-A, NDT3-A, respectively). Sediments at most shallower basin depths
505 (SDT3-C, NDT3-D, and SDT3-D) exhibited peaks slightly deeper in the sediment and of lower
506 magnitude (25.5 , 44.5 , $22.5 \text{ nmol cm}^{-3} \text{ d}^{-1}$ respectively). NDT3-C had no visible GSOB mats
507 present but also exhibited a peak ($133.7 \text{ nmol cm}^{-3} \text{ d}^{-1}$) in sulfate reduction at 0-1 cm depth.

508
509

515
516
517
518

Figure 6. Areal rates of total N₂ production, denitrification, anammox, NH₄⁺ production (DNRA), and N₂O production

519 Sulfate reduction rates at depocenter and A stations decreased sharply below 0-1 cm sediment

520 depth (up to an order of magnitude decrease at NDRO and SDT1-A), while remaining low and

521 steady over depth in C and D station sediment. Integrated sulfate reduction rate (0-14 cm depth)
522 at NDRO ($4.1 \text{ mmol m}^{-2} \text{ d}^{-1}$) was noticeably higher than most other stations with the exception of
523 NDT3-C ($3.8 \text{ mmol m}^{-2} \text{ d}^{-1}$) (Table 2). NDT3-D and NDT3-C exhibited higher integrated rates
524 (2.9 and $3.8 \text{ mmol m}^{-2} \text{ d}^{-1}$) than their southern station counterparts SDT3-D and SDT3-C (1.9 and
525 $1.7 \text{ mmol m}^{-2} \text{ d}^{-1}$).

526 **4. Discussion**

527 **4.1 Giant sulfur-oxidizing bacterial mats proliferated in response to deoxygenation in the**

528 **Santa Barbara Basin**

529 The SBB is an ideal environment to study the effect of transient deoxygenation on benthic
530 biogeochemistry. In November 2019, the SBB was undergoing a transition from oxygenated to
531 anoxic conditions (Qin et al., 2022). When the AT42-19 cruise occurred, most of the bottom
532 water in the basin was hypoxic (B, C, and D stations), except for the depositional center and the
533 A stations. Importantly, separate O₂ measurements from the ROV sensor (Table 1), microprofiler
534 (Fig. 4), and Winkler titration from CTD/rosette casts (Qin et al., 2022) indicated full anoxia in
535 the bottom water at these deeper stations. Notably, bottom water conditions revealed a slight
536 asymmetry between the basin transects (Fig. 1); bottom water along the northern transect had
537 generally more O₂ and NO₃⁻ than the southern transect (e.g., 9 μM at NDT3-A and 0 μM at
538 SDT3-A). This asymmetry indicated differences in the circulation and/or microbial communities
539 between the northern and southern portions of the basin. Whether this asymmetry is a permanent
540 feature of the basin or symptomatic of the specific conditions in November 2019 is unclear;
541 previous studies in the SBB have been restricted to the depocenter or one side of the basin
542 (Sholkovitz, 1973; Reimers et al., 1996; Kuwabara et al., 1999). Regardless of bottom water
543 oxidant concentration, the energetically most powerful terminal electron acceptors (O₂ and NO₃⁻)
544 disappeared in a very narrow zone below the sediment-water interface (Fig. 4 and Figs. 2 and 3,
545 respectively), consistent with their expected rapid consumption by the benthic microbial
546 community.

547

548 The sediment-water interface represents the front-line in a battle between microbes for powerful
549 electron acceptors. In the present study, benthic GSOB mats were primarily limited to the anoxic
550 depocenter of the SBB. Similarly, such mats were replete in the core of the anoxic Peruvian
551 OMZ (Levin et al., 2002; Sommer et al., 2016; Mosch et al., 2012), but absent from the seafloor
552 below the hypoxic, i.e., slightly oxygenated, Mauritanian OMZ (Schroller-Lomnitz et al., 2019).
553 GSOB mats in November 2019 were observed deeper in the basin than in October 2013
554 (Valentine et al., 2016) but in a similar location to June 1988 (Reimers et al., 1996) and April
555 1997 (Kuwabara et al., 1999). During the 2013 sampling, dense GSOB mats were confined to
556 depths between approx. 500-570 m (equivalent to the B stations from this expedition),
557 corresponding with anoxic conditions in the bottom water. This habitat was sandwiched between
558 an anoxic, anitric (i.e., nitrate-free) deep and a hypoxic, nitrigenated (i.e., nitrate-rich) shallower
559 water layer. The difference in depth distribution between the 2013 and 2019 expedition provides
560 evidence that GSOB mats in the SBB are ephemeral and proliferate where the bottom water is
561 anoxic but not anitric.

