Abstract:

To develop the effective strategies for controlling both PM_{2.5} and O₃ levels, it is crucial to understand their synergistic mechanisms, key precursors, and atmospheric physiochemical processes involved. In this study, a wintertime co-occurring O₃ and PM_{2.5} pollution event in a coastal city in southeast China was investigated based on high-time resolution measurements of criteria air pollutants, chemical compositions of PM_{2.5}, and O₃ precursors, such as NO_x, HCHO, and VOCs. The results of this study revealed ~~the characteristics of a positively correlation correlated between~~ PM_{2.5} and MDA8 O₃ concentrations ~~during the whole periods, suggesting and~~ an increase in atmospheric oxidation capacity (AOC) during the cold seasons. Strong correlations ($R^2 = 0.415\text{--}0.477$) ~~were observed~~ between HCHO, Fe, Mn, and sulfate concentrations ~~were observed~~, suggesting the influence of catalyzed oxidation processes in the coastal city. Through an observation-based model (OBM) analysis coupled with the regional atmospheric chemistry mechanism version 2 (RACM2) and the chemical aqueous-phase radical mechanism version 3.0 (CAPRAM 3.0), we found that high concentrations of precursors (SO₂ and HCHO), high relative humidity, and moderately acidic pH conditions enhanced the heterogeneous formation of hydroxymethanesulfonate (HMS) in PM_{2.5}. Furthermore, by employing the Master Chemical Mechanism (OBM-MCM), we verified that disabling the HCHO mechanism could decrease daytime net O₃ production rates by reducing the production rates of

55

56 Introduction

57 Air pollution, dominated by fine particulate matter (PM_{2.5}) and ground-level ozone
58 (O₃), is an important global environmental issue linked to climate change and human
59 health, including cardiovascular and respiratory illnesses and mortality (Xiao et al.,
60 2022; Vohra et al., 2022). To decrease global air pollution and associated mortality, the
61 World Health Organization recently updated its air quality guideline for annual PM_{2.5}
62 exposure from 10 to 5 μg m⁻³ and added the average O₃ concentrations of no more than
63 60 μg m⁻³ during the peak season (WHO, 2021). To develop two-pollutant control
64 strategies to decrease both PM_{2.5} and O₃, there is a need to understand the synergistic
65 mechanisms and spatiotemporal delineation between them (Ivatt et al., 2022; Li et al.,
66 2019b).

67 There are complex synergistic effects between PM_{2.5} and O₃, due to common
68 precursors (e.g., NO_x and VOCs), atmospheric physiochemical processes, and weather
69 systems (Li et al., 2019a; Shao et al., 2022; Jia et al., 2023; Zhang et al., 2022; Qin et
70 al., 2021; Qu et al., 2023). ~~Some studies have reported that O₃ could enhance the~~

带格式的: 字体颜色: 红色

71 ~~formation of secondary PM_{2.5} by strengthening atmospheric oxidation capacity (Qin et~~
72 ~~al., 2022; Zhao et al., 2020).~~ An increase in O₃ concentration will increase oxidizing
73 substances, such as OH, H₂O₂, and RCHO, which promote the oxidation of SO₂, NO_x,
74 and VOCs to secondary inorganic and organic components in PM_{2.5} (Feng et al., 2020;
75 Lu et al., 2019). On the contrary, ~~PM_{2.5} could affect O₃ formation by interfering with~~
76 ~~the radiation intensity of the Earth, providing a multiphase reaction surface and~~
77 ~~affecting the radiation flux and intensity of the boundary layer (Shao et al., 2021; Li et~~
78 ~~al., 2017).~~ In addition, multiphase reactions occur on the surface of atmospheric
79 particles, such as the ~~hydrolysis uptake~~ of ~~N₂O₅-HCHO~~ and HO₂ absorption, thus
80 affecting the formation of O₃ ~~precursors NO₂~~ (Song et al., 2022; Lou et al., 2014).

81 Formaldehyde (HCHO) plays an important role in the photochemical reaction
82 process and secondary aerosol formation (Kalashnikov et al., 2022; Ma et al., 2020;
83 Song et al., 2021; Zong et al., 2021). Most studies have focused on pollution
84 characteristics and sources, particle uptake of HCHO, and their impacts on atmospheric
85 oxidation capacity (Liu et al., 2022b; Wu et al., 2023; Zhang et al., 2021). Recent
86 studies have shown that HCHO can react with hydrogen peroxide (H₂O₂) to produce
87 hydroxymethyl hydroperoxide (HMHP), which rapidly oxidizes dissolved sulfur
88 dioxide (SO₂, aq) to sulfate (Dovrou et al., 2022). Meanwhile, HCHO reacts with
89 dissolved SO₂ (aq) to produce hydroxymethanesulfonate (HMS, HOCH₂SO⁻), which,
90 upon oxidation with the hydroxyl radical (OH), forms sulfate (Ma et al., 2020; Moch et
91 al., 2018, 2020). ~~Totally, Recent studies have reported that~~ atmospheric HCHO
92 contributes to sulfate formation in PM_{2.5} by producing HO₂ radicals and ~~hydroxymethyl~~

带格式的: 字体颜色: 自动设置

93 ~~hydroperoxide (HMHP) or hydroxymethanesulfonate (HMS)~~ (Wu et al., 2023;
94 ~~Dovrou et al., 2022; Campbell et al., 2022).~~ ~~However, T~~these studies highlight the
95 necessity for more observation research to obtain evidence of the contributions of
96 HCHO to HMS formation. ~~HMS is an important organosulfur compound in the~~
97 ~~atmosphere, not only in cloud and fog but also in atmospheric aerosols (Munger et al.,~~
98 ~~1986; Dixon and Aasen, 1999).~~ ~~The misidentification of HMS as inorganic sulfate~~
99 ~~caused the overestimation of the observed particulate sulfate (Ma et al., 2020; Dovrou~~
100 ~~et al., 2022).~~ However, in subtropical coastal regions with apparent HCHO production,
101 further studies are required to investigate the impacts of HCHO on the ~~the formations~~
102 ~~of HMS and ROx radicals synergistic effects between PM_{2.5} and O₃.~~

