Abstract:

In this study, we use a synergy of in-situ and remote sensing measurements collected during the Southwestern FOGs 3D experiment for processes study (SOFOG3D) field campaign in autumn and winter 2019-2020, to analyze the thermodynamic and turbulent processes related to fog formation, evolution, and dissipation across southwestern France. Based on a unique measurement dataset (synergy of cloud radar, microwave radiometer, wind lidar, and weather station) combined with a fog conceptual model, an analysis of the four deepest fog episodes (two radiation fogs and two advection-radiation fogs) is conducted. The results show that radiation and advection-radiation fogs form under deep and thin temperature inversions, respectively. For both fog categories, the transition period from stable to adiabatic fog and the fog adiabatic phase are driven by vertical mixing associated with an increase in turbulence in the fog layer due to mechanical production (turbulence kinetic energy (TKE) up to $0.4 \text{ m}^2 \text{ s}^{-2}$ and vertical velocity variance (σ_w^2) up to $0.04 \text{ m}^2 \text{ s}^{-2}$) generated by increasing wind and wind shear. Our study reveals that fog liquid water path, fog top height, temperature and radar reflectivity profiles and fog adiabaticity derived from the conceptual model evolve in a consistent manner to clearly characterize this transition. The dissipation time is observed at night for the advection-radiation fog case studies and after sunrise for the radiation fog case studies. Night-time dissipation is driven by horizontal advection generating mechanical turbulence (TKE at least $0.3 \text{ m}^2 \text{ s}^{-2}$ and σ_w^2 larger than $0.04 \text{ m}^2 \text{ s}^{-2}$). Daytime dissipation is linked to the combination of thermal and mechanical turbulence related respectively to solar heating (near surface sensible heat flux larger than 10 W m^{-2}) and wind shear. This study demonstrates the added value of monitoring fog liquid water content and depth, combined with wind, turbulence and temperature profiles, and diagnostics such as fog liquid water reservoir and adiabaticity to better explain the drivers of the fog life cycle.

Key words: Fog conceptual model, radiation/advection fog, fog life cycle, turbulence, Southwestern France, SOFOG3D

35 1. Introduction

36 Fog is an extreme meteorological phenomenon forming in several regions of earth under
37 different atmospheric conditions depending on the season and location (Gultepe et al., 2007). It is
38 defined by the suspension of water droplets in the lowest troposphere which reduces the horizontal
39 visibility to lower or at least 1000 m. Fog has significant negative impacts on air, road and marine
40 traffic causing large economical and human losses (Bartok et al., 2012, Bartoková et al., 2015,
41 Huang and Chen, 2016). It also has a high impact on solar energy, particularly in the mid-latitudes
42 during autumn and winter. Based on in-situ measurements, several studies have focused on fog
43 formation at different regions and highlighted the main processes leading to its initiation allowing to
44 define five categories of fog: radiation fog (Price 2019), advection-radiation fog (Gultepe et al.,
45 2007, 2009; Niu et al., 2010a, b, Dupont et al., 2012), advection fog (Koračin et al., 2014; Liu et al.,
46 2016, Fernando et al., 2021), fog by stratus lowering (Koračin et al., 2011; Fathalli et al., 2022) and
47 precipitation fog (Tardif and Rasmussen, 2007; Liu et al., 2012). According to the literature, several
48 processes are identified to drive fog evolution and dissipation depending on each category. Fog
49 formation requires low intensity of turbulence (Nakanishi 2000; Bergot 2013; Price 2019).

50 Dhangar et al., 2021 found that optically thin fog develops under low-turbulence kinetic
51 energy and the transition to dense fog is observed when the turbulence increases and reaches
52 enough values to allow the vertical mixing of the fog layer. The dissipation of radiation fog is
53 usually observed after sunrise and linked with the increase in solar heating leading to the
54 evaporation of water drops and a vertical mixing of water vapor (Roach, 1995; Haeffelin et al.,
55 2010; Maalick et al., 2016). Bergot et al., 2015 relied on large eddy simulations (LES) to
56 characterize the role of dry downdrafts in allowing solar radiation to reach the ground and increase
57 the turbulence, leading to the dissipation. Additionally, Pauli et al., 2022 studied the climatology of
58 fog and low stratus cloud formation and dissipation times in Central Europe using satellite data and
59 showed that fog dissipation is also often related to topography. The dissipation processes are more
60 difficult to study than the fog formation processes, due to the complexity of fog's scale. At the state
61 of the art, based on case studies, numerical weather prediction models (Philip et al., 2016, Bell et
62 al., 2022) and high resolution models (Price et al., 2018, Ducongé et al., 2020, Fathalli et al., 2022)
63 up to LES (Bergot et al., 2015, Mazoyer et al., 2017) have the ability to simulate fog formation in
64 several complex areas. However, they have difficulties in simulating the processes driving fog
65 evolution over land in real time (Steeneveld *et al.*, 2015, Price et al., 2015, Román-Cascón et al.,
66 2016; Wærsted et al., 2019; Pithani et al., 2020, Boutle *et al.*, 2022).

67 Toledo et al., 2021 developed a one-column conceptual model of adiabatic continental fog
68 allowing to define key fog metrics as the equivalent fog adiabaticity by closure and the reservoir of
69 liquid water path (RLWP) that can be estimated in real-time and allowing a diagnostic of fog
70 evolution. Based on seven years of measurements collected at SIRTa (Site Instrumental de
71 Recherche par Télédétection Atmosphérique), a French observatory located at Palaiseau/France,
72 Toledo et al., 2021 have validated their model on the timing of fog dissipation using the RLWP.
73 The limitation of this model is that the estimation of the reservoir depends on fog specific
74 parameters and does not take into account local (turbulence) or large scale (advection) processes .
75 Indeed, to further understand uncertainties associated with the estimation of the RLWP, the
76 validation of the model using data from other measurement sites having a large occurrence of fog is
77 another step before using it as a nowcasting tool.

78 Finding the right instruments allowing nowcasting fog is also another challenge that can be
79 partly resolved by field campaigns combining both in-situ and remote sensing measurements and
80 numerical simulations. At the state of the art, nowcasting fog requires more efforts in in-situ
81 measurements and modelling. In this context, the SOutH westFOGs 3D (SOFOG3D) project, led by
82 Météo-France, was designed to document local processes involved in fog formation, evolution and
83 dissipation to better improve its predictability in numerical weather prediction models.

84 In order to improve our understanding of the processes driving the fog life cycle and to
85 validate the fog conceptual model from Toledo et al., 2021 on another region than the one on which
86 it has been developed, the current study aims at identifying the main dynamical and thermodynamic
87 processes driving fog's formation, evolution, and dissipation in the framework of SOFOG3D
88 project. In particular, the role of horizontal advection, atmospheric stability and turbulence is further
89 analyzed to better identify the drivers of radiation and radiation-advection fog phases. Using an
90 instrumental synergy of in-situ and remote sensing measurements and the fog conceptual model, the
91 phenomenology of fog and the different phases driving its evolution are deeply analyzed
92 considering four heavy fog case studies observed over Southwestern France during Winter 2019-
93 2020.

94 This paper is structured into five sections. The datasets and methodological approach are
95 described in the following section. Section 3 gives an analysis of the processes involved in fog
96 evolution based on two different categories of fog formation phenomenology. Section 4 includes a
97 discussion on the thermodynamical and turbulent processes driving the fog phases and Section 5
98 presents the conclusion.

99 **2. Data and methodology**

100 In a mesoscale context, the SOFOG3D field experiment is located in Southwestern France,
101 in the Nouvelle Aquitaine region (Fig. 1a). The field campaign was carried out during the autumn
102 and winter 2019-2020 period leading to 15 intensive observation periods (IOPs). A unique dataset
103 has been collected across a complex region with a very contrasted topography. This region is
104 bordered in the east by the “Massif Central”, in the west by the Atlantic Ocean, in the north by
105 Bordeaux and in the south by the “Pyrenees”. In the region, several dynamical effects can be
106 observed such as sea breeze, land breeze, and mesoscale foehn circulations influencing the fog life
107 cycle. At the local scale, the supersite under focused here is bordered by two rivers: “La Garonne”
108 to the East and “L’Eyre” to the west (Fig. 1a). These two rivers and the surrounding surface
109 heterogeneities can modulate the fog formation and dissipation times. During the campaign, several
110 in-situ and remote sensing measurements were jointly deployed in the studied area of SOFOG3D.
111 In this paper, our analysis focuses on the data collected in the surroundings of the supersite at
112 Charbonnière, the most instrumented site (Fig. 1b). Below, the descriptions of the in-situ and
113 remote sensing measurements and then the fog conceptual model are presented with emphasis on
114 the main meteorological variables used in this study.

115 **2.1 Dataset**

116 **2.1.1 Surface measurement data**

117 A network of surface weather stations was installed in the study domain of SOFOG3D at the
118 vicinity of Charbonnière, to document the spatial variability of fog and surface heterogeneities at
119 the local scale (Fig. 1b). Four weather stations were also deployed around the supersite in a
120 northeast-southwest transect (Fig. 1b). These stations were installed at Moustey, Cape Sud, Tuzan
121 and Noaillan, almost at the same altitude, and operated continuously with very high temporal
122 resolution (0.1 s time interval) during the period from 18 October 2019 to 31 December 2020. In
123 addition to temperature, pressure, relative humidity sensors and anemometer, a scatterometer
124 provided the visibility used to estimate fog formation and dissipation times at each station.
125 Temperature data are used to characterize the spatial variability of the radiative cooling, and wind
126 speed and direction the local circulations.

127 In this study, fog occurrence is defined using the visibility at the supersite based on an
128 algorithm developed by Tardif and Rasmussen, 2007. This algorithm consists of dividing visibility
129 time series into 10 min blocks. A fog block means that half of the visibility measurements during a
130 10 min period are below 1000 m. Blocks are characterized by a positive or negative construct. A
131 positive construct indicates that five consecutive blocks of which the central block is fog and at least
132 two other blocks are also fog blocks. The opposite means a negative construct. Thus, the fog

133 formation time corresponds to the first fog block in the first positive construct encountered. The fog
134 dissipation time corresponds to the last fog block in the last positive construct before either a
135 negative construct or three consecutive non-fog blocks are encountered. This algorithm discards fog
136 events shorter than 1 hour.

137 Meteo-France installed in a fallow field near the supersite, several sensors as Licor analyzers
138 and sonic anemometers to continuously measure the near-surface (3 m a.g.l) meteorological
139 conditions (air temperature and relative humidity), the three components of the wind, and pressure
140 at 0.3 m a.g.l). These instruments provided high frequency data at 20 Hz. In this study, to document
141 turbulence and thermodynamical processes driving fog phases, we use the sensible heat flux (SHF),
142 turbulence kinetic energy (TKE), and vertical velocity variance (σ_w^2). These variables are estimated
143 using the Eddy-covariance methods (Foken et al., 2004, Mauder et al., 2013) calculated every 30
144 minutes after a high quality control of the data. More details on the data can be found in Canut,
145 2020.

146 **2.1.2 Observation of cloud characteristics**

147 For the monitoring of cloud layers, a BASTA cloud radar (Delanoë et al., 2016) was
148 deployed at Charbonnière and a CL51 Ceilometer at Tuzan (7.4 km northwest of Charbonnière)
149 (Fig. 1b).

150 BASTA is a 95-GHz cloud radar manufactured by the Laboratoire Atmosphères, Milieux,
151 Observations Spatiales (LATMOS) with an absolute calibration method for frequency-modulated
152 continuous wave (FMCW) cloud radars based on corner reflectors (Toledo et al., 2020). From 7
153 November 2019 to 12 March 2020, the radar was operated continuously with a vertical pointing
154 mode having three vertical resolutions (12.5 m, 25 m, and 100 m). It provided radar reflectivity and
155 Doppler velocity. The lowest mode, having its first available gate at 37.5 m a.g.l and 12.5 m of
156 vertical resolution, is used to estimate the cloud top height (CTH) which gives the fog thickness at a
157 time resolution of 30 seconds. It also provides the level of highest concentration of droplets in the
158 fog layer. The CTH is estimated using a radar reflectivity threshold of -34 dBZ.

159 The CL51 is manufactured by Vaisala and automatically provided three estimates of cloud
160 base height (CBH) allowing the detection of cloud decks every 30 seconds with a vertical resolution
161 of 15 m from 10 October 2019 to 2 April 2020. In this study, we use the lowest CBH, which
162 corresponds to the base height of stratus cloud lowering or lifting when fog forms or dissipates,
163 respectively. More information on the data provided by the CL51 can be found in Burnet, 2021.