562

563 As our study represents only a snapshot of an oxygen- and nitrate-driven mat dynamic, we can
564 only speculate how areas of the basin that did not contain GSOB mats in November 2019 fit into
565 this dynamic. For example, mat-forming sulfur bacteria found slightly deeper in the sediment at
566 B stations (see section 3.2) could be progenitors to surface sediment colonization of thick GSOB
567 mats, as it has been recorded in other transiently deoxygenated environments (Jørgensen, 1977).
568 Alternatively, these subsurface colonies could also be remnants of a former surface GSOB mat
569 that retreated under changing redox conditions. Oxygenated conditions in the water preceding
570 the 2019 expedition would, in this context, mean the mats migrated following a previous anoxic

571 event (Qin et al., 2022). If deoxygenation persisted in the SBB after the AT42-19 cruise, then
572 anitria (i.e., anitric conditions - similar to anoxia) would likely follow in the deepest basin water.
573 These conditions would be similar to those seen during the 2013 expedition by D. Valentine and
574 co-workers (Valentine et al., 2016), where GSOB mats formed a contiguous “donut ring” at
575 shallower basin depths.

576

577 **4.2 Shift from benthic denitrification to dissimilatory nitrate reduction to ammonium in**
578 **response to complete deoxygenation in the Santa Barbara Basin**

579

580 Benthic release and uptake of nitrogen species by SBB sediment appeared to be affected by the
581 presence of GSOB mats. While benthic nitrate consumption was evident at all stations based on
582 porewater and in-situ flux measurements, NH_4^+ release from the sediment into the water column
583 increased with station depth (Fig. 5). This trend is supported by the porewater profiles of NH_4^+ ,
584 which tend to increase in steepness with station depth (Figs. 2 & 3). Incubations with $^{15}\text{N}\text{-NO}_3^-$
585 revealed that N_2 production via denitrification and anammox accounted for 86% of NO_3^- removal
586 in the shallow basin (NDT3-D, Fig. 6). Conversely 54% of NO_3^- removal at the depositional
587 center (SDRO) occurred via DNRA (X. Peng et al., to be submitted to this special issue). This
588 data suggests a transition from denitrification-dominated sediment in the oxygenated basin to an
589 increasing influence of DNRA on N-cycling in the deeper, anoxic basin. Placed in the context of
590 other OMZs, nitrate consumption in the shallow SBB sediment (below hypoxic water) was
591 similar to Mauritanian shelf sediments (Dale et al., 2014), while nitrate consumption in the
592 sediment of the deeper SBB (below anoxic water) was similar to anoxic Baltic Sea basins (Dale
593 et al., 2011) and the core Peruvian OMZ (Sommer et al., 2016).

594

595 Declining nitrate concentrations may be as important as anoxia itself to GSOB mat proliferation.

596 High ratios of electron donor (organic matter or sulfide) to electron acceptor (nitrate) encourage

597 DNRA over denitrification (Marchant et al., 2014). In these nitrate-deficient areas in the ocean,

598 DNRA linked to anaerobic ammonium oxidation (anammox) can be more thermodynamically

599 favorable and thus organisms that participate in this consortium could have a competitive

600 advantage over other denitrifying organisms (Jensen et al., 2011). NO_2^- was at or near-zero

601 concentrations in the sediment porewater of all stations, except in the 0-1 cm depth interval of

602 two stations (SDRO and NDT3-A) featuring GSOB mats (Suppl. Table 1). These spikes in NO_2^-