103 Xiamen, a coastal city in southeast China, has frequently experienced PM_{2.5}
104 pollution (with low O₃ concentrations) in winter and O₃ pollution in spring and autumn
105 (Hong et al., 2022; Wu et al., 2019). Our previous studies mainly focused on the
106 pollution characteristics of PM_{2.5} or O₃ in different seasons and their sources associated
107 with anthropogenic emissions and the East Asian monsoon (Liu et al., 2020; Liu et al.,
108 2022a; Hong et al., 2021). At the end of winter and the beginning of spring in 2022, an
109 outbreak of co-occurring O₃ and PM_{2.5} pollution was observed in Xiamen. Therefore,
110 it provided a unique opportunity to study the ~~impacts of HCHO on the formations of~~
111 ~~HMS and ROx radicals interactions among precursors, heterogeneous chemistry, and~~
112 ~~photochemical reactions for the synergistic effects of PM_{2.5} and O₃.~~ In the coastal region,
113 there is an apparent alternation of polluted and clean air masses from continental and
114 ocean areas and a local geographical environment, including relatively high humidity,

115 dense vegetation, and strong atmospheric oxidation capacity (Hu et al., 2022; Wu et al.,
116 2020). Potential ~~synergistic mechanisms~~ roles and mechanisms of HCHO in the
117 photochemical reaction process and HMS formation between O₃ and PM_{2.5} would differ
118 from those in megacities of China, such as the Beijing-Tianjin-Hebei (BTH) Area, the
119 Yangtze River Delta (YRD), and the Pearl River Delta (PRD). Based on the
120 observation-based model (OBM) analysis, the objectives of this study are to (1)
121 characterize the wintertime co-occurring O₃ and PM_{2.5} pollution process in a coastal
122 city; (2) elaborate the influence of HCHO on the heterogeneous formation of
123 ~~hydroxymethanesulfonate (HMS)~~ in PM_{2.5}; (3) explore the mechanisms of HCHO on
124 O₃ pollution and photochemical reactions process.

125

126 **2 Methods and materials**

127 **2.1 Study area**

128 The monitoring site (Institute of Urban Environment, Chinese Academy of
129 Sciences, 118.06° E, 24.61° N) is located in Xiamen, a coastal city in southeast China
130 (Fig. S1). It is situated in a subtropical monsoon climate, with an ~~annual~~ average
131 temperature of ~~23.3~~ 18.5°C and a relative humidity of ~~77.6~~ 63.3% during the wintertime
132 observation. In autumn and winter, cold and dry air masses move northward from inland,
133 while in late spring and summer, the prevailing air masses are southerly, characterized
134 by warm air temperatures and high humidity. The air-monitoring supersite is located on
135 the rooftop of a building, surrounded by residential buildings, educational institutions,

136 a commercial zone, and freeways. The downtown area of Xiamen, with a high
137 population density and frequent traffic jams, is located south of the monitoring site.

138

139 **2.2 Observation**

140 Gas and aerosol species, O₃ precursors, photolysis rate, and meteorological
141 parameters were continuously measured online from February 17 to March 17, 2022.
142 Hourly mass concentrations of PM_{2.5} and PM₁₀ were measured using a tapered element
143 oscillating microbalance (TEOM1405, Thermo Scientific Corp., MA, USA). NO/NO₂,
144 SO₂, and O₃ were monitored using continuous gas analyzers (TEI 42i, 43i, and 49i,
145 Thermo Scientific Corp., MA, USA). HCHO analyzer (FMS-100, Focused Photonics
146 Inc., Hangzhou, China) was used to measure gaseous HCHO based on the Hantzsch
147 reaction, according to our previous method (Liu et al., 2022b). Water-soluble inorganic
148 ions (WSII) in PM_{2.5} (Cl⁻, SO₄²⁻, NO₃⁻, Na⁺, K⁺, NH₄⁺, Mg²⁺, and Ca²⁺) were measured
149 hourly using a Monitoring device for AeRosols and Gases in ambient Air (MARGA
150 2080; Metrohm Applikon B.V.; Delft, Netherlands). Simultaneously, organic carbon
151 (OC) and elemental carbon (EC) in PM_{2.5} were measured using an OC/EC analyzer
152 (model RT-4; Sunset Laboratory Inc.; Tigard, USA). BC was monitored using an
153 Aethalometer (AE31, Magee Scientific, USA) with a PM_{2.5} cut-off inlet. Besides,
154 concentrations of 22 elements (Al, Si, S, Fe, K, Mn, Pb, Ca, Zn, Ba, V, Cu, Ni, As, Cr,
155 Ag, Se, Br, Hg, Sn, Ti, and Sb) were measured using a multi-metal monitor (Xact™
156 625, Cooper Environmental Services, LLT; Portland, USA). Strict quality assurance
157 and quality control procedures were applied, and the maintenance and accuracy of all

158 online instruments were validated (Hong et al., 2021). The detection limits, time
159 resolutions and measured uncertainties of air pollutants were shown in TableS3.

160 A gas chromatograph-mass spectrometer (GC-FID/MS, TH-300B, Wuhan, China)
161 was used to measure ambient VOCs with one-hour time resolution, following the
162 method from our previous studies (Liu et al., 2020a,b). Briefly, the air sample was
163 preconcentrated by cooling to $-160\text{ }^{\circ}\text{C}$ in a cryogenic trap, then heated to $100\text{ }^{\circ}\text{C}$, and
164 subsequently transferred to the secondary trap using high-purity helium (He). The low-
165 carbon (C2-C5) hydrocarbons were detected using a flame ionization detector (FID)
166 with a PLOT ($\text{Al}_2\text{O}_3/\text{KCl}$) column ($15\text{ m} \times 0.32\text{ mm} \times 6.0\text{ }\mu\text{m}$), while other VOC
167 species were quantified using a GC/MS with a DB-624 column ($60\text{ m} \times 0.25\text{ mm} \times 1.4$
168 μm). The instrument can quantify 106 VOC species, including 29 alkanes, 11 alkenes,
169 one alkyne, 17 aromatics, 35 halogenated hydrocarbons, and 13 OVOCs. Calibration
170 was performed daily at 23:11:00 pm using the standard mixtures of US EPA PAMS and
171 TO-15. The detection limits of the measured VOCs ranged from 0.02 ppbv to 0.30 ppbv.

