29 **Abstract:**

30 To develop the effective strategies for controlling both PM<sub>2.5</sub> and O<sub>3</sub> levels, it is crucial  
31 to understand their synergistic mechanisms, key precursors, and atmospheric  
32 physiochemical processes involved. In this study, a wintertime co-occurring O<sub>3</sub> and  
33 PM<sub>2.5</sub> pollution event in a coastal city in southeast China was investigated based on  
34 high-time resolution measurements of criteria air pollutants, chemical compositions of  
35 PM<sub>2.5</sub>, and O<sub>3</sub> precursors, such as NO<sub>x</sub>, HCHO, and VOCs. The results of this study  
36 revealed the characteristics of positively correlated PM<sub>2.5</sub> and MDA8 O<sub>3</sub> concentrations,  
37 and an increase in atmospheric oxidation capacity (AOC) during the cold seasons.  
38 Strong correlations ( $R^2 = 0.415\text{--}0.477$ ) between HCHO, Fe, Mn, and sulfate  
39 concentrations were observed, suggesting the influence of catalyzed oxidation  
40 processes in the coastal city. Through an observation-based model (OBM) analysis  
41 coupled with the regional atmospheric chemistry mechanism version 2 (RACM2) and  
42 the chemical aqueous-phase radical mechanism version 3.0 (CAPRAM 3.0), we found  
43 that high concentrations of precursors (SO<sub>2</sub> and HCHO), high relative humidity, and  
44 moderately acidic pH conditions enhanced the heterogeneous formation of  
45 hydroxymethanesulfonate (HMS) in PM<sub>2.5</sub>. Furthermore, by employing the Master  
46 Chemical Mechanism (OBM-MCM), we verified that disabling the HCHO mechanism  
47 could decrease daytime net O<sub>3</sub> production rates by reducing the production rates of  
48 HO<sub>2</sub>+NO. These results were consistent with the daily values of AOC, OH, HO<sub>2</sub>, and  
49 RO<sub>2</sub> concentrations. This study contributes to a better understanding of the significance

50 of HCHO in photochemical reactions and the formation of HMS in coastal city.

51 **Key words:** PM<sub>2.5</sub>; O<sub>3</sub>; formaldehyde; OBM; coastal city

52

## 53 **Introduction**

54 Air pollution, dominated by fine particulate matter (PM<sub>2.5</sub>) and ground-level ozone  
55 (O<sub>3</sub>), is an important global environmental issue linked to climate change and human  
56 health, including cardiovascular and respiratory illnesses and mortality (Xiao et al.,  
57 2022; Vohra et al., 2022). To decrease global air pollution and associated mortality, the  
58 World Health Organization recently updated its air quality guideline for annual PM<sub>2.5</sub>  
59 exposure from 10 to 5  $\mu\text{g m}^{-3}$  and added the average O<sub>3</sub> concentrations of no more than  
60 60  $\mu\text{g m}^{-3}$  during the peak season (WHO, 2021). To develop two-pollutant control  
61 strategies to decrease both PM<sub>2.5</sub> and O<sub>3</sub>, there is a need to understand the synergistic  
62 mechanisms and spatiotemporal delineation between them (Ivatt et al., 2022; Li et al.,  
63 2019b).

64 There are complex synergistic effects between PM<sub>2.5</sub> and O<sub>3</sub>, due to common  
65 precursors (e.g., NO<sub>x</sub> and VOCs), atmospheric physiochemical processes, and weather  
66 systems (Li et al., 2019a; Shao et al., 2022; Jia et al., 2023; Zhang et al., 2022; Qin et  
67 al., 2021; Qu et al., 2023). An increase in O<sub>3</sub> concentration will increase oxidizing  
68 substances, such as OH, H<sub>2</sub>O<sub>2</sub>, and RCHO, which promote the oxidation of SO<sub>2</sub>, NO<sub>x</sub>,  
69 and VOCs to secondary inorganic and organic components in PM<sub>2.5</sub> (Feng et al., 2020;  
70 Lu et al., 2019). On the contrary, multiphase reactions occur on the surface of

71 atmospheric particles, such as the uptake of HCHO and HO<sub>2</sub> absorption, thus affecting  
72 the formation of O<sub>3</sub> (Song et al., 2022; Lou et al., 2014).

73 Formaldehyde (HCHO) plays an important role in the photochemical reaction  
74 process and secondary aerosol formation (Kalashnikov et al., 2022; Ma et al., 2020;  
75 Song et al., 2021; Zong et al., 2021). Most studies have focused on pollution  
76 characteristics and sources, particle uptake of HCHO, and their impacts on atmospheric  
77 oxidation capacity (Liu et al., 2022b; Wu et al., 2023; Zhang et al., 2021). Recent  
78 studies have shown that HCHO can react with hydrogen peroxide (H<sub>2</sub>O<sub>2</sub>) to produce  
79 hydroxymethyl hydroperoxide (HMHP), which rapidly oxidizes dissolved sulfur  
80 dioxide (SO<sub>2</sub>, aq) to sulfate (Dovrou et al., 2022). Meanwhile, HCHO reacts with  
81 dissolved SO<sub>2</sub> (aq) to produce hydroxymethanesulfonate (HMS, HOCH<sub>2</sub>SO<sup>-</sup>), which,  
82 upon oxidation with the hydroxyl radical (OH), forms sulfate (Ma et al., 2020; Moch et  
83 al., 2018, 2020). Totally, atmospheric HCHO contributes to sulfate formation in PM<sub>2.5</sub>  
84 by producing HO<sub>2</sub> radicals and HMHP or HMS (Wu et al., 2023; Dovrou et al., 2022;  
85 Campbell et al., 2022). However, these studies highlight the necessity for more  
86 observation research to obtain evidence of the contributions of HCHO to HMS  
87 formation. HMS is an important organosulfur compound in the atmosphere, not only in  
88 cloud and fog but also in atmospheric aerosols (Munger et al., 1986; Dixon and Aasen,  
89 1999). The misidentification of HMS as inorganic sulfate caused the overestimation of  
90 the observed particulate sulfate (Ma et al., 2020; Dovrou et al., 2022). However, in  
91 subtropical coastal regions with apparent HCHO production, further studies are  
92 required to investigate the impacts of HCHO on the the formations of HMS and ROx