164 **2.1.3 Temperature, liquid water content, and wind profiling**

165 A microwave radiometer Hatpro (MWR) manufactured by Radiometer Physics GmbH
166 (RPG) was installed at the supersite to characterize thermodynamic atmospheric conditions during
167 the field campaign. From 4 December 2019 to 9 May 2020, the MWR operated continuously at the
168 supersite using two spectral-bands: the K-band which 22.24-31 GHz used for the retrieval of
169 humidity profiles, integrated water vapor (IWV) content and liquid water path (LWP), and the V-
170 band which 51-58 GHz to retrieve temperature profiles. In order to improve the vertical resolution
171 in the boundary layer, the MWR was set up to scan in 10 elevation angles (5° above ground level)
172 every 10 minutes with a zenith pointing each 1 second. Using neural networks, brightness
173 temperatures measured by the MWR at all elevation angles (the lower elevations angles added to
174 measurements at zenith) are inverted to temperature and humidity variables. More details on this
175 method can be found in Martinet et al., 2022. Comparing temperature and humidity profiles
176 retrieved by the MWR with radiosonde data, Martinet et al., 2022 found that air temperature has
177 cold biases below 0.5 K in absolute value below 2 km but increases up to 1.5 K above 4 km
178 altitude. The low biases in the lowest atmosphere allow a good estimation of the lowest temperature
179 inversion under focus in this study. For each case study, the transition from stable to adiabatic fog is
180 estimated using the static atmospheric stability in the lowest atmosphere computed using the
181 temperature profile. The air temperature profiles are also used to characterize the atmospheric
182 conditions linked to the development of fog at Charbonnière. For the absolute humidity, the
183 maximum dry bias of the MWR is around 1.4 g m^{-3} in the lowest troposphere up to 1.7 km and
184 becomes wet above (0.3 g m^{-3}). Martinet et al., 2022 showed that the LWP accuracy has been
185 validated in clear-sky conditions and has shown errors between 1 and 14 g m^{-2} . These error range is
186 in the scope of those defined in the literature (Crewell and Löhnert, 2003; Marke et al., 2016). The
187 LWP is a key parameter to consider for the microphysical characteristics of fog and is used in the
188 conceptual model. More information regarding the data can be found in Martinet, 2021.

189 The WindCube lidar has become a common instrument used in documenting very low
190 atmospheric phenomena such as turbulence (Liao et al., 2020; Kumer et al., 2016). Dias Neto et al.,
191 2023 demonstrated the usefulness of the wind speed and direction estimated using the WindCube
192 V2. Comparing wind from WindCube V2 with GPS radiosonde, they found low biases of 0.52 m s^{-1}
193 and 0.37° for the wind speed and direction, respectively. To investigate the dynamics of the
194 atmosphere at the supersite, a WindCube V2 lidar manufactured by Leosphere was deployed by
195 Météo-France during the field campaign to provide from 1 October 2019 to 10 April 2020, the wind
196 measurements at 10 levels ranging from 40 m to 220 m above ground level (a.g.l). The
197 measurements made at a 1 Hz frequency and a 20 m vertical resolution provided the estimation of
198 turbulence parameters such as the turbulent kinetic energy (TKE). The wind component are

estimated every 10 minutes using a Carrier-to-Noise Ratio (CNR) at least -23 dB and a total data availability of at least 50 %. Note that the CNR depends on atmospheric turbulence characteristics and relative humidity (Aitken et al., 2012). In the presence of fog or low stratus, the Lidar vertical range becomes low. The TKE is computed as the sum of the horizontal variances as in Kumer et al., 2016. Velocity variances are estimated every 30 minutes using the wind components at the high resolution. It is used in this study to analyze the role of turbulence within the foggy-layer to further characterize fog formation, evolution, and dissipation. More details on the WindCube lidar data can be found in Canut et al., 2022.

2.1.4 Fog adiabaticity and reservoir

To further understand fog characteristics, it is essential to focus our analysis on several variables related to the formation, evolution and dissipation of fog. Fog adiabaticity and reservoir are key metrics driving the life cycle of fog. They are estimated using the fog conceptual model (Toledo et al., 2021) developed at SIRTa. This model is a uni-dimensional model inspired by previous numerical models for stratus clouds (Betts, 1982, Albrecht et al., 1990; and Cermak and Bendix, 2011). The basic hypothesis is to consider a well-mixed fog layer and to express the increase in height of the fog liquid water content as a function of the local adiabaticity and the negative of the change in the saturation mixing ratio with height ($\Gamma_{ad}(T,P)$) (equation A1). Fog liquid water path is parameterized as a function depending on the equivalent fog adiabaticity (α_{eq}) and the CTH (equation A3). The equivalent fog adiabaticity is used to characterize the buoyancy in low clouds. α_{eq} varies depending on the in-cloud mixing parameter β and is expressed as $\alpha_{eq} = (1-\beta)$ (Betts, 1982 and Cermak and Bendix, 2011). For low-level clouds, as stratus and stratocumulus, α_{eq} is between 0.6 and 0.9 (Braun et al., 2018) indicating sufficient buoyancy in the cloud layer with an adiabatic profile. To parameterize this parameter in the fog conceptual model, Toledo et al., 2021 used an inversion of Eq. (A3) to define a fog adiabaticity from closure ($\alpha_{eq}^{closure}$) given as:

$$\alpha_{eq}^{closure} = \frac{2(LWP - LWC_0 CTH)}{\Gamma_{ad}(T, P) CTH^2} \quad (1)$$

$\alpha_{eq}^{closure}$ depends on the accumulated liquid water content (LWC) at the fog base (LWC_0), fog thickness (e.g. CTH), the LWP and the adiabaticity. The adiabaticity lapse rate is a function of air temperature and pressure. Toledo et al., 2021 found that the equivalent fog adiabaticity from closure is negative when the LWP is below 30 g m⁻². They defined the transition phase from stable to adiabatic conditions when the equivalent fog adiabaticity from closure is around 0.5. In the conceptual model, this parameter is estimated only for a CTH below 462.5 m with free cloud above.

231 The model considers that the fog dissipates when its liquid water path is below a certain
 232 threshold depending on the local thermodynamic atmospheric conditions. In case of dissipation by
 233 lifting the base height of the fog, Wærsted, 2018 found a deficit in LWP in the fog layer. This
 234 assertion allows defining a minimum amount of LWP necessary to maintain the horizontal visibility
 235 at surface lower or equal to 1000 m, defined as the critical liquid water path (CLWP). Thus, based
 236 on equation A3, the CLWP can be expressed in equation (2) considering a critical liquid water
 237 content at surface (LWC_c).

$$238 \quad CLWP = \frac{1}{2} \alpha_{eq} \Gamma_{ad}(T, P) CTH^2 + LWC_c CTH \quad (2)$$

239 Theoretically, the LWC_c corresponds to the LWC that would cause a 1000 m visibility. It is
 240 estimated from the parameterization of Gultepe et al., 2006 based on the horizontal visibility at
 241 surface.

242 Considering that adiabatic fog exists because the liquid water path in its thickness is strictly
 243 greater or equal to its CLWP (Toledo et al., 2021), it is possible to define an associated quantity
 244 named the fog reservoir of liquid water path (RLWP). The RLWP is defined as the difference
 245 between fog current liquid water path and the critical value, as:

$$246 \quad RLWP = LWP - CLWP = LWP - \frac{1}{2} \alpha_{eq} \Gamma_{ad}(T, P) CTH^2 - LWC_c CTH \quad (3)$$

247 The RLWP depends on the LWC_c (A4), the adiabaticity and fog thickness. The calculation of
 248 RLWP can be used to anticipate the dissipation or thickening of the fog in the coming minutes or
 249 hours. Based on 20 fog cases at SIRTa, Toledo, 2021 found that for a RLWP > 30 g m⁻² in a given
 250 time instant, fog does not dissipate within the following 30 minutes. He also showed that the RLWP
 251 trend decreases before fog dissipation time and increases when fog is persisting. This behaviour
 252 motivates the analysis of the RLWP trend in this study to improve the characterization of the
 253 different fog phases.

254 The number of fog events observed during the SOFOG3D field campaign is not sufficient to
 255 calibrate the fog conceptual model in southeastern France as in SIRTa (Toledo et al., 2021). In this
 256 study, we use the model with its parametrization at SIRTa to further characterize the different
 257 phases observed in the lifetime of fog based on identified case studies. The model is performed
 258 when the visibility is lower than 1000 m. $\alpha_{eq}^{closure}$ is used to characterize the fog transition from
 259 stable phase to adiabatic phase. The RLWP gives an estimation of the excess/deficit of liquid water
 260 of the fog that enables the fog layer to remain at surface or dissipate. It can be used as a diagnostic
 261 of how likely the fog will persist in the coming minutes, hours (nowcasting tool for fog dissipation

time). More details on the fog conceptual model is given in appendices and can be found in Toledo, 2021.

2.2 Case studies and methodological approach

For the whole SOFOG3D campaign, based on the fog defined criteria described in section 2.2.1, 31 fog events are identified during 31 October 2019 - 26 March 2020 period. For each one, a visual inspection of the time-height cross-section of the radar reflectivity from BASTA cloud radar and the cloud base height from the Ceilometer was carried out. We selected the four most developed fog episodes, namely case studies 1 (IOP 5), 2 (IOP 6), 3 (IOP 11) and 4 (IOP 14).

As in Toledo et al., 2021 (their Fig. 3), Figure 2 shows the equivalent adiabaticity by closure versus LWP and CTH for the 4 fog case studied. It indicates that $\alpha_{eq}^{closure}$ reaches 0.5 when $LWP > 20 \text{ g m}^{-2}$ and the $CTH > 150 \text{ m}$ which should be the conditions favorable for the fog to become optically opaque to the infrared radiation. At the supersite, the LWP observed during that transition is lower than the threshold at SIRTa ($LWP > 30 \text{ g m}^{-2}$) (Wærsted et al., 2017 and Toledo et al., 2021). However, there is a consistency between both sites on the computation of the equivalent adiabaticity by closure. This legitimises the choice of the four days, and motivates the use of the $\alpha_{eq}^{closure}$ in this study to define the transition phase between stable and adiabatic fog.

For the selected case studies, Table 1 contains the fog formation and dissipation times, fog formation types, and fog duration at the supersite. For all selected fog events, the formation time of fog is observed between 20:40 and 22:40 UTC and the dissipation time varies from night to daytime. These selected fogs are triggered by radiation (2 cases) or advection-radiation (2 cases) processes.

For each selected case study, temperature profiles from the MWR, radar reflectivity profiles from the BASTA cloud radar and the equivalent fog adiabaticity derived from the conceptual model are used to define the four fog phases characterizing the fog evolution: fog pre-onset, stable fog, adiabatic fog, and fog dissipation. Note that an important time of the fog life cycle is the transition time between stable and adiabatic fog. Each fog phase is defined as following:

1/ Fog pre-onset corresponds to the two hours preceding fog onset associated with cloud free conditions.

2/ In the four cases studies, the stable phase starts at fog onset. It is characterized by a stable temperature profile in the lowest 100 m of the atmosphere.

3/ The transition time separating the stable and adiabatic phases can be defined differently depending on the meteorological variables considered. Price et al., 2011 defined this transition time as the time when the air temperature becomes constant in the fog lowest layer (1.5 - 50 m a.g.l.).

295 Toledo et al., 2021 found that the transition is observed when the equivalent fog adiabaticity by
 296 closure is increasing between 0 and 0.5. In this study, for a better definition of this period, we take
 297 into account the static stability given by the hourly profiles of mean air temperature from the MWR,
 298 the fog geometry (CTH) from the cloud radar, and the $\alpha_{eq}^{closure}$ from the conceptual model. Indeed,
 299 the transition period is defined as the time when the temperature profile becomes unstable or neutral
 300 in the 0-75 m a.g.l layer, while the fog CTH increases with time, and $\alpha_{eq}^{closure}$ increases from 0 to
 301 about 0.5. Note that the thickening of the fog is associated with the elevation of the level of the
 302 maximum radar reflectivity. The transition phase starts when $\alpha_{eq}^{closure} < 0.5$, the CTH suddenly
 303 increases more than 25 m in 5 minutes under a stable or neutral layer. This phase ends when $\alpha_{eq}^{closure}$
 304 reaches 0.5 and the fog layer becomes neutral or unstable.

305 4/ Fog adiabatic phase is characterized by $\alpha_{eq}^{closure}$ around 0.5, a neutral or unstable
 306 temperature profile, and a radar reflectivity that increases with increasing altitude and peaks a few
 307 tenths of meters below cloud top.

308 5/ Fog dissipation phase is defined as being the period between 30 minutes before and after
 309 dissipation time (when horizontal visibility becomes greater than 1 km). Since the fog dissipation
 310 time does not appear abruptly, as it is also driven by thermodynamical processes, we consider this
 311 time range to further document them.

312 Based on these fog phase definitions, in the following, we describe the four case studies. For
 313 each fog event, we document the processes involved in the evolution of fog in each of these phases,
 314 using the fog conceptual model and the instrumental synergy, in order to identify the main
 315 processes driving the fog life cycle.

316 **Table 1 :** Case study number, fog onsets, type of fog formation, fog dissipation times, fog duration
 317 and type of fog dissipation for the four documented case studies. Time is in UTC. Dates are in the
 318 format “dd/mm/yyyy”. “dd” indicates the day, “mm” the month and “yyyy” the year.