172 Ambient meteorological parameters, including relative humidity (RH),
173 temperature (T), wind speed (WS), and wind direction (WD), were obtained using an
174 ultrasonic atmospherium (150WX, Airmar, USA). Photolysis frequencies and HCHO
175 were measured using a photolysis spectrometer PFS-100 and a formaldehyde monitor
176 FMS-100 (Focused Photonics Inc., Hangzhou, China), respectively. The photolysis rate
177 constants include $J(\text{O}^1\text{D})$, $J(\text{NO}_2)$, $J(\text{H}_2\text{O}_2)$, $J(\text{HONO})$, $J(\text{HCHO})$, and $J(\text{NO}_3)$. The
178 distribution of fire spots during the observation periods was obtained from the Fire
179 Information for Resource Management System

180 (<https://firms.modaps.eosdis.nasa.gov/firemap/>). The data for boundary layer height
 181 (BLH) were obtained from the European Centre for Medium-Range Weather Forecasts
 182 (ECMWF) ERA5 hourly reanalysis dataset
 183 (<https://www.ecmwf.int/en/forecasts/datasets/reanalysis-datasets/era5>, last access:
 184 March 24, 2023). [The resolution of ERA-5 reanalysis is 0.25°×0.25°.](#)

185

186 2.3 Positive matrix factorization (PMF) analysis

187 The PMF 5.0 model was applied to quantify high-time-resolution sources of PM_{2.5}
 188 during the observation periods. The details of the model analysis were described in our
 189 previous studies (Hong et al., 2021; Liu et al., 2020). Briefly, Eq. (1) demonstrates j
 190 compound species in the i th sample as the concentration from p independent sources.

$$191 \quad x_{ij} = \sum_{k=1}^p g_{ik} f_{kj} + e_{ij} \quad (1)$$

192 Where e_{ij} is the residual for each species, f_{kj} is the fraction of the j th species from
 193 the k th source, g_{ik} is the species contribution of the k th source to the i th sample, x_{ij} is
 194 the j th species concentration measured in the i th sample, and p is the total number of
 195 independent sources. The Q value (Eq. (2)), based on the uncertainties (μ), was used to
 196 evaluate the steadiness of the solution.

$$197 \quad Q = \sum_{i=1}^n \sum_{j=1}^m \left[\frac{x_{ij} - \sum_{k=1}^p g_{ik} f_{kj}}{\mu_{ij}} \right]^2 \quad (2)$$

198

199 2.4 Observation-based model (OBM)

200 The OBM-MCM model is employed to simulate in situ atmospheric
201 photochemical processes and quantify the O₃ production rate, AOC, and OH reactivity.
202 The details of the OBM-MCM model were reported in our previous studies (Liu et al.,
203 2022a,b). In summary, monitoring data with a one-hour time resolution of air pollutants
204 (i.e., O₃, CO, NO, NO₂, HONO, SO₂, and VOCs), meteorological parameters (i.e., T, P,
205 and RH), and photolysis rate constants ($J(\text{O}^1\text{D})$, $J(\text{NO}_2)$, $J(\text{H}_2\text{O}_2)$, $J(\text{HONO})$, $J(\text{HCHO})$,
206 and $J(\text{NO}_3)$) were input into the OBM-MCM model as constraints for the model
207 simulation. The photolysis rates of other molecules were determined by solar zenith
208 angle and scaled using measured $J\text{NO}_2$ values (Saunders et al., 2003). According to our
209 previous studies, the model incorporates the physical process of deposition within the
210 boundary layer height (BLH), which varies from 300 m during nighttime to 1500 m
211 during the daytime in ~~autumn-winter~~ (Li et al., 2018; Liu et al., 2022). Therefore, dry
212 deposition velocities were used to simulate the deposition loss of certain reactants in
213 the atmosphere (Zhang et al., 2003; Xue et al., 2014).

214 To simulate the concentration of particulate HCHO and its role in the
215 heterogeneous formation of hydroxymethanesulfonate (HMS), the observation-based
216 zero dimensional multiphase chemical box model was used, of which the gas phase
217 chemistry is described by the regional atmospheric chemistry mechanism version 2
218 (RACM2) and the aqueous phase part of the mechanism is represented by the chemical
219 aqueous-phase radical mechanism version 3.0 (CAPRAM 3.0). The mass transfer
220 processes between the gas and aqueous phases is also considered in current model
221 according to Schwartz (1986). The Henry's law constant of HCHO was updated with a

222 value of $0.31 \times 10^8 \text{ M atm}^{-1}$, as estimated by Mitsubishi et al. (2018). Sensitivity analysis
 223 was conducted to evaluate the uncertainties introduced by the Henry's law constant.
 224 details can be found in SI. For major production and loss paths of HMS, dissolved
 225 HCHO reacts with sulfite and bisulfite to form HMS (Eq (3-4)), which can be further
 226 oxidized by aqueous OH radicals (Eq (5)), details about the HMS mechanisms and the
 227 corresponding reaction kinetics are documented in CAPRAM website
 228 (<https://capram.tropos.de/>). To simulate the concentration of particulate HCHO and its
 229 role in the heterogeneous formation of hydroxymethanesulfonate (HMS), we combined
 230 the OBM model with the regional atmospheric chemistry mechanism version 2
 231 (RACM2) and the chemical aqueous phase radical mechanism version 3.0 (CAPRAM
 232 3.0). We also considered the mass transfer processes between the gas and aqueous
 233 phases (Schwartz, 1986). The Henry's law constant of HCHO is $0.31 \times 10^8 \text{ M atm}^{-1}$, as
 234 estimated by Mitsubishi et al. (2018). For the aqueous HMS formation mechanisms,
 235 dissolved HCHO reacts with sulfite and bisulfite to form HMS (Eq (3-4)), which can
 236 be further oxidized by aqueous OH radicals (Eq (5)).

240 For detailed modeling steps of HMS, firstly, the observation data of gaseous NO,
 241 NO₂, O₃, SO₂, CO, NMHCs, HCHO and other ten carbonyls, particulate phase NO₃⁻,
 242 NH₄⁺, and Cl⁻, along with meteorological parameters were averaged or interpolated into

243 a 1-h time resolution and classified into model recognized groups as model inputs,
244 while the measured SO_4^{2-} was used as the initial conditions. Liquid water content (LWC)
245 and aqueous H^+ concentrations, calculated using the ISORROPIA-II model (Hong et
246 al., 2022), were also used as model inputs. Then, model calculations were conducted
247 using the commercial FACSIMILE software, the modeling period was from February
248 26 to March 16, 2022 and each day was regarded as an independent simulation case.
249 The model was constrained every hour by the input observation data for integral
250 calculation. For each case, The integration ran three times in series to steady the
251 unconstrained species (e.g., radicals) , which was initiated at 00:00 local time (LT), and
252 had a step of 1 h and a duration of 24 h. Finally, the modeled HMS concentrations of
253 the third run were outputted with a 1-hour time resolution for further analysis.~~The~~
254 ~~observation data of gaseous NO , NO_2 , O_3 , SO_2 , CO , HCHO , VOCs, particulate phase~~
255 ~~NO_3^- , NH_4^+ , and Cl^- , along with meteorological parameters with a 1 h time resolution~~
256 ~~were interpolated to constrain the model, while the measured SO_4^{2-} was used as the~~
257 ~~initial condition for the model simulation. Liquid water content (LWC) and aqueous H^+~~
258 ~~concentrations, calculated using the ISORROPIA-II model (Hong et al., 2022), were~~
259 ~~also used to constrain the model. Model calculations were conducted from February 26~~
260 ~~to March 16, 2022. For each case, the model was initiated at 00:00 local time (LT), and~~
261 ~~the integration had a step of 1 h and a duration of 24 h.~~