93 radicals.

94 Xiamen, a coastal city in southeast China, has frequently experienced PM<sub>2.5</sub>  
95 pollution (with low O<sub>3</sub> concentrations) in winter and O<sub>3</sub> pollution in spring and autumn  
96 (Hong et al., 2022; Wu et al., 2019). Our previous studies mainly focused on the  
97 pollution characteristics of PM<sub>2.5</sub> or O<sub>3</sub> in different seasons and their sources associated  
98 with anthropogenic emissions and the East Asian monsoon (Liu et al., 2020; Liu et al.,  
99 2022a; Hong et al., 2021). At the end of winter and the beginning of spring in 2022, an  
100 outbreak of co-occurring O<sub>3</sub> and PM<sub>2.5</sub> pollution was observed in Xiamen. Therefore,  
101 it provided a unique opportunity to study the impacts of HCHO on the formations of  
102 HMS and RO<sub>x</sub> radicals. In the coastal region, there is an apparent alternation of polluted  
103 and clean air masses from continental and ocean areas and a local geographical  
104 environment, including relatively high humidity, dense vegetation, and strong  
105 atmospheric oxidation capacity (Hu et al., 2022; Wu et al., 2020). Potential roles and  
106 mechanisms of HCHO in the photochemical reaction process and HMS formation  
107 would differ from those in megacities of China, such as the Beijing-Tianjin-Hebei (BTH)  
108 Area, the Yangtze River Delta (YRD), and the Pearl River Delta (PRD). Based on the  
109 observation-based model (OBM) analysis, the objectives of this study are to (1)  
110 characterize the wintertime co-occurring O<sub>3</sub> and PM<sub>2.5</sub> pollution process in a coastal  
111 city; (2) elaborate the influence of HCHO on the heterogeneous formation of HMS in  
112 PM<sub>2.5</sub>; (3) explore the mechanisms of HCHO on O<sub>3</sub> pollution and photochemical  
113 reactions process.

114

## 115 **2 Methods and materials**

### 116 **2.1 Study area**

117 The monitoring site (Institute of Urban Environment, Chinese Academy of  
118 Sciences, 118.06° E, 24.61° N) is located in Xiamen, a coastal city in southeast China  
119 (Fig. S1). It is situated in a subtropical monsoon climate, with an average temperature  
120 of 18.5°C and a relative humidity of 63.3% during the wintertime observation. In  
121 autumn and winter, cold and dry air masses move northward from inland, while in late  
122 spring and summer, the prevailing air masses are southerly, characterized by warm air  
123 temperatures and high humidity. The air-monitoring supersite is located on the rooftop  
124 of a building, surrounded by residential buildings, educational institutions, a  
125 commercial zone, and freeways. The downtown area of Xiamen, with a high population  
126 density and frequent traffic jams, is located south of the monitoring site.

127

### 128 **2.2 Observation**

129 Gas and aerosol species, O<sub>3</sub> precursors, photolysis rate, and meteorological  
130 parameters were continuously measured online from February 17 to March 17, 2022.  
131 Hourly mass concentrations of PM<sub>2.5</sub> and PM<sub>10</sub> were measured using a tapered element  
132 oscillating microbalance (TEOM1405, Thermo Scientific Corp., MA, USA). NO/NO<sub>2</sub>,  
133 SO<sub>2</sub>, and O<sub>3</sub> were monitored using continuous gas analyzers (TEI 42*i*, 43*i*, and 49*i*,  
134 Thermo Scientific Corp., MA, USA). HCHO analyzer (FMS-100, Focused Photonics  
135 Inc., Hangzhou, China) was used to measure gaseous HCHO based on the Hantzsch