Case study number	Formation time		Fog types	Dissipation time		Fog duration (hh:min)

3. Fog formation, evolution, and dissipation processes

3.1 Radiation fog case studies

3.1.1 Case study 1 (IOP 5) analysis

Figures 3a and 3b indicate the time-cross sections of the radar reflectivity estimated from BASTA cloud radar during case study 1, on the 28-29 December 2019, respectively up to 600 m and 12000 m. They show a clear sky before fog formation time at 22:40 UTC on 28 December 2019. During fog evolution, cloud free conditions are observed above the fog top height until 09:00 UTC when sparse thin high-altitude clouds occur above the cloud radar. Figure 3c presents a quasi-homogeneous fog formation time between the three sites and heterogeneous dissipation time. At Charbonnière, fog dissipated at 11:00 UTC, on 29 December 2019 and two hours earlier at Noaillan. At all sites, low temperatures below 4 °C (Fig. 3e) are observed during the fog period. Near the surface, light winds ($< 1 \text{ m s}^{-1}$) are recorded at all sites from fog pre-onset to fog stable/adiabatic transition times (Fig. 3d and 3f).

The fog pre-onset is marked by a double stratification of the atmospheric boundary layer with a thin inversion from surface up to 100 m and deep and strong inversion (around 8 °C km^{-1}) above (Fig. 4a). Atmospheric conditions are dominated by an easterly wind that reaches 5 m s^{-1} above 100 m a.g.l which could be considered as a nocturnal low-level jet (Fig. 4d). The mean cooling rate near the surface is -0.9 °C h^{-1} . The strong decrease in temperature is associated with a negative SHF (-0.23 W m^{-2}) (Fig. 4h), near surface low wind (0.61 m s^{-1}) (Fig. 3d and 3f) and low turbulence ($\text{TKE} = 0.11 \text{ m}^2 \text{ s}^{-2}$ and $\sigma_w^2 = 0.002 \text{ m}^2 \text{ s}^{-2}$). These conditions lead to thermally-stable atmospheric conditions which are favourable for radiation fog formation (Table 1).

The fog stable phase lasts around 6 h (22:50 - 05:00 UTC) and is characterized on average by a very low negative near surface cooling rate (-0.18 °C h^{-1}), an almost zero SHF, an easterly light wind (0.78 m s^{-1}), low turbulence ($\text{TKE} = 0.07 \text{ m}^2 \text{ s}^{-2}$, $\sigma_w^2 = 0.01 \text{ m}^2 \text{ s}^{-2}$), negative $\alpha_{\text{eq}}^{\text{closure}}$ (-1.3) (Fig. 4e), low LWP (2.18 g m^{-2}) (Fig. 4g), slight increase in time of the fog thickness up to 50 m, and relatively stable temperature inversion height. These characteristics maintain the fog thermally stable with an horizontal visibility of 736 m on average.

The transition time from stable to adiabatic fog is observed between 05:00 and 07:00 UTC (02:00 duration) and associated with a lowest visibility (198 m), a transition in the vertical profiles of air temperature (Fig. 4a) from stable at 05:00 to unstable at 06:00 UTC in the fog layer, a deepening of the cold layer, an increase of the mean SHF reaching 4.4 W m^{-2} and around 10 W m^{-2} at the phase end (Fig. 4h), an increase of the turbulence (TKE up to $0.15 \text{ m}^2 \text{ s}^{-2}$ and σ_w^2 up to $0.04 \text{ m}^2 \text{ s}^{-2}$) generated by the strengthening of the wind speed (1.14 m s^{-1}) and its shift in direction from East to Southeast. From 05:00 to 06:00 UTC, the coldest temperature shifts from the surface up to 50 m

a.g.l, the vertical profile of radar reflectivity increases with height, indicating a vertical development of fog (Fig. 4b) generated by turbulence processes. At the end of this phase, $\alpha_{eq}^{closure}$ reaches 0.5 which is consistent with the threshold obtained at the SIRTa site by Toledo et al., 2021. σ_w^2 values observed are higher than the threshold fixed by Price et al., 2019 for a thermally-stable surface layer. The LWP (28 g m^{-2}) and RLWP ($+15 \text{ g m}^{-2}$) peak at the end of the transition phase consistently with a decrease in visibility. Due to the simultaneous increase in SHF, TKE and σ_w^2 , the transition phase is driven by both thermal and mechanical turbulence.

The fog adiabatic phase is observed between 07:00 and 11:00 UTC (04:00 duration) at the supersite and characterized by a vertical development of fog up to 187.5 m (Fig. 4b) and the arrival of sparse high clouds (Fig. 3a and 3b) associated with the lowering of the temperature inversion top height above the fog top (Fig. 4c). Note that these clouds have no effect on the radiative cooling at the top height of the fog. The fog layer becomes warmer ($+0.77 \text{ }^\circ\text{C h}^{-1}$ on average) and its LWP and RLWP reach 26.16 g m^{-2} and $+6.38 \text{ g m}^{-2}$, respectively. The turbulence gradually increases in the fog layer (Fig. 4f) ($\text{TKE} = 0.23 \text{ m}^2 \text{ s}^{-2}$) due to an increase of the horizontal wind speed (2.4 m s^{-1}) combined with an increase of the vertical shear and the wind shift from southeasterly to easterly (Fig. 4d). In the same way, σ_w^2 increases to $0.04 \text{ m}^2 \text{ s}^{-2}$ and is driven both by the vertical wind shear and the increase in SHF (12.9 W m^{-2}) (Fig. 4h). For this case study, the moderate mechanical and thermal turbulence causes the vertical mixing in the fog layer, which slightly increases the surface horizontal visibility (370 m) and fog top height (185 m).

At the supersite, in the absence of any cloud above the fog layer, the fog dissipates after sunrise. It is marked by a continue increase in SHF (Fig. 4h) due to solar radiation (daytime atmospheric convection), negative RLWP (-11.39 g m^{-2}), an increase in CTH (290 m), LWP (maximum of 43.34 g m^{-2}), stable $\alpha_{eq}^{closure}$ around 0.63, and more thermal turbulence ($\sigma_w^2 = 0.06 \text{ m}^2 \text{ s}^{-2}$) allowing more vertical mixing. Based on the RLWP, the fog conceptual model would predict a deficit of liquid water in the fog layer one hour before the lifting of its base height (Fig. 4g). The fog dissipation phase is induced by the increase of the vertical mixing generated by the thermal (solar heating) and mechanical turbulence associated with TKE values larger than $0.4 \text{ m}^2 \text{ s}^{-2}$ (Fig. 4f).

In summary, for this radiative fog event, the fog conceptual model is consistent with the in-situ measurements of turbulence on the timing of the different fog phases. It has provided additional elements for understanding the different phases of the fog life cycle.

3.1.2 Case study 2 (IOP 6) analysis

384 As in case study 1, case study 2 is a radiation fog that forms under clear skies a few hours
385 after sunset (Fig. 5a and 5b), under a double stratification of the low atmosphere (Fig. 6a), southerly
386 very low near-surface wind speed (0.2 m s^{-1}), low TKE ($0.06 \text{ m}^2 \text{ s}^{-2}$) and negative surface SHF. The
387 fog lasts 12 h and completely dissipates around 08:40 UTC, on 6 January 2020 at the supersite (see
388 Table 1) and at 04:30 UTC at Noaillan revealing more spatial variability than in case study 1.

389 The fog stable phase last 3 h 20 min (20:40 to 00:00 UTC), half the time of case study 1,
390 with fog characteristics similar to those of case study 1. A 2-hour fog transition phase is observed
391 from 00:00 to 02:00 UTC, (02:00 duration as for IOP 5) at the supersite (Fig. 6a and 6b) and
392 characterized by positive SHF (7.76 W m^{-2}) and larger values of TKE ($0.23 \text{ m}^2 \text{ s}^{-1}$) allowing vertical
393 mixing and transition towards adiabatic fog. A significantly longer fog adiabatic phase is observed
394 from 02:00 to 08:40 UTC (twice longer than in IOP 5). The first period from 02:00 to 05:00 UTC is
395 characterized by continued positive SHF (10 W m^{-2}) (Fig. 6h) and significant turbulence (TKE > 0.2
396 $\text{m}^2 \text{ s}^{-2}$ and $\sigma_w^2 > 0.02 \text{ m}^2 \text{ s}^{-2}$) (Fig. 6f) leading to a deeper fog with relatively high LWP (42 g m^{-2}), and
397 a positive RLWP until 04:30 UTC (Fig. 6g). The second period from 05:00 to 08:40 UTC is
398 characterized by continued positive SHF, significant $\sigma_w^2 (> 0.02 \text{ m}^2 \text{ s}^{-2})$, while the TKE decreases ($<$
399 $0.2 \text{ m}^2 \text{ s}^{-2}$) associated with the decrease in wind speed in the fog layer. A sharp decrease in LWP,
400 with a reduction of fog top height leads to RLWP oscillating around 0 g m^{-2} , while the horizontal
401 visibility increases and then decreases again. During this period, the sharp decrease in LWP ($< 20 \text{ g}$
402 m^{-2}) results in a fog layer that is not very resilient to the significant turbulence, as shown by the very
403 low RLWP values and rapidly changing horizontal visibility (Fig. 5c). The decrease in LWP could
404 be driven by production of drizzle, as scientist reported droplet freezing on the tethered balloon. Fog
405 dissipation occurred after sunrise (08:40 UTC), under positive SHF (14 W m^{-2}), driven by the
406 turbulence associated with mechanical and thermal processes (mean TKE $\sim 0.28 \text{ m}^2 \text{ s}^{-2}$ and σ_w^2
407 $\sim 0.048 \text{ m}^2 \text{ s}^{-2}$).

408 3.2 Radiation-advection fog case studies

409 Case study 3 and 4 correspond to two fog cases that form after sunset (near 21 UTC) in a moist
410 westerly flow, with an initial condensation about 100 m a.g.l (ultra-low stratus or elevated fog)
411 followed by a rapid subsidence of the cloud layer to the ground (see Figures 7 and 9, respectively).
412 West-east gradients are observed in terms of temperature and fog formation time, combined with a
413 weak temperature inversion at the time of fog formation, justifying the classification of fog
414 formation by advection-radiation processes (Ryznar, 1977).

415 3.2.1 Case study 3 (IOP 11) analysis

416 In spite of different formation conditions for case study 3, compared to case 1 and 2, the stable fog
 417 phase of this case is characterized by fog conditions that are similar to those of case 1 and 2 (Figure
 418 8): slightly negative SHF, low turbulence ($\text{TKE} = 0.03 \text{ m}^2 \text{ s}^{-2}$) and low LWP ($< 10 \text{ g m}^{-2}$). Case study
 419 3 differs from the previous case studies with a longer duration for the stable-to-adiabatic fog
 420 transition (03:30 duration) during which SHF remains slightly negative, TKE remains mostly below
 421 $0.03 \text{ m}^2 \text{ s}^{-2}$, and CTH, LWP and $\alpha_{\text{eq}}^{\text{closure}}$ increase progressively, while RLWP remains relatively
 422 stable ($5\text{-}10 \text{ g m}^{-2}$). In case study 3, the very short fog adiabatic phase (1 hour) is characterized by
 423 increasing vertical wind shear near fog top height (Fig. 8d) that generates dynamical instability
 424 driving the vertical mixing, reducing the temperature inversion above fog top (Fig. 8c), and
 425 promoting vertical development of the fog layer. The rapid increase in CTH is not sufficiently
 426 compensated by the increase in LWP, leading to a decrease in RLWP (Fig. 8g) and subsequent
 427 increase in near-surface visibility and dissipation of the fog. Increasing wind aloft brings warm drier
 428 air over the top of the fog that then mixing into it ($\text{TKE} = 0.33 \text{ m}^2 \text{ s}^{-2}$ and $\sigma_w^2 = 0.07 \text{ m}^2 \text{ s}^{-2}$),
 429 evaporating fog droplets, reducing the RLWP to negative values and causing the fog to lift into low
 430 stratus. The fog dissipation phase is thus driven by the advection of warm air at the supersite (Fig.
 431 7e).

432 **3.2.2 Case study 4 (IOP 14) analysis**

433 As in case study 3, fog case study 4 starts with a very low stratus fog, subsidence of the
 434 cloud layer resulting in a fog. The fog layer is perturbed by the advection from the northwest
 435 (captured in Meteosat Second image, not shown) around 00:30 UTC of another stratus with a base
 436 height above the fog top height. From 04:00 UTC, the fog becomes intermittent with a first
 437 dissipation observed at that time and a definitive dissipation around 07:00 UTC.