603 (and more pronounced, NO_3^-) are likely caused by the bursting of GSOB vacuoles during

604 centrifugation (Reimers et al., 1996). GSOB mats can be associated with symbiotic anaerobic

605 ammonium-oxidizing (anammox) bacteria (Prokopenko et al., 2006). Since the anammox process

606 utilizes NO_2^- as the electron acceptor and NH_4^+ as the electron donor, a consortium of GSOB

607 mats and anammox bacteria were possible given the right conditions for proliferation in the SBB

608 depocenter. Anoxia could trigger the uptake of NO_3^- into bacterial vacuoles, creating declining

609 NO_3^- concentrations that are more favorable to DNRA in the bottom water. In these conditions,

610 GSOB in the SBB benthic environment could utilize their ability to perform DNRA to out-

611 compete similar denitrifying taxa, and proliferate into thick, contiguous mats. While low-nitrate

612 conditions could benefit GSOB mats, the mats do not persist once bottom water reaches anoxia,

613 as evidenced by GSOB mat distribution during the 2013 expedition (Valentine et al., 2016).

614

615

616 **4.3 Microbial mat proliferation and benthic phosphate remineralization dependent on high**
617 **rates of organic matter degradation in the Santa Barbara Basin**

618

619 Organic carbon delivery to the benthic environment appears to be a key control on sulfate
620 reduction rates near the sediment-water interface as well as microbial mat proliferation. Sulfate
621 reduction rates in the SBB depocenter are most similar in magnitude and profile (i.e., highest
622 rates found at the sediment-water interface and decline drastically thereafter) to those found in
623 sediments below the transiently deoxygenated portion of the Peruvian shelf (e.g., 4.1 mmol m^{-2}
624 d^{-1} at the SBB NDRO station vs. $2.5\text{-}3.8 \text{ mmol m}^{-2} \text{ d}^{-1}$ at 128-144 m water depth on the Peruvian
625 margin (Gier et al., 2016; Treude et al., 2021)). The TOC content of surface sediments in these
626 two regions are both high and within the same order of magnitude; 5.3% in SBB depocenter
627 compared with 7.6% in the Peruvian margin 145 m depth (Noffke et al., 2012). In comparison,
628 sulfate reduction rates in the SBB were at least one order of magnitude lower than found in
629 sediment below the OMZ on the Namibian Shelf, which has much higher TOC contents of $>10\%$
630 (Brüchert et al., 2003; Bremner, 1981). Sulfate reduction rates in the shelf sediments below the
631 Eastern Arabian OMZ were an order of magnitude lower ($0.18 - 1.27 \text{ mmol m}^{-2} \text{ d}^{-1}$) than rates in
632 the SBB depocenter (Naik et al., 2017) despite similar hypoxic to anoxic bottom water
633 conditions. These lower rates were attributed to the relatively low benthic organic matter
634 delivery compared to other transiently deoxygenated systems (surface sediment TOC content
635 approx. 2 – 3%) (Naik et al., 2017). Sedimentary organic matter content appears to be important
636 in the proliferation of GSOB mats; too much TOC could result in toxic levels of sulfide at the
637 sediment-water interface (*Beggiatoa* exhibit an aversion to sulfidic sediments but toxicity has not