136 reaction, according to our previous method (Liu et al., 2022b). Water-soluble inorganic  
137 ions (WSII) in PM<sub>2.5</sub> (Cl<sup>-</sup>, SO<sub>4</sub><sup>2-</sup>, NO<sub>3</sub><sup>-</sup>, Na<sup>+</sup>, K<sup>+</sup>, NH<sub>4</sub><sup>+</sup>, Mg<sup>2+</sup>, and Ca<sup>2+</sup>) were measured  
138 hourly using a Monitoring device for AeRosols and Gases in ambient Air (MARGA  
139 2080; Metrohm Applikon B.V.; Delft, Netherlands). Simultaneously, organic carbon  
140 (OC) and elemental carbon (EC) in PM<sub>2.5</sub> were measured using an OC/EC analyzer  
141 (model RT-4; Sunset Laboratory Inc.; Tigard, USA). BC was monitored using an  
142 Aethalometer (AE31, Magee Scientific, USA) with a PM<sub>2.5</sub> cut-off inlet. Besides,  
143 concentrations of 22 elements (Al, Si, S, Fe, K, Mn, Pb, Ca, Zn, Ba, V, Cu, Ni, As, Cr,  
144 Ag, Se, Br, Hg, Sn, Ti, and Sb) were measured using a multi-metal monitor (Xact™  
145 625, Cooper Environmental Services, LLT; Portland, USA). Strict quality assurance  
146 and quality control procedures were applied, and the maintenance and accuracy of all  
147 online instruments were validated (Hong et al., 2021). The detection limits, time  
148 resolutions and measured uncertainties of air pollutants were shown in TableS3.

149 A gas chromatograph-mass spectrometer (GC-FID/MS, TH-300B, Wuhan, China)  
150 was used to measure ambient VOCs with one-hour time resolution, following the  
151 method from our previous studies (Liu et al., 2020a,b). Briefly, the air sample was  
152 preconcentrated by cooling to -160 °C in a cryogenic trap, then heated to 100 °C, and  
153 subsequently transferred to the secondary trap using high-purity helium (He). The low-  
154 carbon (C2-C5) hydrocarbons were detected using a flame ionization detector (FID)  
155 with a PLOT (Al<sub>2</sub>O<sub>3</sub>/KCl) column (15 m × 0.32 mm × 6.0 μm), while other VOC  
156 species were quantified using a GC/MS with a DB-624 column (60 m × 0.25 mm × 1.4  
157 μm). The instrument can quantify 106 VOC species, including 29 alkanes, 11 alkenes,

158 one alkyne, 17 aromatics, 35 halogenated hydrocarbons, and 13 OVOCs. Calibration  
159 was performed daily at 11:00 pm using the standard mixtures of US EPA PAMS and  
160 TO-15. The detection limits of the measured VOCs ranged from 0.02 ppbv to 0.30 ppbv.

161 Ambient meteorological parameters, including relative humidity (RH),  
162 temperature (T), wind speed (WS), and wind direction (WD), were obtained using an  
163 ultrasonic anemometer (150WX, Airmar, USA). Photolysis frequencies and HCHO  
164 were measured using a photolysis spectrometer PFS-100 and a formaldehyde monitor  
165 FMS-100 (Focused Photonics Inc., Hangzhou, China), respectively. The photolysis rate  
166 constants include  $J(\text{O}^1\text{D})$ ,  $J(\text{NO}_2)$ ,  $J(\text{H}_2\text{O}_2)$ ,  $J(\text{HONO})$ ,  $J(\text{HCHO})$ , and  $J(\text{NO}_3)$ . The  
167 distribution of fire spots during the observation periods was obtained from the Fire  
168 Information for Resource Management System  
169 (<https://firms.modaps.eosdis.nasa.gov/firemap/>). The data for boundary layer height  
170 (BLH) were obtained from the European Centre for Medium-Range Weather Forecasts  
171 (ECMWF) ERA5 hourly reanalysis dataset  
172 (<https://www.ecmwf.int/en/forecasts/datasets/reanalysis-datasets/era5>, last access:  
173 March 24, 2023). The resolution of ERA-5 reanalysis is  $0.25^\circ \times 0.25^\circ$ .

174

### 175 **2.3 Positive matrix factorization (PMF) analysis**

176 The PMF 5.0 model was applied to quantify high-time-resolution sources of  $\text{PM}_{2.5}$   
177 during the observation periods. The details of the model analysis were described in our  
178 previous studies (Hong et al., 2021; Liu et al., 2020). Briefly, Eq. (1) demonstrates  $j$   
179 compound species in the  $i$ th sample as the concentration from  $p$  independent sources.

$$x_{ij} = \sum_{k=1}^p g_{ik} f_{kj} + e_{ij} \quad (1)$$

180

181 Where  $e_{ij}$  is the residual for each species,  $f_{kj}$  is the fraction of the  $j$ th species from  
 182 the  $k$ th source,  $g_{ik}$  is the species contribution of the  $k$ th source to the  $i$ th sample,  $x_{ij}$  is  
 183 the  $j$ th species concentration measured in the  $i$ th sample, and  $p$  is the total number of  
 184 independent sources. The Q value (Eq. (2)), based on the uncertainties ( $\mu$ ), was used to  
 185 evaluate the steadiness of the solution.

$$Q = \sum_{i=1}^n \sum_{j=1}^m \left[ \frac{x_{ij} - \sum_{k=1}^p g_{ik} f_{kj}}{\mu_{ij}} \right]^2 \quad (2)$$