438 The 2-hour long fog stable phase is also characterized by a cooling rate near -1°C h^{-1} , slightly
 439 negative SHF and low turbulence ($\text{TKE} < 0.1 \text{ m}^2 \text{ s}^{-2}$). The relatively short transition from stable to
 440 adiabatic fog ($< 1 \text{ h } 30 \text{ min}$) is characterized by an increase in mechanically-driven turbulence
 441 (wind shear, Figure 10d) with a southerly wind that likely brings additional moisture, leading to a
 442 rapid increase in both CTH and LWP (near 40 g m^{-2}).

443 Fog adiabatic phase is observed from 00:20 to 04:00 UTC (03:40 duration) followed by a
 444 temporary dissipation of the fog from 04:00 to 05:30 UTC and a definitive fog dissipation at 07:00
 445 UTC. This adiabatic phase is characterized by a 250-300 m deep fog with $40\text{-}50 \text{ g m}^{-2}$ LWP. The
 446 mechanically driven TKE ranges between $0.2\text{-}0.4 \text{ m}^2 \text{ s}^{-2}$ (Figure 10f) which confirms the turbulence
 447 that a relatively deep fog layer can withstand. The evolution of RLWP to negative values after
 448 04:00 UTC (Figure 10g) shows that the conceptual model captures the transition from an adiabatic

449 fog with low near-surface visibility (< 300 m) to one with horizontal visibility at or above 1000 m
450 (Figure 9c). The definitive dissipation is not associated with increasing turbulence, but rather with
451 the presence of middle-altitude clouds that likely reduce significantly the fog top radiative cooling,
452 as precisely characterized by Waersted et al. (2017), and hence liquid water content production.
453 Indeed, Figure 10g reveals a significant LWP reduction after 6:30 UTC, that explains the definitive
454 dissipation of the fog before sunrise.

455 **4. Discussion**

456 Figure 11 shows the mean vertical profiles of air temperature derived from the MWR and
457 radar reflectivity measured by the cloud radar for each fog phase and each case study. It highlights
458 the thermal and microphysical characteristics of fog phases and differences in atmospheric
459 conditions between fog categories: radiation and radiation-advection fogs.

460 For radiation fog case studies (1 and 2), fog develops below the dry, warm and cloud free
461 stable atmospheric boundary layer (Fig. 4c and 6c). Atmospheric conditions preceding (two hours
462 before) fog formation are dominated by a strong and thick temperature inversion (more than $14\text{ }^{\circ}\text{C}$
463 and 1000 m) which is associated with anticyclonic conditions over Europe favouring easterly wind
464 and clear sky across the studied area. These atmospheric conditions allow a strong surface radiative
465 cooling, negative heat fluxes and cooling of near surface air at a rate of -0.9 and $-0.7\text{ }^{\circ}\text{C h}^{-1}$ for case
466 study 1 and 2, respectively. This cooling is associated with low turbulence indicated by low values
467 of TKE ($0.18\text{ m}^2\text{ s}^{-2}$ in case 1, and 0.06 in case 2) and near surface vertical velocity variance ($\sigma_w^2 <$
468 $0.003\text{ m}^2\text{ s}^{-2}$) which reinforce the surface thermally stable boundary layer (Fig. 11a and 11b)
469 favoring the triggering of radiation fog. These results are consistent with the definition of radiation
470 fog proposed by Price, 2019.

471 In advection-radiation fog case studies (3 and 4), two hours before fog formation, a westerly
472 sea breeze is present, transporting mild wet air from the ocean. Surface heat fluxes are negative,
473 favoring cooling of the near-surface air ($-1\text{ }^{\circ}\text{C h}^{-1}$ in case study 3 and $-0.5\text{ }^{\circ}\text{C h}^{-1}$ in case study 4) and
474 turbulent mixing is low ($\text{TKE} < 0.06\text{ m}^2\text{ s}^{-2}$). An East-West gradient of formation and dissipation is
475 observed in line with the westerly synoptic advection of Atlantic inflow. Fog forms earlier in the
476 West and dissipates later in the East. The combination of advection and radiative cooling favours
477 stratus fog formation at about 150 m a.g.l followed by a rapid (less than 30 min) lowering of its base
478 height to the surface triggering the onset of the fog in an unstable (case 3) and neutral (case 4)
479 surface atmospheric boundary layer (Fig. 11c and 11d).

480 The stable fog phase is characterized by a stable temperature profile and radar reflectivity
481 which is maximum near the surface and decreases with height (see Fig. 11). The fog remains

shallow (less than 100 m) with a low LWP ranging less than 12 g m^{-2} proportional to fog depth (Table 2). The equivalent fog adiabaticity by closure parameter ($\alpha_{\text{eq}}^{\text{closure}}$) is typically negative during the stable phase indicating that the fog is not in an adiabatic phase. The near-surface temperature decreases very moderately ($-0.2 \text{ }^{\circ}\text{C h}^{-1}$) in cases 1 and 2, while the air keeps cooling at about $-1 \text{ }^{\circ}\text{C h}^{-1}$ in cases 3 and 4. For the four cases, surface heat fluxes are slightly negative (-3 to 0 W m^{-2}) and turbulence remains low (TKE at about $0.1 \text{ m}^2 \text{ s}^{-2}$ and σ_w^2 at $0.01 \text{ m}^2 \text{ s}^{-2}$). This phase is characterized by very low LWPs ($1\text{-}2 \text{ g m}^{-2}$ for radiation fogs and $6\text{-}11 \text{ g m}^{-2}$ for advection-radiation fog). For radiation fog cases, the stable phase lasts around 6 and 4 hours, respectively, while for advection-radiation cases, it lasts around 2 hours. This is consistent with the strength of the surface inversion of each category of fog, as shown in Figure 11. These macrophysical characteristics of the fog stable phase are consistent with those found by Toledo et al., 2021.

The transition from stable to adiabatic phases is a key period in the fog life cycle. This period is well characterized using the macrophysical parameters of the conceptual model, namely the equivalent fog adiabaticity by closure ($\alpha_{\text{eq}}^{\text{closure}}$) parameter of the fog, the fog geometry (CTH) and fog LWP. During the transition from stable to adiabatic phases, these three parameters increase significantly (see Table 2). In particular, $\alpha_{\text{eq}}^{\text{closure}}$ evolves progressively from negative values towards $+0.5$ (Toledo et al., 2021). The transition phase lasts from 1 h 30 min to 3 h 30 min, however its timing of occurrence is quite variable (case 1 at (05:00 - 07:00 UTC), case 2 (00:00 - 02:00 UTC), case 3 (23:00 - 02:30 UTC), and case 4 (23:30 - 01:00 UTC). During this phase, a change is observed in static stability from stable profiles to neutral adiabatic profiles (Fig. 11), while the radar reflectivity profile presents maximum values near the ground that decrease with height (Fig. 11). In cases 1, 2 and 4, the transition phase is characterized by an increase in turbulence that can explain the decrease in thermal stability of the fog layer, either shown in the vertical velocity variance ($\sigma_w^2 \geq 0.02 \text{ m}^2 \text{ s}^{-2}$) associated with positive surface heat fluxes (cases 1 and 2), or TKE exceeding $0.3 \text{ m}^2 \text{ s}^{-2}$ (cases 2 and 4). In all the cases, the fog LWP increases significantly which allows a more efficient radiative cooling of the fog layer, hence contributing to the destabilization of the fog layer. In case 3, the transition phase is not marked by a significant increase in turbulence. The transition is more progressive than in the other case studies, with gradual increases of CTH, LWP and $\alpha_{\text{eq}}^{\text{closure}}$ during this long phase (03:30 duration).

According to temperature vertical profiles from the MWR, at the end of the transition time from stable to adiabatic fog, the temperature profile becomes neutral or slightly unstable. This is consistent with the definition of the transition given by Price et al., 2011. We also find that it is during this period that the fog reaches its maximum value of RLWP, showing that the LWP

increases beyond the critical liquid water path value, which gives information on the persistence of fog.

For radiation fog case studies, the adiabatic phase lasts 04:00 and 06:40 hours for case 1 and 2 respectively, maintaining the fog life cycle during the night until after sunrise. In cases 3 and 4, the adiabatic phase is shorter and lasts 01:00 and 03:40 hours, respectively, with a night-time dissipation at 03:40 and 04:00 UTC, respectively. In this fog phase, for radiation fog, the LWP ranges from 22-26 g m⁻² with CTH near 187.5 m a.g.l. The fog is deeper for advection-radiation fog cases with LWP / CTH at 30 g m⁻² / 200 m a.g.l and 43 g m⁻² / 287.5 m a.g.l, respectively (Table 2). The adiabatic phase is characterized by an equivalent fog adiabatic closure parameter near or above 0.5, and a positive yet low RLWP. For all the cases except case 3, the adiabatic phase is associated with moderate turbulence in the fog layer ($0.2 < \text{TKE} < 0.4 \text{ m}^2 \text{ s}^{-2}$ and $0.03 < \sigma_w^2 < 0.04 \text{ m}^2 \text{ s}^{-2}$) which indicates significant vertical mixing generating an unstable surface atmospheric boundary layer (Fig. 11). This finding is consistent with the result of Ju et al., 2020 who based their analysis on one case study and Ghude et al., 2023, Dhangar et al., 2021 and Zhou and Ferrier, 2008 for more case studies analysis. In addition, this phase can also be driven by horizontal advection (mesoscale and synoptic systems) as in the case study 3.

This study shows two distinct fog dissipation periods, at night and after sunrise. Daytime dissipation is observed for radiative fog cases and night-time dissipation for advection-radiation ones. All of them are observed when $\alpha_{\text{eq}}^{\text{closure}} > 0.5$, $\text{TKE} > 0.3 \text{ m}^2 \text{ s}^{-2}$, $\sigma_w^2 > 0.04 \text{ m}^2 \text{ s}^{-2}$, and the LWP $> 40 \text{ g m}^{-2}$ (except case study 2). For cases 1 and 2, turbulence is thermally driven by positive SHF, while for cases 3 and 4, the night-time turbulence increase is mechanically driven by increased wind speed. For all case studies, the RLWP decreases significantly from the stable phase to the dissipation phase, confirming that dissipation through fog-base lifting is linked to insufficient liquid water content in the fog layer, as suggested by the conceptual model. For case 3, the RLWP becomes negative 20 min after dissipation. This delay is likely due to very rapid changes in LWP and CTH at the fog dissipation time.

5. Summary and Conclusions

The SOFOG3D field campaign provides a unique dataset documenting thermodynamic and dynamical atmospheric circulations to further understand the processes driving fog formation and dissipation over Southeastern France. Based on an innovative instrumental synergy combining in-situ and remote sensing measurements, combined with an adiabatic fog conceptual model, this study documented key processes and conditions such as advection, turbulent mixing, radiative cooling, atmospheric stability, fog water content and depth, presence of clouds above. We analysed

the role of these processes and impacts of these conditions on fog formation, evolution and dissipation, focusing on four fog case studies: two radiation and two advection-radiation fogs. For each case study, we defined the different phases characterizing the fog life cycle, namely (i) its formation, (ii) an initial phase where the fog develops under thermally stable conditions, (iii) a transition phase towards an adiabatic fog, (iv) an adiabatic phase during which the fog vertical profile is adiabatic, and (v) a dissipation phase where the fog base lifts.

The results showed that for both radiation fog cases, the conditions are marked by very cold atmospheric conditions associated with a continental easterly nocturnal low-level jet. For these cases, the stable fog phase develops under strong surface radiative cooling and weak turbulence, in a deep temperature inversion layer. The stable phase lasts as long as the wind speed and turbulence remain very low (typically 1 m s^{-1} and $0.1 \text{ m}^2 \text{ s}^{-2}$). The transition phase is driven by an increase of wind speed and turbulence in the fog layer, reaching 2 m s^{-1} and $0.2 \text{ m}^2 \text{ s}^{-2}$, respectively. This increased turbulence is of mechanical origin (increased wind shear associated with an evolution of the airmass) hence its time of occurrence varies widely from one case to the other (05 and 00 UTC, respectively). The adiabatic phase is characterized by sustained turbulence ($0.2 < \text{TKE} < 0.4 \text{ m}^2 \text{ s}^{-2}$) sufficient to ensure vertical mixing in the fog layer. The fog layer is then typically deeper than 100 m, and the LWP exceeds 20 g m^{-2} . For these fog events, dissipation time is observed after sunrise, when both thermal and dynamic production of the turbulence are high ($\text{TKE} > 0.4 \text{ m}^2 \text{ s}^{-1}$ and $\sigma_w^2 > 0.04 \text{ m}^2 \text{ s}^{-2}$). For both fog cases, we observe simultaneous increase of near-surface visibility and decrease of the fog LWP reservoir (RLWP) derived from the fog conceptual model, about one hour before dissipation time.