638 been quantified, (Preisler et al., 2007)) whereas too little sulfide would not provide enough
639 electron donor for the GSOB's chemoautotrophic metabolism.
640
641 The profiles of several indicators for benthic anaerobic organic matter remineralization (total
642 alkalinity, DIC, PO_4^{3-} , NH_4^+) increased in steepness with increasing water depth (Figs. 2 A-E &
643 3A-F). One divergence from this trend can be seen in PO_4^{3-} profiles from the shallow C and D
644 stations, which also featured low rates of sulfate reduction. PO_4^{3-} profiles in these sediment track
645 closely to Fe^{2+} profiles; both solutes dip in concentration in areas with visible iron sulfide
646 formation (e.g., 5-11 cm in NDT3-D as seen in Fig. 2A). Additionally, several stations that
647 exhibited high sulfate reduction rates in surface sediment (e.g., SDT1-A) showed almost no
648 change in PO_4^{3-} at depths below 5 cm (e.g., Fig. 2 K-O compared to Fig. 2 A-E). This
649 phenomenon has been previously documented in SBB sediment and is attributed to the
650 precipitation of carbonate fluorapatite (Reimers et al., 1996). The confinement of these flat PO_4^{3-}
651 profiles to stations with $>100 \text{ nmol cm}^{-3} \text{ d}^{-1}$ sulfate reduction in surface sediment suggests that
652 this mineralogical sink of PO_4^{3-} in SBB sediment may be dependent on high sulfate reduction
653 rates, owing to the bicarbonate produced by sulfate reduction (Reimers et al., 1996), and is not
654 found throughout the basin. Flat PO_4^{3-} profiles were also reported from the transiently
655 deoxygenated portion of the Peruvian OMZ, where phosphate mineral precipitation has been
656 documented (Noffke et al., 2012). Similar to the shallow margins of the SBB, PO_4^{3-} in
657 Mauritanian OMZ porewater tracks closely with changes in porewater Fe^{2+} (Schroller-Lomnitz
658 et al., 2019), indicating that iron mineralization/dissolution mechanics hold a greater influence
659 on PO_4^{3-} concentrations under hypoxic bottom waters.
660

661 **4.3 Iron cycling dictates the location of sulfate reduction in Santa Barbara Basin sediment.**

662

663 While low or absent oxygen concentrations in the bottom water appeared to facilitate sulfate
664 reduction close to the sediment-water interface in the SBB (e.g., NDRO and NDT3-A as seen in
665 fig. 2N and 2O), iron sulfide formation in deeper sediment layers may also play a crucial role in
666 controlling the distribution of sulfate reduction. SBB sediments showed a wide vertical and
667 horizontal heterogeneity of redox states based on visual appearance (Fig. 1A-K). Sediment
668 beneath the hypoxic bottom water at the shallowest D stations was reddish, consistent with a
669 high content of iron oxides. Interestingly, porewater Fe^{2+} concentrations in shallower parts of the
670 basin (e.g., NDT3-D, max. $\sim 700 \mu\text{M Fe}^{2+}$) were an order of magnitude larger than those found
671 anywhere in both the Peruvian (max ~ 60 and $\sim 30 \mu\text{M Fe}^{2+}$, respectively; Noffke et al., 2012;
672 Plass et al., 2020) and Mauritanian (max. $\sim 50 \mu\text{M Fe}^{2+}$; Schroller-Lomnitz et al 2019) OMZ.
673 Deeper in the basin, bands of black sediment that appear mid-core at NDT3-C (6-14 cm) and
674 SDT3-C (6-10 cm) indicate the formation of iron sulfides as a result of sulfide produced by
675 sulfate reduction (Canfield, 1989). At the C stations, peaks in sulfate reduction were located in
676 the surface sediment, above the iron sulfide layers, and declined below approx. 4 cm, indicating
677 a discrepancy between observed peak sulfate reduction activity and the mineralogical clues left
678 behind by the process.

679

680 Comparing data from shallow stations at the same depth (e.g., NDT3-C vs. SDT3-C) revealed
681 differences in sediment sulfate reduction in the SBB, potentially due to changes in iron
682 mineralogy. Both D-stations had similar bottom water conditions (Table 1), sulfate reduction
683 rates (Fig. 3W-AG), porewater concentrations of solutes (Figs. 2 and 3), and visual sediment