186

187

#### 188 **2.4 Observation-based model (OBM)**

189 The OBM-MCM model is employed to simulate in situ atmospheric  
 190 photochemical processes and quantify the O<sub>3</sub> production rate, AOC, and OH reactivity.  
 191 The details of the OBM-MCM model were reported in our previous studies (Liu et al.,  
 192 2022a,b). In summary, monitoring data with a one-hour time resolution of air pollutants  
 193 (i.e., O<sub>3</sub>, CO, NO, NO<sub>2</sub>, HONO, SO<sub>2</sub>, and VOCs), meteorological parameters (i.e., T, P,  
 194 and RH), and photolysis rate constants ( $J(O^1D)$ ,  $J(NO_2)$ ,  $J(H_2O_2)$ ,  $J(HONO)$ ,  $J(HCHO)$ ,  
 195 and  $J(NO_3)$ ) were input into the OBM-MCM model as constraints for the model  
 196 simulation. The photolysis rates of other molecules were determined by solar zenith  
 197 angle and scaled using measured  $JNO_2$  values (Saunders et al., 2003). According to our  
 198 previous studies, the model incorporates the physical process of deposition within the  
 199 boundary layer height (BLH), which varies from 300 m during nighttime to 1500 m

200 during the daytime in winter (Li et al., 2018; Liu et al., 2022). Therefore, dry deposition  
201 velocities were used to simulate the deposition loss of certain reactants in the  
202 atmosphere (Zhang et al., 2003; Xue et al., 2014).

203 To simulate the concentration of particulate HCHO and its role in the  
204 heterogeneous formation of hydroxymethanesulfonate (HMS), the observation-based  
205 zero dimensional multiphase chemical box model was used, of which the gas phase  
206 chemistry is described by the regional atmospheric chemistry mechanism version 2  
207 (RACM2) and the aqueous phase part of the mechanism is represented by the chemical  
208 aqueous-phase radical mechanism version 3.0 (CAPRAM 3.0). The mass transfer  
209 processes between the gas and aqueous phases is also considered in current model  
210 according to Schwartz (1986). The Henry's law constant of HCHO was updated with a  
211 value of  $0.31 \times 10^8 \text{ M atm}^{-1}$ , as estimated by Mitsuishi et al. (2018). Sensitivity analysis  
212 was conducted to evaluate the uncertainties introduced by the Henry's law constant,  
213 details can be found in SI. For major production and loss paths of HMS, dissolved  
214 HCHO reacts with sulfite and bisulfite to form HMS (Eq (3-4)), which can be further  
215 oxidized by aqueous OH radicals (Eq (5)), details about the HMS mechanisms and the  
216 corresponding reaction kinetics are documented in CAPRAM website  
217 (<https://capram.tropos.de/>).

221 For detailed modeling steps of HMS, firstly, the observation data of gaseous NO,  
222 NO<sub>2</sub>, O<sub>3</sub>, SO<sub>2</sub>, CO, NMHCs, HCHO and other ten carbonyls, particulate phase NO<sub>3</sub><sup>-</sup>,  
223 NH<sub>4</sub><sup>+</sup>, and Cl<sup>-</sup>, along with meteorological parameters were averaged or interpolated into  
224 a 1-h time resolution and classified into model recognized groups as model inputs,  
225 while the measured SO<sub>4</sub><sup>2-</sup> was used as the initial conditions. Liquid water content (LWC)  
226 and aqueous H<sup>+</sup> concentrations, calculated using the ISORROPIA-II model (Hong et  
227 al., 2022), were also used as model inputs. Then, model calculations were conducted  
228 using the commercial FACSIMILE software, the modeling period was from February  
229 26 to March 16, 2022 and each day was regarded as an independent simulation case.  
230 The model was constrained every hour by the input observation data for integral  
231 calculation. For each case, The integration ran three times in series to steady the  
232 unconstrained species (e.g., radicals) , which was initiated at 00:00 local time (LT), and  
233 had a step of 1 h and a duration of 24 h. Finally, the modeled HMS concentrations of  
234 the third run were outputted with a 1-hour time resolution for further analysis.