The analysis on the advection-radiation case studies shows that they have the shortest life cycle linked to the low surface boundary layer stability, because they occur under westerly air masses that evolved during the night (change in wind direction, increased wind shear). In this category of fog, the processes driving the stable, stable/adiabatic transition and adiabatic phases are similar to those of the radiation fog category. However, in one case, we observe a transition phase that occurs with a more subtle increase in turbulence than in the other three cases. As a result, the increase in LWP and CTH is very slow; it takes more than 3 hours to reach adiabatic conditions. Dissipation occurs before sunrise in both cases. In one case it is due to a sudden increase in wind speed and wind shear leading to TKE values exceeding $0.4 \text{ m}^2 \text{ s}^{-1}$. In the other case, we have a deep adiabatic fog ($\text{CTH} > 200 \text{ m}$) with sustained turbulence ($0.2 < \text{TKE} < 0.4 \text{ m}^2 \text{ s}^{-2}$) where the LWC production is barely sufficient to maintain the fog all the way down to the surface. The conceptual model shows negative RLWP values, while the visibility oscillates around 1 km. The full

581 dissipation of the fog is here associated with the presence of a cloud above the fog that further
582 reduces the LWC production.

583 In summary, this paper provides quantitative analyses of key parameters and conditions that
584 drive the fog life cycle. The level of turbulent mixing in the fog, of both thermal and mechanical
585 origin is key to understand important transitions (from stable to adiabatic, and from adiabatic to
586 dissipation). This level of turbulence should be analysed considering the depth of the fog and its
587 liquid water path. Our study confirms that the RLWP, combined with visibility is an interesting
588 parameter to study the state of the fog, even though LWP and RLWP measured during SOFOG3D
589 present lower values than at the SIRTAs site, close to the uncertainty of the measurement. Fog
590 formation, evolution and dissipation across southern France require an analysis of the synoptic
591 atmospheric circulation in terms of wind, cloud cover, and thermodynamical processes. Indeed, this
592 paper highlights that fog nowcasting tools in this region needs in addition to the numerical weather
593 prediction models, a cloud radar, a microwave radiometer, a wind lidar, a surface energy balance,
594 and meteorological stations. Operationalizing these instruments would allow to improve fog
595 nowcasting, which will reduce its socio-economic impacts in this region.

596 **Appendix A: Fog conceptual model parametrization**

597 **A.1 Liquid water content**

598 The conceptual model for adiabatic fog has been developed at SIRTAs by Toledo et al.,
599 2021. This model is a unidimensional model inspired by previous numerical models for stratus
600 clouds (Betts, 1982, Albrecht et al., 1990; and Cermak and Bendix, 2011) (see equation 1). The
601 basic hypothesis is to consider a well-mixed fog layer and express the increase with height of the
602 fog liquid water content as a function of the local adiabaticity ($\alpha(z)$) and the negative of the change
603 in the saturation mixing ratio with height ($\Gamma_{ad}(T,P)$), given in equation A1.

$$604 \quad \frac{dLWC(z)}{dz} = \alpha(z) \Gamma_{ad}(T, P) \quad (A1)$$

605 Where T and P are air temperature and pressure, respectively. z is the height above the
606 surface and varies between 0 and the cloud top height (CTH). By integrating equation 1, it is
607 important to take into account fog geometry which is different from that of the stratus cloud. For a
608 fog, the LWC at the base is non-zero due to the presence of liquid droplets down to the ground
609 level. This presence of droplets drives surface visibility reduction and water deposition on the soil.
610 Thus, as indicated in equation A2, the vertical integral of the $LWC(z)$ is a function of the variation
611 with height of the adiabaticity, $\Gamma_{ad}(T,P)$ and the measurement of the LWC at surface (LWC_0). This
612 equation shows that the LWC increases with the thickness of the fog up to the height where upward

613 motions of moisture from the surface are constrained by downward motions of dry air from the fog
614 top height (Walker, 2003; Cermak and Bendix, 2011). From this interface level, the LWC decreases
615 with height and becomes zero at the fog top height (Brown and Roach, 1976; Cermak and Bendix,
616 2011).

$$617 \quad LWC(z) = \int_{z'=0}^{z'=z} \alpha(z') \Gamma_{ad}(T, P) dz' + LWC_0 \quad (A2)$$

618 **A.2 Liquid water path**

619 The fog liquid water path (LWP) represents the total amount of liquid water present in the
620 fog layer. It can be estimated by integrating equation A2 in height considering that the fog thickness
621 is equivalent to the CTH (equation A3). An approximation assuming a constant adiabaticity is
622 introduced by using the equivalent fog adiabaticity term α_{eq} . This simplifies the calculation, since a
623 complete computation would require a knowledge of the vertical profile of adiabaticity which
624 depends on the thermodynamic properties of the fog layer. In this conceptual model, the LWC is
625 treated as if it increased linearly with height from the surface to the CTH. At the surface level the
626 LWC from the model and fog are the same, connecting a given LWP with surface LWC. This
627 quantity is converted to visibility values using Gultepe et al., 2006 parametrization. Hence, the
628 conceptual model connects fog LWP with its CTH and surface visibility values, it provides an
629 estimation of the equivalent fog adiabaticity.

$$630 \quad LWP = \frac{1}{2} \alpha_{eq} \Gamma_{ad}(T, P) CTH^2 + LWC_0 CTH \quad (A3)$$

631 **Data availability.** All the data used in this study are hosted by the the French national center for
632 Atmospheric data and services AERIS in the link <https://sofog3d.aeris-data.fr/catalogue/#masthead>.
633 Data access can be free following the conditions fixed by the SOFOG3D project.

634 **Competing interests.** The authors claim no conflict of interest for this study.

828 **List of tables**

829 **Table 1 :** Case study number, fog onsets, type of fog formation, fog dissipation times, fog duration
830 and type of fog dissipation for the four documented case studies. Time is in UTC. Dates are in the
831 format “dd/mm/yyyy”. “dd” indicates the day, “mm” the month, and “yyyy” the year.

832 **Table 2 :** Summary of fog features at the supersite during the five defined phases during its
833 evolution for each case study. The formation, dissipation times are estimated using the visibility (m)
834 from the Scatterometer. The transition from stable to adiabatic fog is defined using temperature
835 from the microwave radiometer. The cooling rate (dT/dt), wind speed (WS), and wind direction
836 (WD) are derived from the meteorological station. Sensible heat flux (SHF), turbulent kinetic
837 energy (TKE) and the vertical velocity variance (σ_w^2) at 3 m a.g.l are derived from the flux station.
838 The liquid water path (LWP) is estimated from the MWR. The fog reservoir of liquid weather path
839 (RLWP) and the equivalent adiabaticity of closure $\alpha_{eq}^{closure}$ parameter are computed by the
840 conceptual model. Cloud top height (CTH) and middle and high cloud base and top heights are
841 derived from the radar reflectivity from Basta cloud radar.”-” indicates that the variables are not
842 measurable or calculable.

843 List of figures

844 **Figure 1:** In a), the geographical map of the study area of the SOFOG3D field campaign including
845 the five instrumented sites (Agen, Bergerac, Biscarrosse, Mont-de-Marsan, and Saint-Symphorien)
846 where a microwave radiometer was installed (adapted from
847 [https://fr.wikipedia.org/wiki/Grand_Sud-Ouest_fran%C3%A7ais#/media/
848 Fichier:Topographic map of South-West France with main rivers and cities.svg](https://fr.wikipedia.org/wiki/Grand_Sud-Ouest_fran%C3%A7ais#/media/Fichier:Topographic_map_of_South-West_France_with_main_rivers_and_cities.svg)). Blue lines
849 indicate the rivers. The cities are indicated in black dots. The most instrumented domain around the
850 supersite is indicated in a) by the red rectangle. In b), the orography of a 100 x 100 km² domain
851 centered on Charbonnière which includes locations of four of the meteorological stations installed
852 around the supersite used in this study. Orography data are from the National Aeronautics and
853 Spatial Administration (NASA) shuttle radar topography mission (SRTM) (90 m of resolution).

854 **Figure 2:** (a) Scatter plot of the equivalent adiabaticity by closure versus the CTH and LWP at the
855 supersite. b) Boxplot of the equivalent adiabaticity by closure versus the different LWP ranges from
856 the MWR. In b), numbers at the figure top indicate total values included in each boxplot and
857 computed between 2 hours before and after the fog. Horizontal dashed line indicates the threshold
858 of the equivalent adiabaticity from closure defining the transition from stable to adiabatic fog.

859 **Figure 3:** In (a-b) time-height cross-section from surface up to 600 and 12000 m, respectively of
860 radar reflectivity from Basta (shaded) radar, time evolution of the cloud top height from Basta (red
861 line), and the cloud base height from the Celiometer (CL51) (green line). Time evolution of (c)
862 surface visibility, (d) 10 m wind speed, (e) 2 m air temperature, and (f) 10 m wind direction
863 observed on the 28-29 December 2019 (case study 1, IOP 5) at the five meteorological stations (in
864 red, black, blue, green, and pink lines for Moustey (1 m a.g.l), Charbonnière (3 m a.g.l), Cape Sud
865 (3 m a.g.l), Tuzan (3 m a.g.l), and Noaillan (1 m a.g.l), respectively) deployed around the supersite.
866 Note that wind was not collected at Tuzan. In (c), the visibility measured at Moustey was
867 interrupted by technical issues. Vertical black dashed lines indicate fog formation (left) and
868 dissipation (right) times. Green dashed lines show the transition time from stable fog to adiabatic
869 fog (fog mature phase). Red dashed line indicates the sunrise.

870 **Figure 4:** Evolution of fog macrophysical characteristics observed on the 28-29 December 2019
871 (case study 1, IOP 5) at Charbonnière. In (a-b) vertical profiles of air temperature from the Hatpro
872 microwave radiometer (MWR) and radar reflectivity from Basta radar, respectively. In (c) time-
873 height cross-section of air temperature from the MWR (shaded), time evolution of inversion top

874 height (ITH) (open gray circles), inversion base height (IBH) (open gray squares), cloud top height
875 (CTH) from the cloud radar (open black squares), and the cloud base height (CBH) from the
876 Celiometer (open black circles). In (d) wind speed (shaded) and direction (arrows) from the
877 WindCube. Arrows in (d) indicate only the direction of the horizontal flow. Time evolution of (e)
878 air temperature at 3 m a.g.l from the meteorological station (red line) and equivalent adiabaticity of
879 closure from the fog conceptual model (blue line), (f) the mean of the turbulent kinetic energy
880 (TKE) in the layer 40 – 220 m for the WindCube (black line) and the TKE (blue line) and vertical
881 velocity variance (red line) at 3 m a.g.l from the flux station at Charbonnière, (g) the LWP estimate
882 from the MWR (blue line), the RLWP from the fog conceptual model (red line), and (h) sensible
883 heat fluxes (SHF) (red and blue lines, respectively) from the flux station. Vertical black dashed lines
884 indicate fog formation and dissipation times. Green dashed lines indicate the transition period (fog
885 mature phase) from stable to adiabatic fog. The red dashed line indicates sunrise.

886 **Figure 5:** As in Figure 3 but for the 5-6 January 2020 (case study 2, IOP 6). In (c), only
887 Charbonnière and Noaillan have valid data. In (c), the visibility measured at Moustey, Tuzan and
888 Cape Sud were interrupted by technical issues.

889 **Figure 6:** As in Figure 4 but for the 5-6 January 2020 (case study 2, IOP6).

890 **Figure 7:** As in Figure 3 but for the 8-9 February 2020 (case study 3, IOP 11).

891 **Figure 8:** As in Figure 4 but for the 8-9 February 2020 (case study 3, IOP 11).

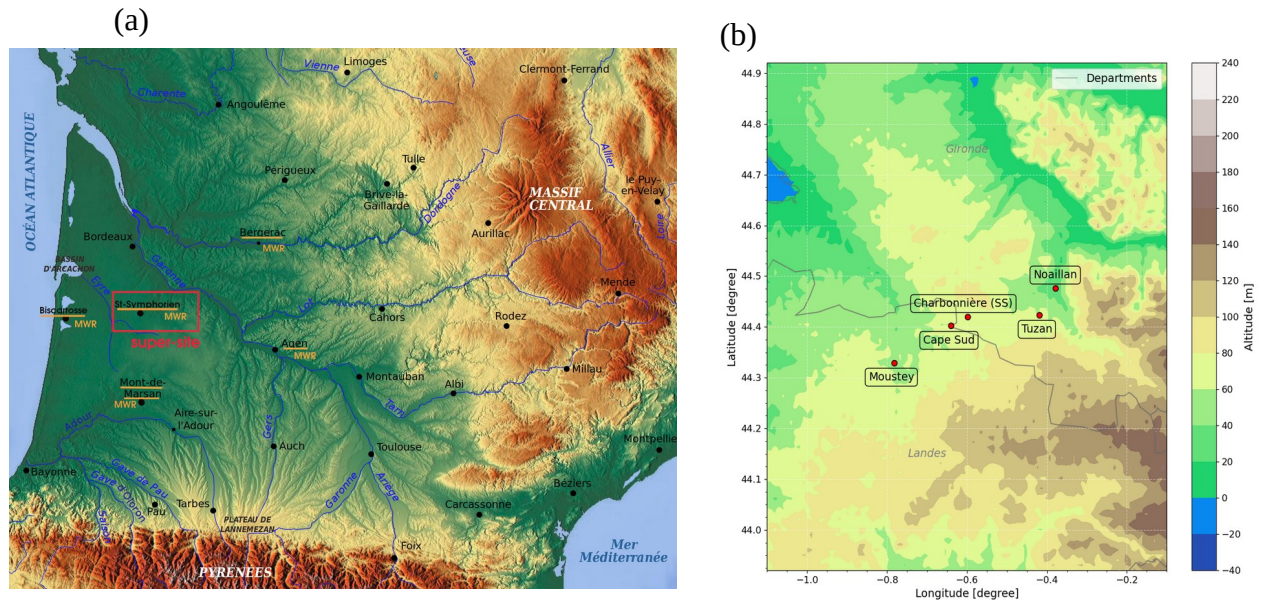

892 **Figure 9:** As in Figure 3 but for the 7-8 March 2020 (case study 4, IOP 14).