262

263 **2.5 Backward trajectory analysis**

264 Hybrid Single Particle Lagrangian Integrated Trajectory (HYSPLIT) was used to

265 analyze the air masses before and during the PM_{2.5} and O₃ pollution period. The 72 h
266 backward trajectories at a height of 100 m obtained from the National Oceanic and
267 Atmospheric Administration were run every hour. Cluster analysis was performed, and
268 four clusters were determined based on the total spatial variance (TSV).
269

270 3 Results and discussions

271 3.1 Overview of co-occurring O₃ and PM_{2.5} pollution

272 The time series of criteria air pollutants, O₃ precursors, and meteorological
273 parameters from February 17 to March 17, 2022 are shown in Fig. 1. Two typical PM_{2.5}
274 and O₃ pollution episodes (EP1: February 26 to March 5; EP2: March 11 to March 17)
275 were observed, compared to the other periods (Pre-EP1: February 11 to February 25
276 and Pre-EP2: March 16 to March 10) affected by rainfall. The mean concentrations of
277 PM_{2.5} during EP1 and EP2 were 51.9 μg m⁻³ and 35.3 μg m⁻³, respectively, compared
278 to 9.03 μg m⁻³ during Pre-EP1 (Table S1). The concentrations of other air pollutants,
279 such as O₃, SO₂, NO₂, PM₁₀, OC, EC, BC, HCHO, and VOCs, showed a significant
280 increasing trend during EP1 and EP2. During the monitoring periods, the

281 concentrations of measured HCHO ranged from 0.68 ppbv and 3.59 ppbv (Table S1).
282 According to our previous studies (Liu et al., 2023), the average levels of the measured
283 HCHO in spring and autumn in Xiamen were 2.9 ± 0.3 ppbv and 3.2 ± 1.4 ppbv,
284 respectively. Totally, the HCHO level in Xiamen was lower than that in megacities
285 (Table S2), such as Beijing (summer: 11.39±5.58 ppbv), Hongkong (summer:

带格式的: 缩进: 首行缩进: 2 字符

286 8.07±1.94 ppbv), and Guangzhou (summer: 6.69±1.98 ppbv), while was comparable to
287 the coastal cities, including Shenzhen (spring: 3.4±1.6 ppbv), Yantai (summer:
288 3.90±1.12 ppbv), and Shanghai (summer:3.31±1.43 ppbv). In the coastal cities of
289 southeastern China, halogenated VOC is one of important VOC species, which
290 originated from industrial emissions and solvent usage (Chen et al., 2022; Ji et al., 2022;
291 Liu et al., 2022). In this study, during the monitoring period, backward trajectories
292 showed air mass transport from the northeast, which brought halogenated VOC from
293 Quanzhou city, an industrial city adjacent to Xiamen.

294 The maximum PM_{2.5} and O₃ concentrations were approximately 100 μg m⁻³ and
295 200 μg m⁻³, respectively. The maximum daily 8 h average (MDA8) O₃ concentrations
296 were calculated according to the Ambient Air Quality Standard of China. Fig. S2 shows
297 the positive correlation between PM_{2.5} and MDA8 O₃ concentrations during the whole
298 period. In Xiamen, a coastal city in Southeast China, the annual mean concentrations
299 of criteria air pollutants from 2015 to 2021 were significantly lower than in other
300 Chinese cities (Fig. S3) (Li et al., 2022; Shao et al., 2022). Meanwhile, inter-annual
301 averaged concentrations of O₃ and Ox in winter were shown in Fig S3, suggesting an
302 increase in atmospheric oxidation capacity (AOC) during the cold seasons. Therefore,
303 these two typical PM_{2.5} and O₃ pollution episodes (EP1 and EP2) ~~might beare~~ worth
304 exploring in terms of the formation mechanisms and synergistic effects of PM_{2.5} and O₃
305 in the coastal city.