235

## 236 **3 Results and discussions**

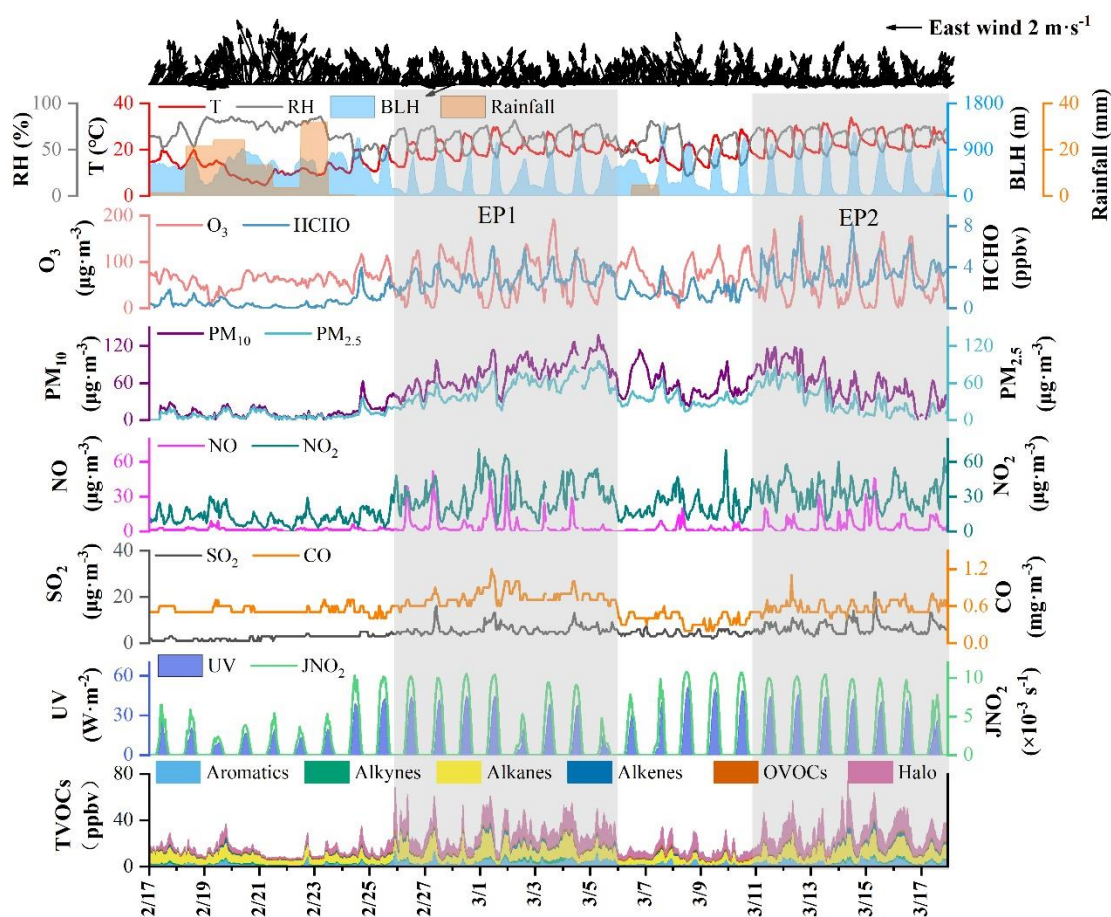

### 237 **3.1 Overview of co-occurring O<sub>3</sub> and PM<sub>2.5</sub> pollution**

238 The time series of criteria air pollutants, O<sub>3</sub> precursors, and meteorological  
239 parameters from February 17 to March 17, 2022 are shown in Fig. 1. Two typical PM<sub>2.5</sub>  
240 and O<sub>3</sub> pollution episodes (EP1: February 26 to March 5; EP2: March 11 to March 17)  
241 were observed, compared to the other periods (Pre-EP1: February 11 to February 25

242 and Pre-EP2: March 16 to March 10) affected by rainfall. The mean concentrations of  
243  $\text{PM}_{2.5}$  during EP1 and EP2 were  $51.9 \mu\text{g m}^{-3}$  and  $35.3 \mu\text{g m}^{-3}$ , respectively, compared  
244 to  $9.03 \mu\text{g m}^{-3}$  during Pre-EP1 (Table S1). The concentrations of other air pollutants,  
245 such as  $\text{O}_3$ ,  $\text{SO}_2$ ,  $\text{NO}_2$ ,  $\text{PM}_{10}$ , OC, EC, BC, HCHO, and VOCs, showed a significant  
246 increasing trend during EP1 and EP2. During the monitoring periods, the  
247 concentrations of measured HCHO ranged from 0.68 ppbv and 3.59 ppbv (Table S1).  
248 According to our previous studies (Liu et al., 2023), the average levels of the measured  
249 HCHO in spring and autumn in Xiamen were  $2.9 \pm 0.3$  ppbv and  $3.2 \pm 1.4$  ppbv,  
250 respectively. Totally, the HCHO level in Xiamen was lower than that in megacities  
251 (Table S2), such as Beijing (summer:  $11.39 \pm 5.58$  ppbv), Hongkong (summer:  
252  $8.07 \pm 1.94$  ppbv), and Guangzhou (summer:  $6.69 \pm 1.98$  ppbv), while was comparable to  
253 the coastal cities, including Shenzhen (spring:  $3.4 \pm 1.6$  ppbv), Yantai (summer:  
254  $3.90 \pm 1.12$  ppbv), and Shanghai (summer:  $3.31 \pm 1.43$  ppbv). In the coastal cities of  
255 southeastern China, halogenated VOC is one of important VOC species, which  
256 originated from industrial emissions and solvent usage (Chen et al., 2022; Ji et al., 2022;  
257 Liu et al., 2022). In this study, during the monitoring period, backward trajectories  
258 showed air mass transport from the northeast, which brought halogenated VOC from  
259 Quanzhou city, an industrial city adjacent to Xiamen.

260 The maximum  $\text{PM}_{2.5}$  and  $\text{O}_3$  concentrations were approximately  $100 \mu\text{g m}^{-3}$  and  
261  $200 \mu\text{g m}^{-3}$ , respectively. The maximum daily 8 h average (MDA8)  $\text{O}_3$  concentrations  
262 were calculated according to the Ambient Air Quality Standard of China. Fig. S2 shows  
263 the positive correlation between  $\text{PM}_{2.5}$  and MDA8  $\text{O}_3$  concentrations during the whole

264 period. In Xiamen, a coastal city in Southeast China, the annual mean concentrations  
 265 of criteria air pollutants from 2015 to 2021 were significantly lower than in other  
 266 Chinese cities (Fig. S3) (Li et al., 2022; Shao et al., 2022). Meanwhile, inter-annual  
 267 averaged concentrations of O<sub>3</sub> and Ox in winter were shown in Fig S3, suggesting an  
 268 increase in atmospheric oxidation capacity (AOC) during the cold seasons. Therefore,  
 269 these two typical PM<sub>2.5</sub> and O<sub>3</sub> pollution episodes (EP1 and EP2) are worth exploring  
 270 in terms of the formation mechanisms and synergistic effects of PM<sub>2.5</sub> and O<sub>3</sub> in the  
 271 coastal city.