893 **Figure 10:** As in Figure 4 but for the 7-8 March 2020 (case study 4, IOP 14). The LWP, RLWP,
894 and $\alpha_{eq}^{closure}$ are disrupted between 00:30 and 02:30 UTC because the LWP estimated by the MWR
895 take into account the liquid water in the advected stratus.

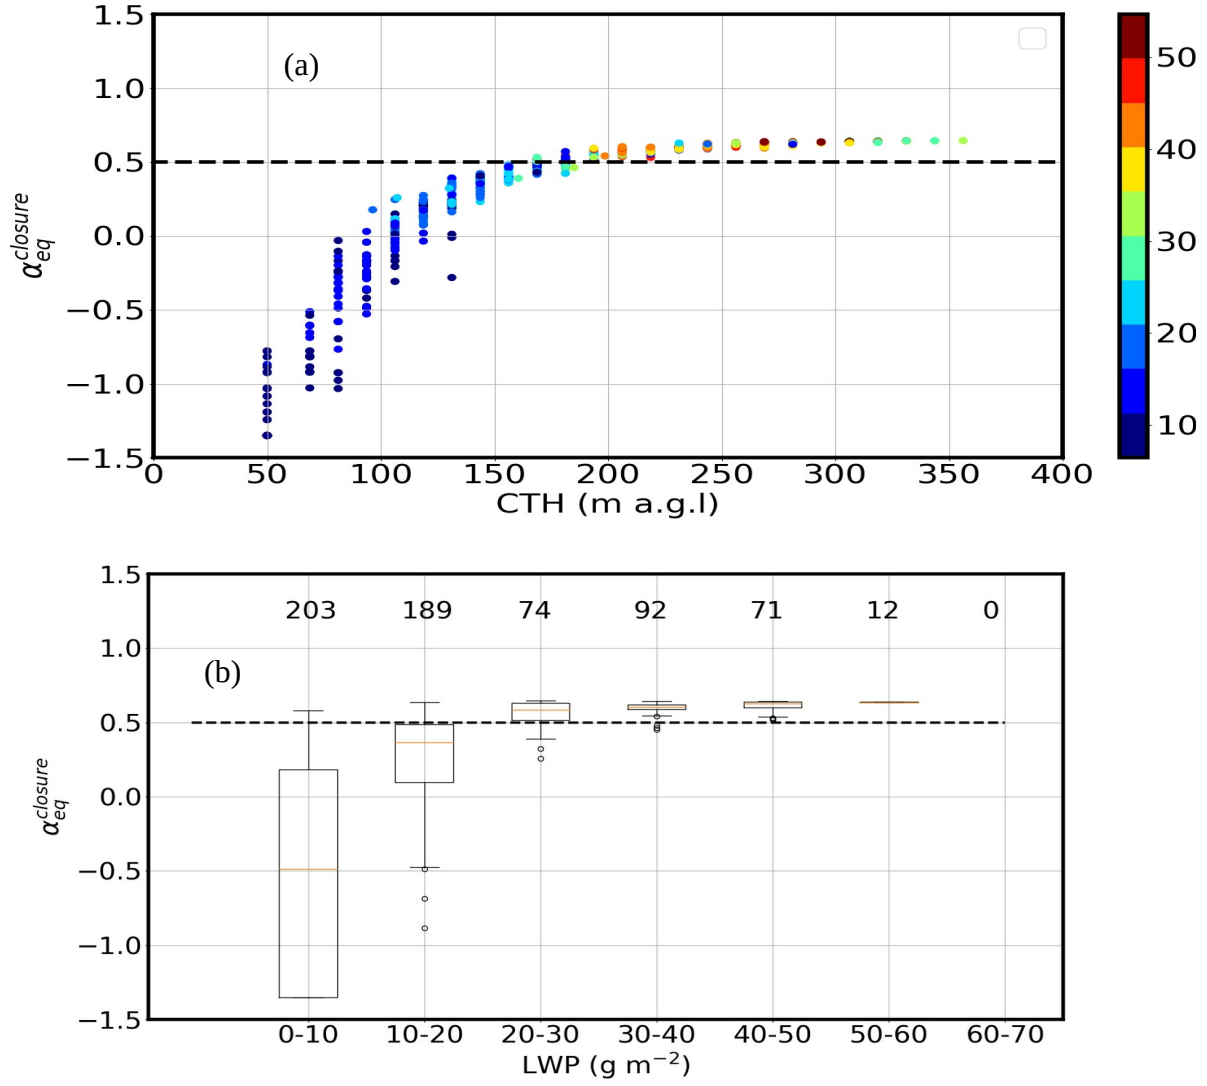

896 **Figure 11:** Vertical profiles of air temperature and radar reflectivity put together for each fog case
897 study: (a) for case study 1, (b) case study 2, (c) case study 3 and (d) case study 4. Line and shaded
898 area indicate the mean and standard deviation of air temperature and radar reflectivity during each
899 fog phase.

Table 2 : Summary of fog features at the supersite, during the five defined phases during its evolution for each case study. The formation, dissipation times are estimated using the visibility (m) from Scatterometer. The cooling rate (dT/dt), wind speed (WS) and wind direction (WD) are derived from the meteorological station. Sensible heat flux (SHF), turbulent kinetic energy (TKE), and the vertical velocity variance (σ_w^2) at 3 m a.g.l are derived from the flux station. The liquid water path (LWP) is estimated from the MWR. The fog reservoir of liquid weather path (RLWP) and the equivalent adiabaticity of closure $\alpha_{eq}^{closure}$ parameter are computed by the conceptual model. Cloud top height (CTH) and middle and high cloud base and top heights are derived from the radar reflectivity from Basta cloud radar. "-" indicates that the variables are not measurable or calculable.

908 **Figure 1 :** In a), the orography of the study area of the SOFOG3D field campaign including the five
 909 instrumented sites (Agen, Bergerac, Biscarrosse, Mont-de-Marsan, and Saint-Symphorien) where a
 910 microwave radiometer was installed (adapted from [https://fr.wikipedia.org/wiki/Grand Sud-](https://fr.wikipedia.org/wiki/Grand_Sud-Ouest_fran%C3%A7ais#/media/Fichier:Topographic_map_of_South-West_France_with_main_rivers_and_cities.svg)
 911 [Ouest_fran%C3%A7ais#/media/Fichier:Topographic_map_of_South-](https://fr.wikipedia.org/wiki/Grand_Sud-Ouest_fran%C3%A7ais#/media/Fichier:Topographic_map_of_South-West_France_with_main_rivers_and_cities.svg)
 912 [West_France_with_main_rivers_and_cities.svg](https://fr.wikipedia.org/wiki/Grand_Sud-Ouest_fran%C3%A7ais#/media/Fichier:Topographic_map_of_South-West_France_with_main_rivers_and_cities.svg)). Blue lines indicate the rivers. The cities are
 913 indicated in black dots. The most instrumented domain around the supersite is indicated in a) by the
 914 red rectangle. In b), the orography of a 100 x 100 km² domain centered on Charbonnière which
 915 includes locations of four of the meteorological stations installed around the supersite and used in
 916 this study. Orography data are from the National Aeronautics and Spatial Administration (NASA)
 917 shuttle radar topography mission (SRTM) (90 m of resolution).

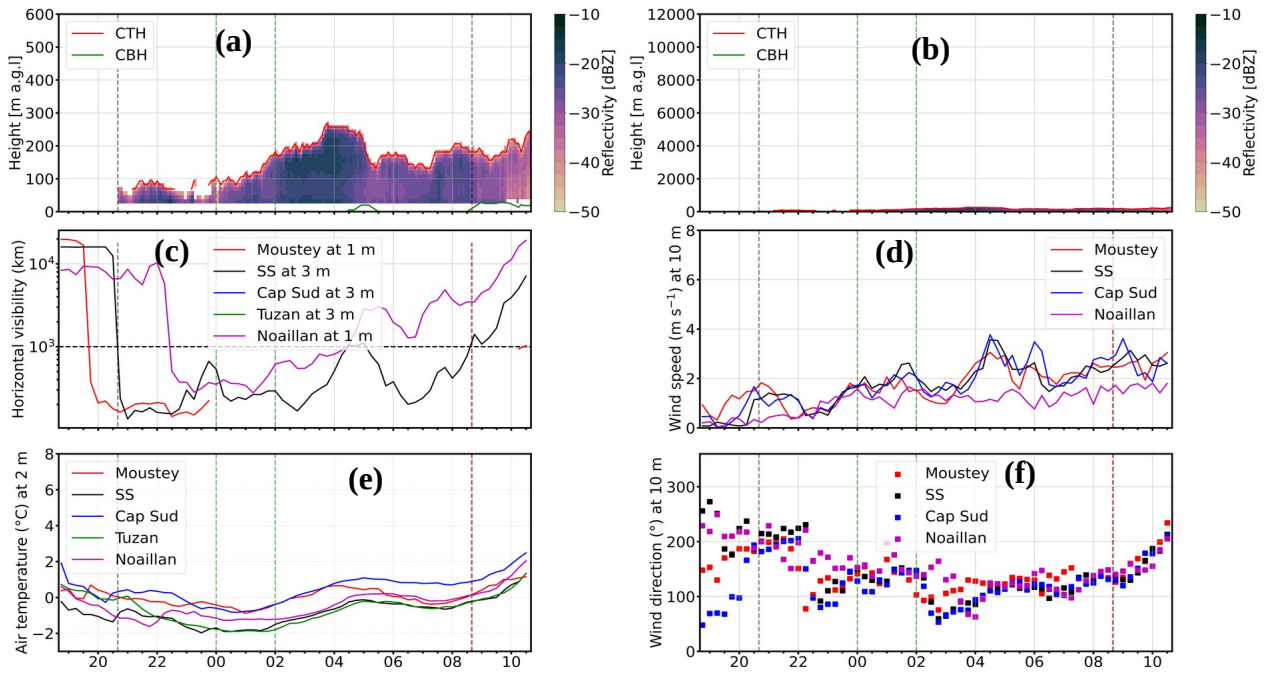

918 **Figure 2:** In (a) Scatter plot of the equivalent adiabaticity by closure versus the CTH and LWP
 919 (colored circles) at the supersite. b) Boxplot of the equivalent adiabaticity by closure versus the
 920 different LWP ranges from the MWR. In b), numbers at the figure top indicate total values included
 921 in each boxplot and computed between 2 hours before and after the fog. Horizontal dashed line
 922 indicates the threshold of the equivalent adiabaticity from closure defining the transition from stable
 923 to adiabatic fog.