684 characteristics (Section 3.1). On the contrary, there are some noticeable differences in the
685 porewater geochemistry between the two C-stations, which in contrast to D-stations are below
686 the SBB sill depth, irrespective of similar bottom water oxygen conditions. NDT3-C porewater
687 Fe^{2+} concentration (Fig. 2G) peaked in the top 1 cm of sediment (similar to deeper stations)
688 while SDT3-C porewater Fe^{2+} concentration (Fig. 3H) peaked around 5-cm sediment depth.
689 NDT3-C sediment (Table 1B) exhibited iron sulfide formation from approx. 6-14 cm sediment
690 depth, while SDT3-C sediment (Table 1J) had a much narrower band around 8-10 cm (the same
691 depth at which Fe^{2+} concentrations decrease in the porewater). Finally, the sulfate reduction rate
692 at NDT3-C (Fig. 2L) mirrored deeper station profiles (e.g., NDRO in Fig. 2O) rather than other
693 shallow station profiles (e.g., SDT3-C in Fig. 3N). While sulfate reduction rates for B-stations
694 are absent, porewater Fe^{2+} profiles show a similar difference between the north and south basin
695 (Fig. 2H compared to Fig. 3I) as did visual sediment characteristics (Table 1C compared to 1I).
696 This difference in biogeochemical profiles and apparent mineralogy between the north and south
697 C and B stations could be a result of hydrographic and/or bathymetric differences in the basin
698 (Sholkovitz and Gieskes, 1971; Bograd et al., 2002), but a discernable link between the
699 differences in sediment biogeochemistry and the differences in bottom water oxygen (Table 1)
700 need to be further explored.

701

702 Deeper in the basin (depocenter and A-stations), porewater Fe^{2+} concentrations in sediment
703 beneath anoxic bottom water (max. $84 \mu\text{M Fe}^{2+}$) were similar to concentrations found below the
704 Peruvian OMZ in 2008 under anoxic bottom water conditions (78 m water depth, max. $80 \mu\text{M}$
705 Fe^{2+}) (Noffke et al., 2012). SBB porewater Fe^{2+} concentrations were an order of magnitude
706 larger than those found at a similar site on the Peruvian shelf (75 m water depth, max. $1 \mu\text{M}$

707 Fe^{2+}) in 2017 during a kelvin-wave-associated “Coastal El Niño” event that created oxygenated
708 bottom waters during the sampling and the disappearance of previously observed dense GSOB
709 mats (Plass et al., 2020). As the SBB water column was undergoing rapid deoxygenation in the
710 weeks preceding this study (Qin et al., 2022), the sediments below the sill appeared to be
711 actively shifting from a ferruginous state to a sulfidic state, with this change starting around the
712 C stations and being complete in the depocenter. Comparing apparent iron sulfide formation with
713 dips in porewater Fe^{2+} concentrations in C-station profiles (Fig. 1B compared to Fig. 2G and Fig.
714 1J compared to Fig. 3H) signals a shift away from a ferruginous state occurring just below the
715 SBB sill.

716

717 C-station porewater Fe^{2+} concentrations and sulfate reduction rates indicate that migration of the
718 sulfate reduction zone towards the sediment-water interface is associated with iron sulfide
719 formation deeper in the sediment. The activity of cable bacteria, which are able to bridge the gap
720 between the oxidized sediment-water interface and reduced sediment below using a biofilament
721 (Pfeffer et al., 2012), could explain the interplay between sulfate reduction and iron cycling in
722 SBB sediments. Cable bacteria contain the genes required for DNRA (Kjeldsen et al., 2019) and
723 can perform nitrate reduction in incubation experiments (Marzocchi et al., 2014), but their direct
724 transformation of NO_3^- in the environment appears limited (Kessler et al., 2019) and they appear
725 to be inactive in anoxic aquatic environments (Seitaj et al., 2015; Marzocchi et al., 2018). Cable
726 bacteria primarily conduct aerobic sulfide oxidation (Pfeffer et al., 2012), though they can also
727 utilize Fe^{2+} as an electron donor (Seitaj et al., 2015). The maximum recorded filament length of
728 cable bacteria is 7 cm (Van De Velde et al., 2016), roughly in line with the appearance of black
729 sediment in the SBB C-station sediments. Further, cable bacteria have been found to directly