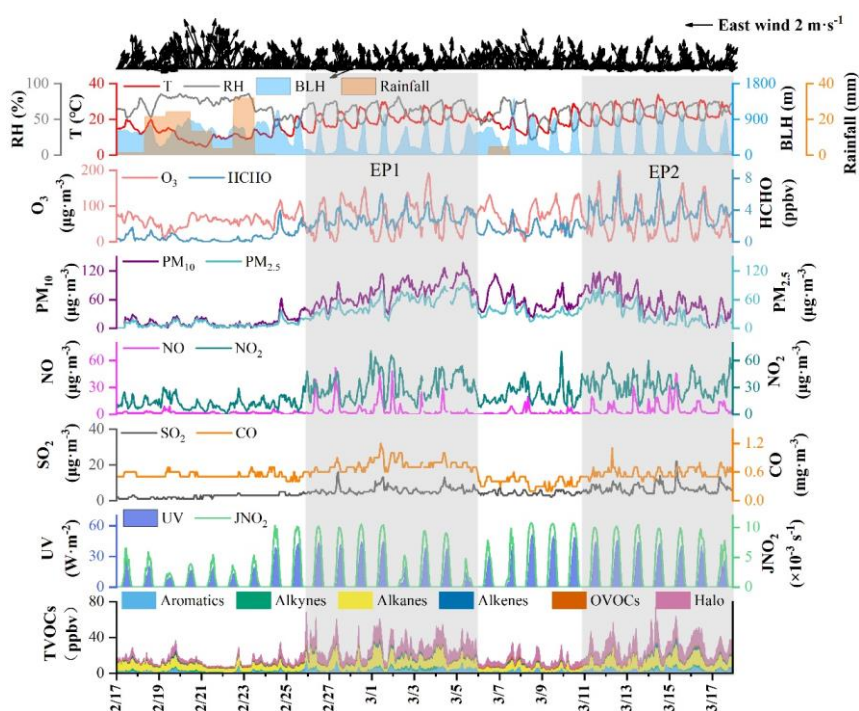

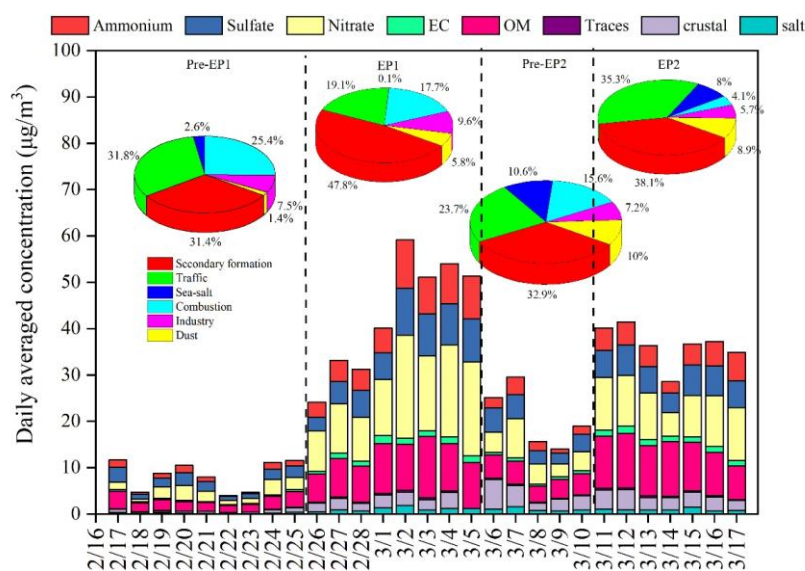

Fig. 1. Time series of various air pollutants and meteorological parameters

3.2 Chemical compositions and sources of PM_{2.5}

As shown in Figure 2, an overall increasing trend is clearly observed in both bulk PM_{2.5} and its major components during EP1 and EP2. Nitrate and organic matter (OM) remain the top two dominant PM_{2.5} components, followed by sulfate and ammonium. The mean concentrations of SO₄²⁻, NO₃⁻, and NH₄⁺ during EP1 and EP2 were 7.07 μg m⁻³ and 5.87 μg m⁻³, 14.95 μg m⁻³ and 9.69 μg m⁻³, and 6.77 μg m⁻³ and 4.46 μg m⁻³, respectively (Table S1). The increase in EC indicates the contributions of local anthropogenic emission sources, such as vehicle exhausts (Fig. 2). The concentrations

317 and percentages of OC and EC during different periods are illustrated in Fig. S4 and
 318 Table S1. The average OC and EC concentrations during EP1 and EP2 were $6.36 \mu\text{g m}^{-3}$
 319 m^{-3} and $7.48 \mu\text{g m}^{-3}$ and $1.23 \mu\text{g m}^{-3}$ and $1.29 \mu\text{g m}^{-3}$, respectively, which were notably
 320 higher than those during Pre-EP1 and Pre-EP2. These results are consistent with the
 321 increase in primary emissions and secondary formation contributing to complex air
 322 pollution during the rapid urbanization and industrialization stages in China (Xiao et
 323 al., 2022; Jiang et al., 2022).

324
 325 **Fig. 2. Time series of $\text{PM}_{2.5}$ chemical composition and sources apportionment by the PMF**
 326 **model. In the legends, OM refers to organic matter, calculated as $1.4 \times \text{OC}$; “Tracers” includes**
 327 **elements other than Na, Cl, S, K, Al, Si, Ca, Fe; “Crustal” represents crustal materials,**
 328 **calculated as $1.89 \times \text{Al} + 2.14 \times \text{Si} + 1.4 \times \text{Ca} + 1.43 \times \text{Fe}$; and “Salts” includes Na^+ and Cl^- .**

329 The PMF model was applied to conduct high-time-resolution source
 330 apportionment of $\text{PM}_{2.5}$, based on online hourly measurement data (Hong et al., 2021;
 331 Chow et al., 2022). The factor profiles and the contributions of various sources to $\text{PM}_{2.5}$

332 are shown in Fig. 2 and Fig. S5. Previous studies have indicated that construction and
333 road dust is characterized by high loadings of Al, Si, Ca²⁺, Na⁺, Mg²⁺, and Zn (Rienda
334 and Alves, 2021). In this study, the factor of dust (Factor 1) was identified by the high
335 contributions of Si (Fig. S5). The PMF analysis revealed that the contribution of dust
336 to PM_{2.5} ranged from 5.8% to 8.9% during EP1 and EP2, compared to 1.4% during Pre-
337 EP1 (Fig.2). Factor 2, contributing to the high loading of metal elements (Mn, Zn, Fe,
338 Pb, and As), was characterized by industrial emissions (Belis et al., 2019). The
339 contributions from the industry during EP1 and EP2 remained constant. In factor 3, K⁺
340 was dominant, and it was identified as coming from combustion sources (Watson et al.,
341 2001). Biomass burning could change the contribution of combustion to PM_{2.5} at the
342 monitoring site through long-range transport. During EP2, the influence of combustion
343 sources (e.g., biomass burning) significantly decreased, due to reduced anthropogenic
344 emissions and the arrival of clean air masses from the ocean (Figs. S6 and S7). Factor
345 4, with the highest proportion of Na⁺ and Mg²⁺ loadings, was associated with the
346 influence of sea-salt aerosol (Polissar et al., 1998). The percentages of sea salt (8-10%)
347 during Pre-EP2 and EP2 were relatively high. Factor 5 exhibited high contributions of
348 EC, OM, and Pb, which are general indicators of vehicle exhaust (Belis et al., 2019).
349 During EP2, the contribution of traffic increased up to 35.3%. Factor 6 was associated
350 with secondary aerosol, characterized by high loadings of SO₄²⁻, NO₃⁻, and NH₄⁺. The
351 increased contributions of secondary formation during EP1 and EP2 accounted for 47.8%
352 and 38.1%, respectively.

353

354 **3.3 Formation mechanism of PM_{2.5}**

355 As shown in Fig. S8, SO₄²⁻ was correlated with NH₄⁺ (R² = 0.72–0.88), and the
356 line fit of NH₄⁺ and SO₄²⁻ showed a slope of 1.78-2.67, suggesting the dominant form
357 of (NH₄)₂SO₄. Similarly, NO₃⁻ was also correlated with NH₄⁺ (R² = 0.77–0.93),
358 indicating the presence of NH₄NO₃. In addition, the ratio of NH₄⁺ to the sum of NO₃⁻
359 and SO₄²⁻ was close to 1, indicating complete neutralization of sulfate and nitrate by
360 ammonium (Fig. 8c). However, there was no significant difference in the existing form
361 of SNA in PM_{2.5} during EP1 and EP2 under different periods.