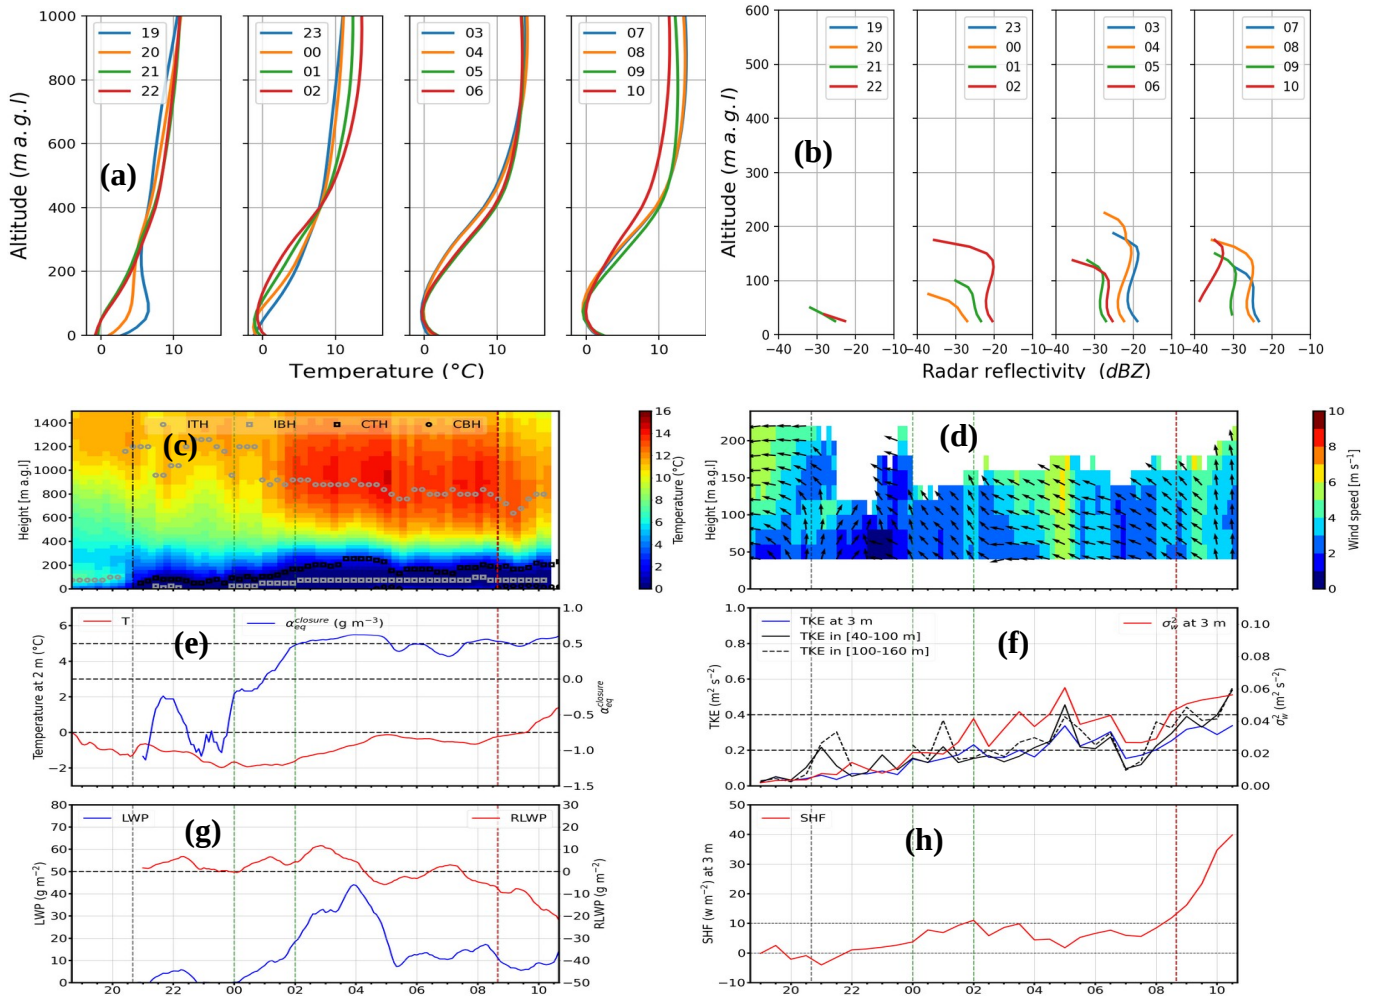

924 **Figure 3:** In (a-b) time-height cross-section from surface up to 600 and 12000 m, respectively of radar
 925 reflectivity from Basta (shaded) radar, time evolution of the cloud top height from Basta (red line),
 926 and the cloud base height from the Celiometer (CL51) (green line). Time evolution of (c) surface
 927 visibility, (d) 10 m wind speed, (e) 2 m air temperature, and (f) 10 m wind direction observed on the
 928 28-29 December 2019 (case study 1, IOP 5) at the five meteorological stations (in red, black, blue,
 929 green, and pink lines for Moustey (1 m a.g.l), Charbonnière (3 m a.g.l), Cape Sud (3 m a.g.l), Tuzan
 930 (3 m a.g.l), and Noaillan (1 m a.g.l), respectively) deployed around the supersite. Note that wind was
 931 not collected at Tuzan. In (c), the visibility measured at Moustey was interrupted by technical issues.
 932 Vertical black dashed lines indicate fog formation (left) and dissipation (right) times. Green dashed
 933 lines show the transition time from stable fog to adiabatic fog (fog mature phase). Red dashed line
 934 indicates the sunrise.

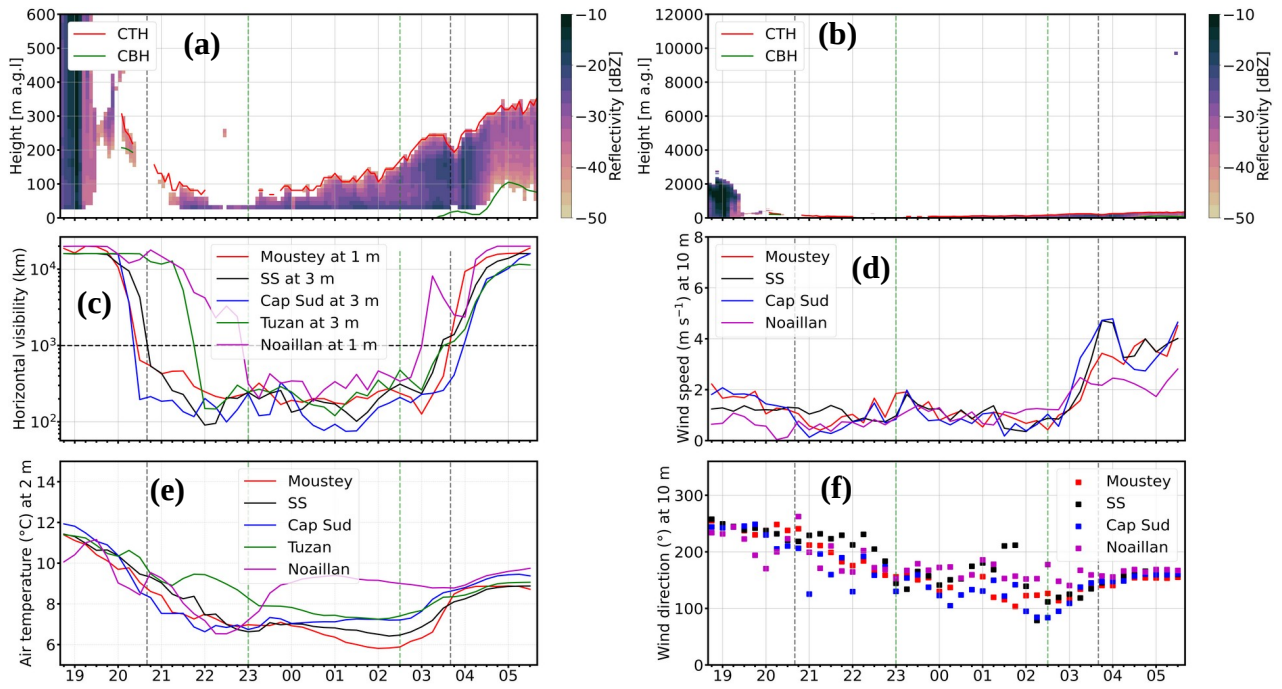

935 **Figure 4:** Evolution of fog macrophysical characteristics observed on the 28-29 December 2019 (case study
 936 1, IOP 5) at Charbonnière. In (a-b) vertical profiles of air temperature from the Hatpro microwave radiometer
 937 (MWR) and radar reflectivity from Basta radar, respectively. In (c) time-height cross-section of air
 938 temperature from the MWR (shaded), time evolution of inversion top height (ITH) (open gray squares),
 939 inversion base height (IBH) (open gray squares), cloud top height (CTH) from the cloud radar (open black
 940 squares), and the cloud base height (CBH) from the Celiometer (open black circles). In (d) wind speed
 941 (shaded) and direction (arrows) from the WindCube. Arrows in (d) indicate only the direction of the
 942 horizontal flow. Time evolution of (e) air temperature at 3 m a.g.l from the meteorological station (red line)
 943 and equivalent adiabaticity of closure from the fog conceptual model (blue line), (f) the mean of the turbulent
 944 kinetic energy (TKE) in the layer 40 – 220 m for the WindCube (black line) and the TKE (blue line) and
 945 vertical velocity variance (red line) at 3 m a.g.l from the flux station at Charbonnière, (g) the LWP estimate
 946 from the MWR (blue line), the RLWP from the fog conceptual model (red line), and (h) sensible heat fluxes
 947 (SHF) (red and blue lines, respectively) from the flux station. Vertical black dashed lines indicate fog
 948 formation and dissipation times. Green dashed lines indicate the transition period (fog mature phase) from
 949 stable to adiabatic fog. The red dashed line indicates sunrise.

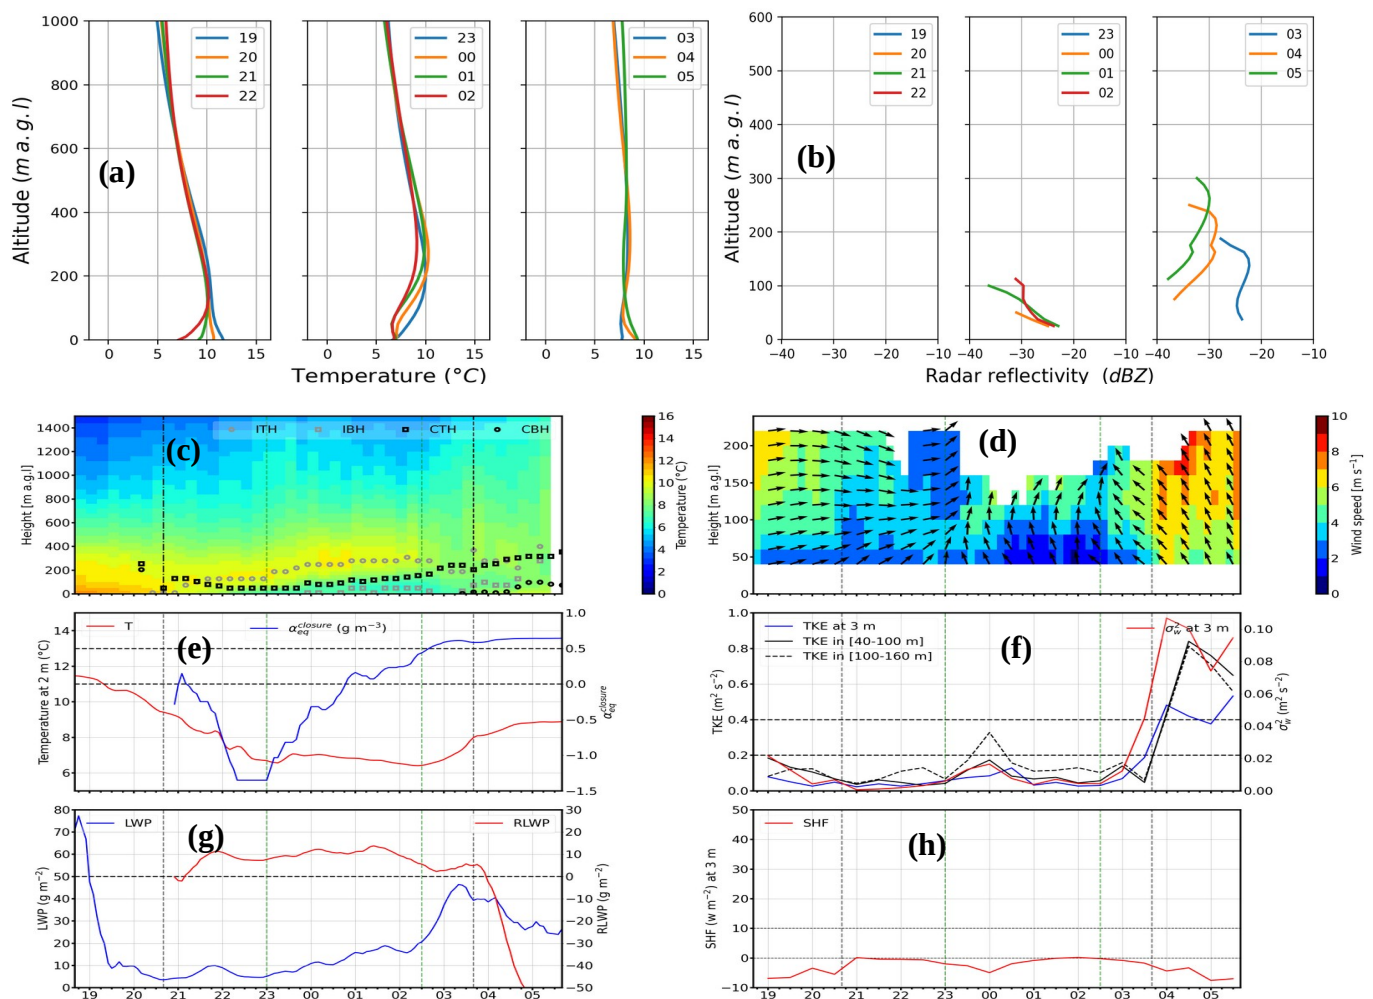

950 **Figure 5:** As in Figure 3 but for the 5-6 January 2020 (case study 2, IOP 6). In (c), only Charbonnière
 951 and Noaillan have valid data. In (c), the visibility measured at Moustey, Tuzan and Cape Sud were
 952 interrupted by technical issues.