730 compete with GSOB in transiently deoxygenated systems, with cable bacteria active under
731 oxygenated conditions and GSOB active in anoxic conditions (Seitaj et al., 2015). Cable
732 bacteria can also prevent the formation of euxinic conditions at the sediment-water interface via
733 the creation of an iron-oxide buffer (formed through Fe^{2+} oxidation) in near-surface sediments
734 (Seitaj et al., 2015). Therefore, if cable bacteria activity in the SBB decreased with declining
735 oxygen concentrations below the sill, their iron oxide buffer could have been reduced,
736 encouraging the sulfate reduction zone to migrate towards the sediment surface (as seen at
737 NDT3-C). The presence of cable bacteria can be detected by a slight increase in pH below the
738 sediment-water interface (typically $\text{pH} > 8$) (Schauer et al., 2014), which was not reflected in our
739 pH results, but forthcoming DNA analyses from these sediments should elucidate the role cable
740 bacteria play in the SBB. Additionally, forthcoming sequential iron and sulfur extractions from
741 SBB sediments should provide more information about the differences in early diagenesis
742 throughout the basin.

743

744 **4.4 Iron and phosphate flux into SBB bottom water is a feature of transient deoxygenation.**

745

746 As postulated previously (Kuwabara et al., 1999), oxidation of iron sulfides at the sediment-
747 water interface upon basin flushing with oxygen likely encourages microbial iron reduction
748 following later deoxygenation. This iron reduction causes strong Fe^{2+} and PO_4^{3-} fluxes out of
749 SBB depocenter sediment. High porewater Fe^{2+} concentration ($>100 \mu\text{M}$) in the SBB D stations
750 (Figs. 3L and V) indicate regions of prolific bacterial iron reduction in the sediment. As basin
751 depth increases and oxygen concentration in the water decreases, the zone of iron reduction thins
752 and is found closer to the sediment-water interface (Figs. 2 & 3). Further, high benthic fluxes of

753 Fe^{2+} and PO_4^{3-} were observed in the transiently anoxic depocenter (Fig. 5). High Fe^{2+} and PO_4^{3-}
754 fluxes were also seen on the Peruvian shelf during transient anoxia (Noffke et al., 2012). The
755 release of these solutes was interpreted to be sourced from a layer of reactive iron hydroxides
756 existing near the sediment surface, likely established during a recent oxygenation event. Similar
757 conditions, i.e., visibly oxidized (reddish) sediment laminae and a thin zone of iron reduction
758 apparent from a peak in Fe^{2+} at the sediment-water interface, were found in sediment from the
759 SBB depocenter. These analogous observations highlight the importance of alternating redox
760 conditions to establish high benthic iron fluxes. On the contrary, the persistently anoxic core of
761 the Peruvian OMZ appears to have little to no benthic flux of Fe^{2+} and PO_4^{3-} into the bottom
762 water (Noffke et al., 2012). Here, iron at the sediment-water interface is hypothesized to be
763 locked up in iron sulfides, which are rarely re-oxidized due to persistent anoxia.

764

765 It is further notable that benthic fluxes of Fe^{2+} and PO_4^{3-} from the SBB depocenter were approx.
766 five times higher (Fig. 5) compared to the Peruvian shelf (4.9 vs. 0.9 $\text{mmol Fe}^{2+} \text{ m}^{-2} \text{ d}^{-1}$ and 3.6
767 vs. 0.8 $\text{mmol PO}_4^{3-} \text{ m}^{-2} \text{ d}^{-1}$, respectively) (Noffke et al., 2012). Based on Fe^{2+} profiles, the zone of
768 iron reduction in Peruvian shelf sediments extended down to approx. 10 cm, while the zone
769 appeared to be much shallower and narrower (less than the top 5 cm) in the SBB depocenter.
770 These differences in magnitude of Fe^{2+} concentration and Fe^{2+} and PO_4^{3-} flux between the SBB
771 depocenter and the Peruvian shelf could be attributed to differences in the recency and
772 magnitude of reoxygenation events. The release of Fe^{2+} from sediment into the bottom water
773 could create a buffer against reoxygenation in transiently deoxygenated systems, giving a
774 competitive advantage to anaerobic benthic metabolisms (Dale et al., 2013; Wallmann et al.,
775 2022). Additionally, both Fe^{2+} and PO_4^{3-} release from the SBB sediment could allow for higher

776 rates of primary productivity if those constituents diffused into the photic zone (Robinson et al.,
777 2022). The fate of Fe^{2+} and PO_4^{3-} diffusing into SBB waters from the sediment-water interface is
778 a focus of ongoing work within the basin.