272  
 273 **Fig. 1. Time series of various air pollutants and meteorological parameters**

274

### 275 3.2 Chemical compositions and sources of PM<sub>2.5</sub>

276 As shown in Figure 2, an overall increasing trend is clearly observed in both bulk  
277 PM<sub>2.5</sub> and its major components during EP1 and EP2. Nitrate and organic matter (OM)  
278 remain the top two dominant PM<sub>2.5</sub> components, followed by sulfate and ammonium.  
279 The mean concentrations of SO<sub>4</sub><sup>2-</sup>, NO<sub>3</sub><sup>-</sup>, and NH<sub>4</sub><sup>+</sup> during EP1 and EP2 were 7.07 μg  
280 m<sup>-3</sup> and 5.87 μg m<sup>-3</sup>, 14.95 μg m<sup>-3</sup> and 9.69 μg m<sup>-3</sup>, and 6.77 μg m<sup>-3</sup> and 4.46 μg m<sup>-3</sup>,  
281 respectively (Table S1). The increase in EC indicates the contributions of local  
282 anthropogenic emission sources, such as vehicle exhausts (Fig. 2). The concentrations  
283 and percentages of OC and EC during different periods are illustrated in Fig. S4 and  
284 Table S1. The average OC and EC concentrations during EP1 and EP2 were 6.36 μg  
285 m<sup>-3</sup> and 7.48 μg m<sup>-3</sup> and 1.23 μg m<sup>-3</sup> and 1.29 μg m<sup>-3</sup>, respectively, which were notably  
286 higher than those during Pre-EP1 and Pre-EP2. These results are consistent with the  
287 increase in primary emissions and secondary formation contributing to complex air  
288 pollution during the rapid urbanization and industrialization stages in China (Xiao et  
289 al., 2022; Jiang et al., 2022).

290

291 **Fig. 2. Time series of PM<sub>2.5</sub> chemical composition and sources apportionment by the PMF**  
 292 **model. In the legends, OM refers to organic matter, calculated as 1.4×OC; “Tracers” includes**  
 293 **elements other than Na, Cl, S, K, Al, Si, Ca, Fe; “Crustal” represents crustal materials,**  
 294 **calculated as 1.89×Al+2.14×Si+1.4×Ca+1.43×Fe; and “Salts” includes Na<sup>+</sup> and Cl<sup>-</sup>.**

295 The PMF model was applied to conduct high-time-resolution source  
 296 apportionment of PM<sub>2.5</sub>, based on online hourly measurement data (Hong et al., 2021;  
 297 Chow et al., 2022). The factor profiles and the contributions of various sources to PM<sub>2.5</sub>  
 298 are shown in Fig. 2 and Fig. S5. Previous studies have indicated that construction and  
 299 road dust is characterized by high loadings of Al, Si, Ca<sup>2+</sup>, Na<sup>+</sup>, Mg<sup>2+</sup>, and Zn (Rienda  
 300 and Alves, 2021). In this study, the factor of dust (Factor 1) was identified by the high  
 301 contributions of Si (Fig. S5). The PMF analysis revealed that the contribution of dust  
 302 to PM<sub>2.5</sub> ranged from 5.8% to 8.9% during EP1 and EP2, compared to 1.4% during Pre-  
 303 EP1 (Fig.2). Factor 2, contributing to the high loading of metal elements (Mn, Zn, Fe,  
 304 Pb, and As), was characterized by industrial emissions (Belis et al., 2019). The

305 contributions from the industry during EP1 and EP2 remained constant. In factor 3,  $K^+$   
306 was dominant, and it was identified as coming from combustion sources (Watson et al.,  
307 2001). Biomass burning could change the contribution of combustion to  $PM_{2.5}$  at the  
308 monitoring site through long-range transport. During EP2, the influence of combustion  
309 sources (e.g., biomass burning) significantly decreased, due to reduced anthropogenic  
310 emissions and the arrival of clean air masses from the ocean (Figs. S6 and S7). Factor  
311 4, with the highest proportion of  $Na^+$  and  $Mg^{2+}$  loadings, was associated with the  
312 influence of sea-salt aerosol (Polissar et al., 1998). The percentages of sea salt (8-10%)  
313 during Pre-EP2 and EP2 were relatively high. Factor 5 exhibited high contributions of  
314 EC, OM, and Pb, which are general indicators of vehicle exhaust (Belis et al., 2019).  
315 During EP2, the contribution of traffic increased up to 35.3%. Factor 6 was associated  
316 with secondary aerosol, characterized by high loadings of  $SO_4^{2-}$ ,  $NO_3^-$ , and  $NH_4^+$ . The  
317 increased contributions of secondary formation during EP1 and EP2 accounted for 47.8%  
318 and 38.1%, respectively.