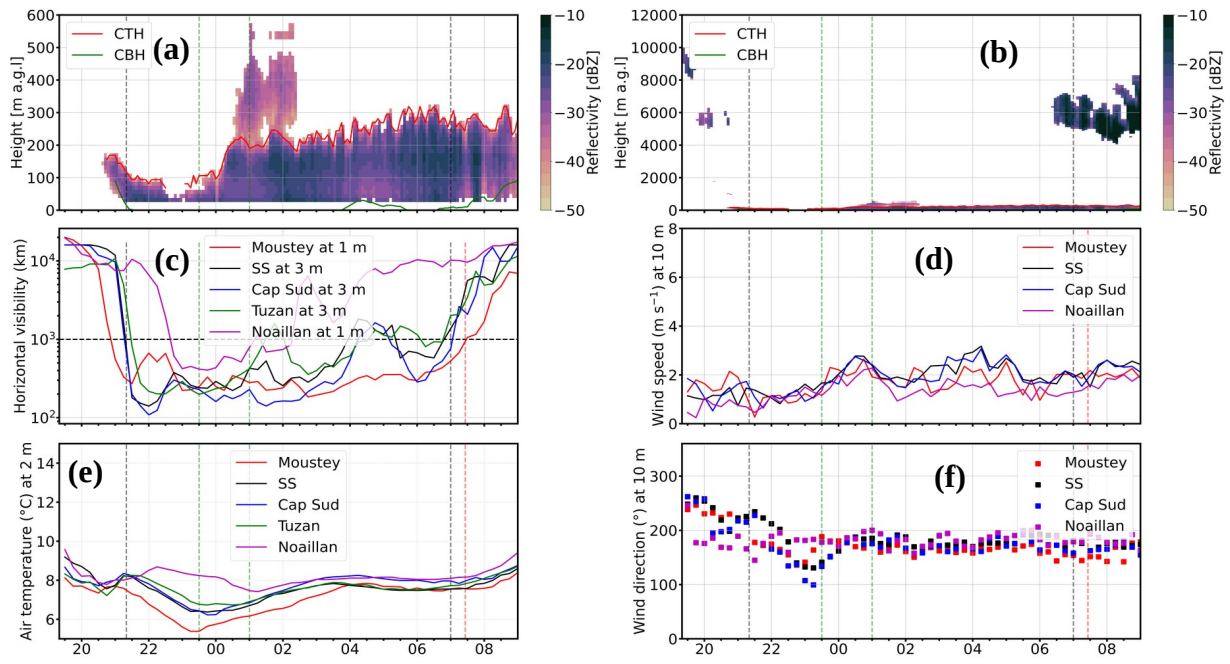

953 **Figure 6:** As in Figure 4 but for the 5-6 January 2020 (case study 2, IOP6). The red vertical dashed
 954 line indicates the sunrise.

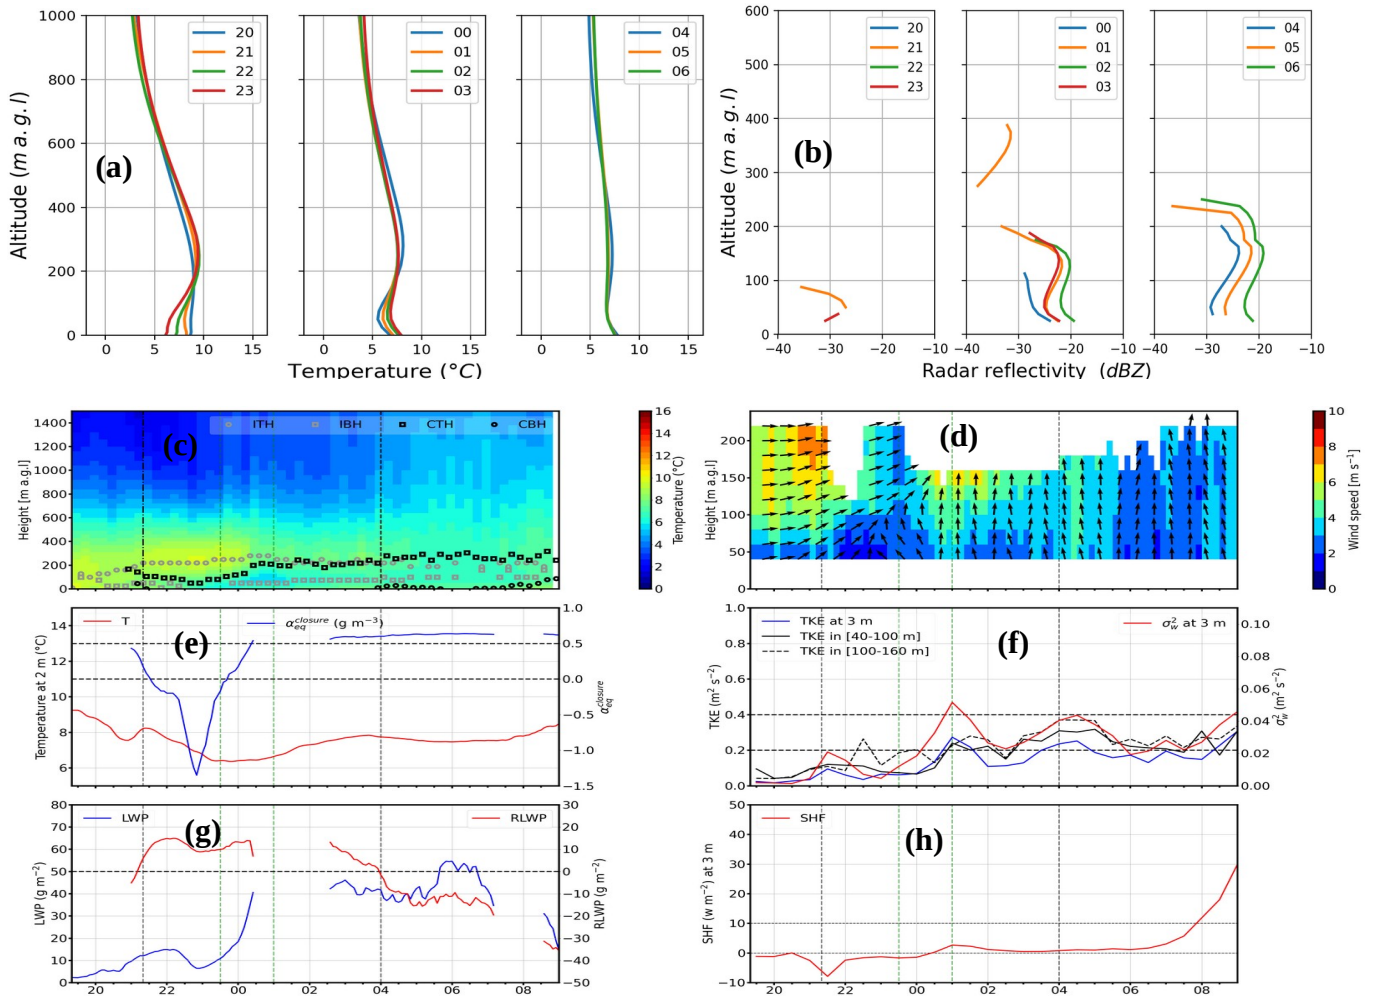

955 **Figure 7 :** As in Figure 3 but for the 8-9 February 2020 (case study 3, IOP 11)

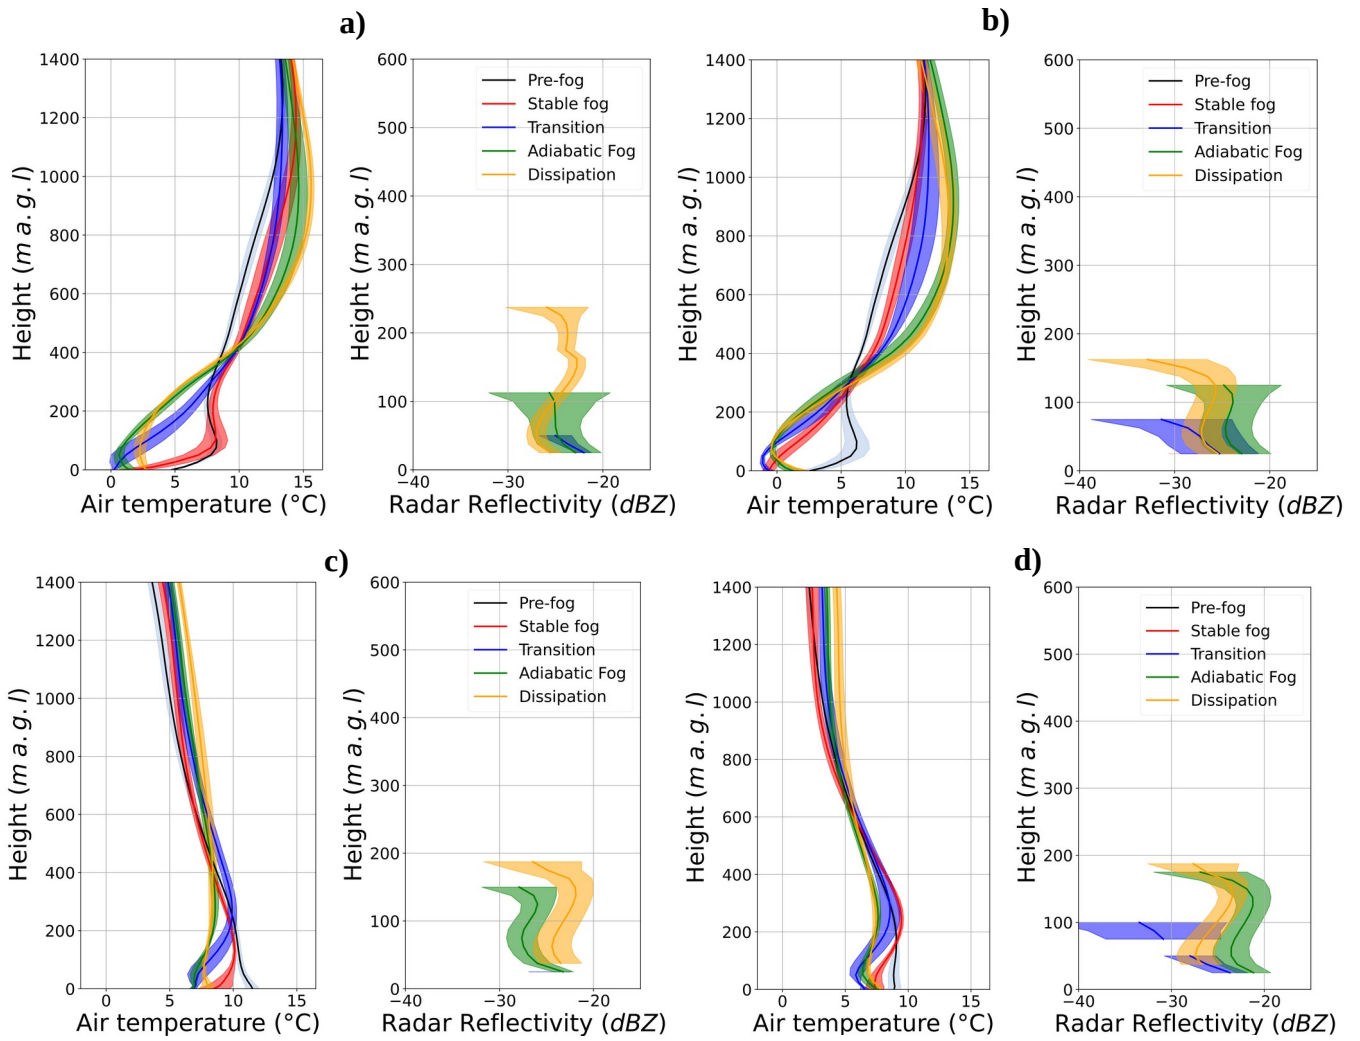

956 **Figure 8:** As in Figure 4 but for the 8-9 February 2020 (case study 3, IOP 11).

957 **Figure 9 :** As in Figure 3 but for the 7-8 March 2020 (case study 4, IOP 14).

958 **Figure 10 :** As in Figure 4 but for the 7-8 March 2020 (case study 4, IOP 14). The LWP, RLWP, and
 959 $\alpha_{eq}^{closure}$ are disrupted between 00:30 and 02:30 UTC because the LWP estimated by the MWR take
 960 into account the liquid water in the advected stratus.

961 **Figure 11:** Vertical profiles of air temperature and radar reflectivity put together for each fog case study (a) for case 1,
 962 (b) case 2, (c) case 3 and (d) case 4. Line and shaded area indicate the mean and standard deviation of air temperature
 963 and radar reflectivity during each fog phase.