779

780 **5 Conclusions**

781

782 This research expands upon the wealth of science already conducted in the SBB and other
783 transiently deoxygenated environments by examining changes in benthic biogeochemistry
784 promoted by the onset of anoxia. We found that GSOB mats proliferate in the SBB where the
785 bottom water is anoxic and nitrate concentrations are declining, initiating a shift from primarily
786 denitrification to an increase in DNRA. We conclude that GSOB mat proliferation in the SBB is
787 confined to areas of the benthic environment with anoxic (though not completely anoxic) bottom
788 water. The sulfate reduction zone is elevated to the surface sediments underneath these mats,
789 but mat presence alone seems insufficient to change the depth of sulfate reduction. We conclude
790 that changes in iron mineralogy, specifically the formation of an iron sulfide layer deeper in
791 sediments, encourages the elevation of the sulfate reduction zone. If anoxic events become
792 longer and more frequent in the SBB because of global warming (Qin et al., 2022; Stramma et
793 al., 2008), the iron oxide buffer built up in shallower depths (e.g., NDT3-B) could be exhausted,
794 allowing for surface sulfate reduction and the proliferation of GSOB mats in shallower margins
795 of the basin than currently seen. Further, the same transient deoxygenation that allows for these
796 mats to flourish also allows for a high Fe^{2+} and PO_4^{3-} flux into the SBB water column. In order to
797 fully understand the complex changes in the benthic environment in response to deoxygenation,
798 genomic and molecular work of the upper sediment community needs to be characterized.

799 Overall, the insights gleaned from this research will aid in the understanding of fundamental

800 biogeochemical changes that occur when marine environments become anoxic.

801 **Acknowledgements**

802 We thank the captain, crew, and scientific party of the R/V Atlantis, and the crew of the ROV
803 Jason for their technical and logistical support during the research expedition AT42-19. We also
804 thank Q. Qin, E. Arrington, M. O’Beirne, A. Mazariegos, X. Moreno, A. Eastman, and K.
805 Gosselin for assisting with shipboard analyses. We further thank M. Alisch from the Max-
806 Planck-Institute in Bremen, Germany for DIC analyses. We thank G. Eickert-Grötzschel, V.
807 Hübner, A. Niclas, I. Schröder, and C. Wigand from the Max-Planck-Institute in Bremen,
808 Germany for constructing the microsensors. We acknowledge J. Matthews from the UC Davis
809 Stable Isotope facility for assisting with solid phase analyses. Funding for this work was
810 provided by the US National Science Foundation, NSF OCE-1756947 and OCE-1830033 (to
811 DLV) and OCE-1829981 (to TT). Further support was provided by the Max Planck Society and
812 the Alfred Wegener Institute for Polar and Marine Research.

814 **Data availability.**

815 Biogeochemical data presented in this manuscript are accessible through the Biological &
816 Chemical Oceanography Data Management Office (BCO-DMO) at the following landing pages:
817 <https://www.bco-dmo.org/dataset/867007>; <https://www.bco-dmo.org/dataset/867113>;
818 <https://www.bco-dmo.org/dataset/867221>; <https://www.bco-dmo.org/dataset/896706>

819 **Author contributions.**

820 TT, DV, FK, NL, and JT designed the project. DJY, SK, JT, DR, and TT processed sediment
821 cores at sea. DJY conducted geochemical analyses of sediment porewater and benthic flux
822 chamber water. DJY prepared TOC and TON samples. DR and SK analyzed sediment porosity
823 and density. TT and SK performed shipboard sulfate reduction incubations. DJY and DR
824 conducted sulfate reduction analyses. DJY, NL, and JT transformed and interpreted ROV Jason
825 data. FJ and FW operated BFC and microprofilers and analyzed associated data. XP conducted
826 ¹⁵N experiments and analyses.