319

### 320 **3.3 Formation mechanism of $PM_{2.5}$**

321 As shown in Fig. S8,  $SO_4^{2-}$  was correlated with  $NH_4^+$  ( $R^2 = 0.72-0.88$ ), and the  
322 line fit of  $NH_4^+$  and  $SO_4^{2-}$  showed a slope of 1.78-2.67, suggesting the dominant form  
323 of  $(NH_4)_2SO_4$ . Similarly,  $NO_3^-$  was also correlated with  $NH_4^+$  ( $R^2 = 0.77-0.93$ ),  
324 indicating the presence of  $NH_4NO_3$ . In addition, the ratio of  $NH_4^+$  to the sum of  $NO_3^-$   
325 and  $SO_4^{2-}$  was close to 1, indicating complete neutralization of sulfate and nitrate by  
326 ammonium (Fig. 8c). However, there was no significant difference in the existing form

327 of SNA in PM<sub>2.5</sub> during EP1 and EP2.

328 The variations of sulfur oxidation rate (SOR) and nitrogen oxidation rate (NOR)  
329 under different periods are shown in Table S1. It should be noted that SOR (0.38±0.18)  
330 and NOR (0.32±0.08) during EP1 were the highest, indicating a high oxidation rate of  
331 SO<sub>2</sub> and NO<sub>2</sub>. According to RH, T, and UV (Table S1), noticeable differences in  
332 meteorological conditions were observed under different periods. In this study, LWC  
333 was positively correlated with SO<sub>4</sub><sup>2-</sup>, NO<sub>3</sub><sup>-</sup>, and NH<sub>4</sub><sup>+</sup> (known as the secondary  
334 inorganic aerosol, SIA) (Fig. S9), suggesting the influence of the aqueous phase process,  
335 including reactions with O<sub>3</sub>, OH, H<sub>2</sub>O<sub>2</sub>, and organic peroxides (Gen et al., 2019; Wang  
336 et al., 2023).

337 Current studies have found that O<sub>3</sub>, H<sub>2</sub>O<sub>2</sub>, OH, and transition-metal-catalyzed  
338 (TMI) O<sub>2</sub> can trigger the secondary formation of SO<sub>4</sub><sup>2-</sup> (Hong et al., 2021; Gen et al.,  
339 2019). However, the relative importance of these oxidants in enhancing the formation  
340 of SO<sub>4</sub><sup>2-</sup> is still a topic of debate. As shown in Fig. 3(b) and (c), a good correlation was  
341 found between SO<sub>4</sub><sup>2-</sup> and Fe and Mn. The TMI-catalyzed oxidation contributed to the  
342 formation of SO<sub>4</sub><sup>2-</sup>, which occurred in both cloud processes and during haze episodes  
343 (Li et al., 2020) because the Mn catalytic reaction rapidly occurred at the aerosol surface  
344 and could oxidize S(IV) through the production of intermediate Mn(III) (Wang et al.,  
345 2021). Even at very low concentrations of Mn, the Mn catalytic reaction, consuming  
346 oxygen and SO<sub>2</sub>, could produce sulfate. Under low aerosol pH conditions, the catalytic  
347 reaction of TMIs plays an important role in the oxidation of S(IV). In this study, low  
348 aerosol pH ranged from 2 to 4 was observed, indicating the potential influence of TMI-

349 catalyzed oxidation. In the future, it is vital to further evaluate the interaction of sulfate  
350 formation and Fe/Mn, and to elucidate the main pathway of the S(IV) oxidation in the  
351 coastal areas. In addition, as an important intermediate product in atmospheric  
352 photochemical reactions, the formation and removal of HCHO are closely related to  
353 OH and HO<sub>2</sub> radicals, which directly affect atmospheric reactivity and oxidation ability  
354 (Wu et al., 2023; Zhang et al., 2021). In this study, the correlations ( $R^2 = 0.415$ ) between  
355 HCHO and sulfate concentrations were also examined, as displayed in Fig. 3(a). Recent  
356 studies have shown that HCHO can react with hydrogen peroxide (H<sub>2</sub>O<sub>2</sub>) to produce  
357 hydroxymethyl hydroperoxide, which rapidly oxidizes dissolved sulfur dioxide (SO<sub>2</sub>,  
358 aq) to sulfate (Dovrou et al., 2022).

359

360 **Fig.3. Correlations between the concentrations of sulfate and HCHO (a), Fe (b), and Mn (c)**