362 The variations of sulfur oxidation rate (SOR) and nitrogen oxidation rate (NOR)
363 under different periods are shown in Table S1. It should be noted that SOR (0.38±0.18)
364 and NOR (0.32±0.08) during EP1 were the highest, indicating a high oxidation rate of
365 SO₂ and NO₂. According to RH, T, and UV (Table S1), noticeable differences in
366 meteorological conditions were observed under different periods. In this study, LWC
367 was positively correlated with SO₄²⁻, NO₃⁻, and NH₄⁺ (known as the secondary
368 inorganic aerosol, SIA) (Fig. S9), suggesting the influence of the aqueous phase process,
369 including reactions with O₃, OH, H₂O₂, and organic peroxides (Gen et al., 2019; Wang
370 et al., 2023).

371 Current studies have found that O₃, H₂O₂, OH, and transition-metal-catalyzed
372 (TMI) O₂ can trigger the secondary formation of SO₄²⁻ (Hong et al., 2021; Gen et al.,
373 2019). However, the relative importance of these oxidants in enhancing the formation
374 of SO₄²⁻ is still a topic of debate. As shown in Fig. 3(b) and (c), a good correlation was
375 found between SO₄²⁻ and Fe and Mn. The TMI-catalyzed oxidation contributed to the

376 formation of SO_4^{2-} , which occurred in both cloud processes and during haze episodes
377 (Li et al., 2020) because the Mn catalytic reaction rapidly occurred at the aerosol surface
378 and could oxidize S(IV) through the production of intermediate Mn(III) (Wang et al.,
379 2021). Even at very low concentrations of Mn, the Mn catalytic reaction, consuming
380 oxygen and SO_2 , could produce sulfate. Under low aerosol pH conditions, the catalytic
381 reaction of TMIs plays an important role in the oxidation of S(IV). In this study, low
382 aerosol pH ranged from 2 to 4 was observed, indicating the potential influence of TMI-
383 catalyzed oxidation. In the future, it is vital to further evaluate the interaction of sulfate
384 formation and Fe/Mn, and to elucidate the main pathway of the S(IV) oxidation in the
385 coastal areas. In addition, as an important intermediate product in atmospheric
386 photochemical reactions, the formation and removal of HCHO are closely related to
387 OH and HO_2 radicals, which directly affect atmospheric reactivity and oxidation ability
388 (Wu et al., 2023; Zhang et al., 2021). In this study, the correlations ($R^2 = 0.415$) between
389 HCHO and sulfate concentrations were also examined, as displayed in Fig. 3(a). Recent
390 studies have shown that HCHO can react with hydrogen peroxide (H_2O_2) to produce
391 hydroxymethyl hydroperoxide, which rapidly oxidizes dissolved sulfur dioxide (SO_2 ,
392 aq) to sulfate (Dovrou et al., 2022). ~~Meanwhile, HCHO reacts with dissolved SO_2 (aq)~~
393 ~~to produce hydroxymethanesulfonate (HMS), which, upon oxidation with the hydroxyl~~
394 ~~radical (OH), forms sulfate (Ma et al., 2020; Meeh et al., 2020).~~

395

396 **Fig.3. Correlations between the concentrations of sulfate and HCHO (a), Fe (b), and Mn (c)**

397

398 **3.4 Effects of HCHO on HMS in PM_{2.5}**

399 To calculate the particulate concentrations of HCHO and its contributions to the
 400 heterogeneous formation of HMS, we conducted the in-situ multiphase chemical
 401 simulations by combining the zero dimensional multiphase chemical box model with
 402 RACM2 and CAPRAM 3.0~~we combined the OBM model with RACM2 and CAPRAM~~
 403 ~~3.0~~. During EP1 and EP2, the concentrations of HCHO (aq) and HMS (aq), as well as
 404 the particulate sulfur molar percentage, increased with the rise of SO₂, SO₄²⁻, and
 405 HCHO concentrations (Fig. 4). Also, particulate sulfur molar percentage was higher
 406 during the pollution periods, which may due to the high concentrations of gaseous
 407 precursors (SO₂, HCHO) and favorable aerosol properties (i.e. pH and aerosol water

带格式的: 字体: 小四

带格式的: 字体: 小四

408 content) promoted the heterogeneous processes. Previous studies have modeled that 1
409 ppb of gas-phase HCHO could yield up to ~5 $\mu\text{g m}^{-3}$ HMS and identified that HCHO
410 emissions was one of key factors controlling HMS formation during the winter haze
411 (Moch et al., 2018). All above signify the important contributions of HCHO on the
412 heterogeneous formation of HMS and particulate sulfur chemistry, especially during
413 the pollution periods.

414 However, the molar ratio of HMS to sulfate were very low, suggesting the limited
415 contributions of HMS concentrations to inorganic sulfate concentrations. Potential roles
416 of HCHO in the HMS formation in coastal city of southeast China was differed from
417 those in the megacities of China.

418 ~~The increase in sulfate concentration was associated~~
419 ~~with the increase in LWC (Fig. S9). Previous studies indicated that the pH and liquid~~
420 ~~water content of aerosols were the main factors influencing the HCHO uptake~~
421 ~~coefficient (γ). Moreover, γ has a strong positive exponential relationship with aqueous~~
422 ~~sulfate concentration (Xu et al., 2022). Meanwhile, Previous studies found that HCHO~~
423 ~~reacts with dissolved SO_2 (aq) to produce hydroxymethanesulfonate (HMS), which,~~

424 ~~upon oxidation with the hydroxyl radical (OH), forms sulfate (Ma et al., 2020; Moch et~~
425 ~~al., 2020). Ma et al. (2020) reported that heterogeneous formation of HMS accounted~~
426 ~~for 15% of OM, and resulted in 36% overestimates of sulfate during the winter haze in~~

427 ~~Beijing. The increase in sulfate concentration was associated with the increase in LWC~~
428 ~~(Fig. S9). Previous studies indicated that the pH and liquid water content of aerosols~~
429 ~~were the main factors influencing the HCHO uptake coefficient (γ). Moreover, γ has a~~
~~strong positive exponential relationship with aqueous sulfate concentration (Xu et al.,~~

 434 **sulfur molar percentage observed at different pollution levels/stages. – The simulated HCHO**
 435 **(aq) and HMS (aq) were also presented. In the box-whisker plots, the whiskers, boxes, and**

436 ~~points indicate the 5th/95th, 25th/75th, 50th percentiles, and mean values. The particulate~~
437 ~~sulfur molar percentage was calculated as $[n(\text{SO}_4^{2-})+n(\text{HMS})]/[n(\text{SO}_4^{2-})+n(\text{HMS})+n(\text{SO}_2)]$. In~~
438 ~~the box-whisker plots, the whiskers, boxes, and points indicate the 5th/95th, 25th/75th, 50th~~
439 ~~percentiles, and mean values.~~

440 As shown in Fig. 5, the concentration of HMS exhibited a similar diurnal variation
441 to that of HCHO (aq). These findings are consistent with the fact that HMS is formed
442 through the reaction between dissolved SO₂ and formaldehyde (HCHO) in aerosol
443 liquid water. In our previous studies, we observed that gaseous HCHO showed an
444 increasing trend after sunrise, peaking at noon due to photochemical reactions (Liu et
445 al., 2022b). However, during EP1 and EP2, high concentrations of HCHO (aq) were
446 observed during nighttime. Meanwhile, the heterogeneous formation of HMS also
447 occurred, resulting in elevated HMS concentrations during nighttime.

带格式的： 字体： 小四

448 **Figure 5. Diurnal variations of calculated HCHO (aq) and HMS (aq) at different pollution**
449 **levels**

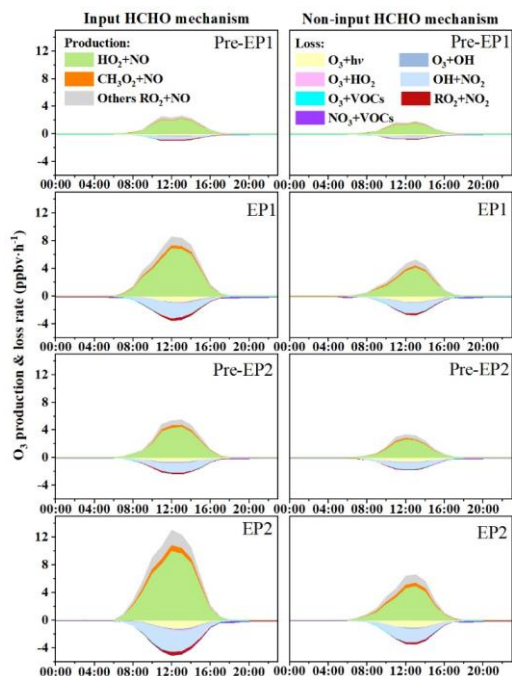

451 ~~In this study, h~~High concentrations of HMS were ~~observed-captured~~ under high
452 RH and moderately acidic pH conditions (Fig. 65). Previous studies have also indicated
453 that high RH promotes rapid HMS formation during winter haze, as the aerosol water
454 content could provide numerous reaction interfaces for HMS formation (Ma et al.,
455 2020). Meanwhile, atmospheric sulfur tended to distribute into the particle phase with
456 increasing RH. Fig. 65 shows that HMS formation is favored under pH conditions close
457 to 4.0. Previous studies reported that high HMS concentrations were found under
458 moderate-pH conditions, as low pH inhibits HMS formation, and high pH is unsuitable
459 for its preservation (Ma et al., 2020; Campbell et al., 2022). Therefore, the combination
460 of high precursor concentrations (SO₂ and HCHO), high RH, and moderately acidic pH
461 enhanced the heterogeneous formation of HMS in ~~this-the~~ coastal city.

462
463 **Figure 65. Evolution of HMS (aq) distribution with increasing RH, colored according to**
464 **aerosol pH.**
465

466 3.5 Effects of HCHO on O₃ formation

467 To investigate the effects of HCHO on O₃ formation during the co-occurring O₃
468 and PM_{2.5} pollution period, the OBB was used to quantify the detailed O₃ production
469 and loss pathways in both scenarios: input HCHO (IH) and non-input HCHO (NIH)
470 (Fig. 7-6 and Fig. S49S9). The daytime production rates of HO₂+NO and RO₂+NO in
471 the IH scenario were calculated to be 6.84 and 1.25 ppbv h⁻¹ for EP1 and 9.91 and 2.17
472 ppbv h⁻¹ for EP2, respectively. Meanwhile, the predominant O₃ loss reaction in this
473 scenario was OH+NO₂, with rates of 2.26 ppbv h⁻¹ for EP1 and 3.17 ppbv h⁻¹ for EP2,
474 followed by O₃ photolysis with rates of 0.77 ppbv h⁻¹ and 1.10 ppbv h⁻¹. In contrast,
475 the daytime production rates of HO₂+NO and RO₂+NO in the NIH scenario were 4.03
476 and 0.85 ppbv h⁻¹ for EP1 and 4.86 and 1.29 ppbv h⁻¹ for EP2, respectively. These
477 results indicate that disabling the HCHO mechanism reduced the production rates of
478 HO₂+NO by 41% for EP1 and 51% for EP2. In addition, the average maximum net O₃
479 production rate ~~observed~~ with the IH scenario was 5.02 ppb h⁻¹ for EP1 and 7.93 ppb
480 h⁻¹ for EP2, approximately two times higher than the values of 2.48 ppb h⁻¹ and 3.14
481 ppb h⁻¹ ~~observed~~ with the NIH scenario. The results showed that the daytime net O₃
482 production rates decreased by 50–60% when the HCHO mechanism was disabled,
483 probably due to the decrease in RO_x concentrations and radical propagation rates (Wu
484 et al., 2023; Zhang et al., 2021).

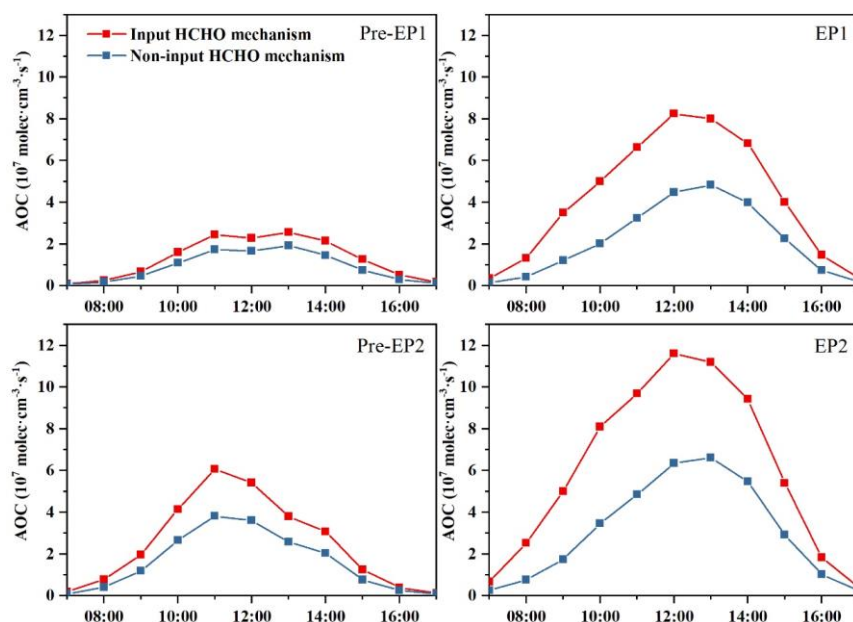

485

486 **Figure 76.** O₃ production and loss rates by the OBM with and without the HCHO
 487 mechanism

488 The atmospheric oxidation capacity (AOC) is a critical factor in determining the
 489 production rate of secondary pollutants and atmospheric photochemical pollution (Jia
 490 et al., 2023; Qin et al., 2022). In this study, AOC is calculated as the sum of the oxidation
 491 rates of various primary pollutants (e.g., CO, NO_x, and VOCs) by major oxidants (i.e.,
 492 OH, O₃, and NO₃). The model-simulated AOC, OH, HO₂, and RO₂ under different
 493 periods are shown in Fig. 8-7 and Fig. 98. The daily maximum AOC during EP1 and
 494 EP2 was 8.24×10^7 and 11.6×10^7 molecules $\text{cm}^{-3} \text{s}^{-1}$, respectively, which were higher
 495 than those (2.56×10^7 and 5.39×10^7 molecules $\text{cm}^{-3} \text{s}^{-1}$) in other periods. However,
 496 when the HCHO mechanism was disabled, the daily maximum AOC during different

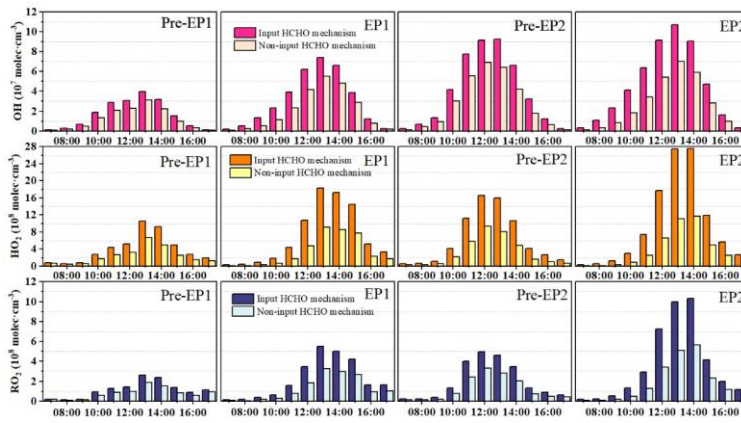

497 stages decreased significantly. Especially, HCHO played much important role in AOC
 498 during the co-occurring PM_{2.5} and O₃ pollution periods. All these results are comparable
 499 to rural sites in Hong Kong (6.2×10^7) and Berlin (1.4×10^7 molecules cm⁻³ s⁻¹) but
 500 lower than those observed in highly polluted cities, such as Santiago (3.2×10^8
 501 molecules cm⁻³ s⁻¹) and Shanghai (1.0×10^8 molecules cm⁻³ s⁻¹) (Li et al., 2018; Xue et
 502 al., 2016; Liu et al., 2022a). These studies have reported that the variations in AOC are
 503 related to precursor concentrations/types and photochemical conditions.

504
 505 **Figure 87.** Atmospheric oxidation capacity (AOC) calculated by the OBM with and without
 506 the HCHO mechanism.

507 In addition, the maximum daily concentrations of OH, HO₂, and RO₂ exhibited a
 508 similar pattern to that of AOC in both the IH and NIH scenarios (Fig. 98). Therefore,
 509 the O₃ production rate during EP1 and EP2 was consistent with the maximum daily

510 values of AOC, OH, HO₂, and RO₂. The differences in RO_x levels between the IH and
 511 NIH model scenarios were also calculated (Fig. S4+S10). In this study, disabling the
 512 HCHO mechanism led to decreased RO_x concentrations, affecting the O₃ formation.
 513 These results highlight the significance of HCHO in the photochemical reactions
 514 occurring in the coastal city during the co-occurring O₃ and PM_{2.5} pollution
 515 period events.

516
 517 **Figure 98.** OH, HO₂, and RO₂ concentrations modeled by the OBM with or without the
 518 **HCHO mechanism**
 519

520

521

522 **Conclusions**

523 A wintertime co-occurring O₃ and PM_{2.5} pollution event was selected to investigate
524 the synergistic effects between PM_{2.5} and O₃ in a coastal city in southeast China. The
525 results demonstrated a positive correlation between PM_{2.5} and MDA8 O₃
526 concentrations during the whole periods, indicating the enhancement of atmospheric
527 oxidation capacity (AOC) during cold seasons. The result of positive matrix
528 factorization (PMF) analysis suggested that the contribution of secondary formation to
529 PM_{2.5} increased during the pollution events, implying that the elevated AOC promoted
530 the oxidation of SO₂, NO_x, and VOCs, leading to the formation of secondary inorganic
531 and organic components. We also ~~observed~~found the significant correlations ($R^2 =$
532 0.415–0.477) between HCHO, Fe, Mn, and sulfate concentrations, suggesting the
533 influence of catalyzed oxidation in the coastal city. Through OBM analysis, we
534 demonstrated that high concentrations of precursors (SO₂ and HCHO), high RH, and
535 moderately acidic pH conditions enhanced the heterogeneous formation of
536 hydroxymethanesulfonate (HMS). Meanwhile, we verified that the input HCHO
537 mechanism increased the concentrations of RO_x and net O₃ production rates. Moreover,
538 the production rates of HO₂+NO and RO₂+NO were enhanced, indicating that HCHO
539 affected O₃ formation by controlling the efficiencies of radical propagation. This study
540 highlighted the influence of the HCHO mechanism on photochemical reactions and the
541 formation of HMS in co-occurring O₃-and PM_{2.5} ~~pollution~~ in coastal cities and was
542 beneficial for improving air quality and protecting public health.