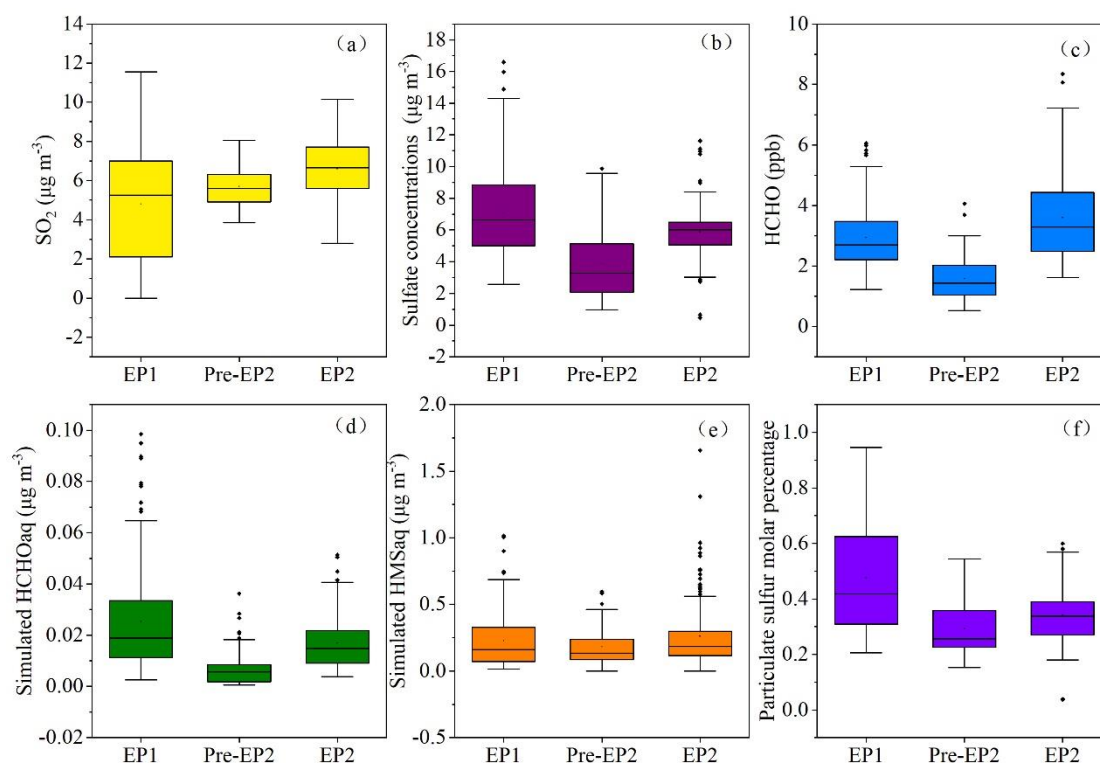

361

### 362 3.4 Effects of HCHO on HMS in PM<sub>2.5</sub>

363 To calculate the particulate concentrations of HCHO and its contributions to the  
364 heterogeneous formation of HMS, we conducted the in-situ multiphase chemical  
365 simulations by combining the zero dimensional multiphase chemical box model with  
366 RACM2 and CAPRAM 3.0. During EP1 and EP2, the concentrations of HCHO (aq)  
367 and HMS (aq), as well as the particulate sulfur molar percentage, increased with the  
368 rise of SO<sub>2</sub>, SO<sub>4</sub><sup>2-</sup>, and HCHO concentrations (Fig. 4). Also, particulate sulfur molar  
369 percentage was higher during the pollution periods, which may due to the high  
370 concentrations of gaseous precursors (SO<sub>2</sub>, HCHO) and favorable aerosol properties  
371 (i.e. pH and aerosol water content) promoted the heterogeneous processes. Previous  
372 studies have modeled that 1 ppb of gas-phase HCHO could yield up to ~5 μg m<sup>-3</sup> HMS  
373 and identified that HCHO emissions was one of key factors controlling HMS formation  
374 during the winter haze (Moch et al., 2018). All above signify the important contributions  
375 of HCHO on the heterogeneous formation of HMS and particulate sulfur chemistry,  
376 especially during the pollution periods.

377 However, the molar ratio of HMS to sulfate were very low, suggesting the limited  
378 contributions of HMS concentrations to inorganic sulfate concentrations. Potential roles  
379 of HCHO in the HMS formation in coastal city of southeast China was differed from  
380 those in the megacities of China. Previous studies found that HCHO reacts with  
381 dissolved SO<sub>2</sub> (aq) to produce hydroxymethanesulfonate (HMS), which, upon  
382 oxidation with the hydroxyl radical (OH), forms sulfate (Ma et al., 2020; Moch et al.,  
383 2020). Ma et al. (2020) reported that heterogeneous formation of HMS accounted for

384 15% of OM, and resulted in 36% overestimates of sulfate during the winter haze in  
385 Beijing.

386  
387 **Figure 4. Concentrations of SO<sub>2</sub>, SO<sub>4</sub><sup>2-</sup>, and HCHO observed at different pollution stages.**  
388 **The simulated HCHO (aq) and HMS (aq) were also presented. The particulate sulfur molar**  
389 **percentage was calculated as  $[n(\text{SO}_4^{2-})+n(\text{HMS})]/[n(\text{SO}_4^{2-})+n(\text{HMS})+ n(\text{SO}_2)]$ . In the box-**  
390 **whisker plots, the whiskers, boxes, and points indicate the 5<sup>th</sup>/95<sup>th</sup>, 25<sup>th</sup>/75<sup>th</sup>, 50<sup>th</sup> percentiles,**  
391 **and mean values.**

392 High concentrations of HMS were captured under high RH and moderately acidic  
393 pH conditions (Fig. 5). Previous studies have also indicated that high RH promotes  
394 rapid HMS formation during winter haze, as the aerosol water content could provide  
395 numerous reaction interfaces for HMS formation (Ma et al., 2020). Meanwhile,  
396 atmospheric sulfur tended to distribute into the particle phase with increasing RH. Fig.  
397 5 shows that HMS formation is favored under pH conditions close to 4.0. Previous  
398 studies reported that high HMS concentrations were found under moderate-pH

399 conditions, as low pH inhibits HMS formation, and high pH is unsuitable for its  
400 preservation (Ma et al., 2020; Campbell et al., 2022). Therefore, the combination of  
401 high precursor concentrations (SO<sub>2</sub> and HCHO), high RH, and moderately acidic pH  
402 enhanced the heterogeneous formation of HMS in the coastal city.

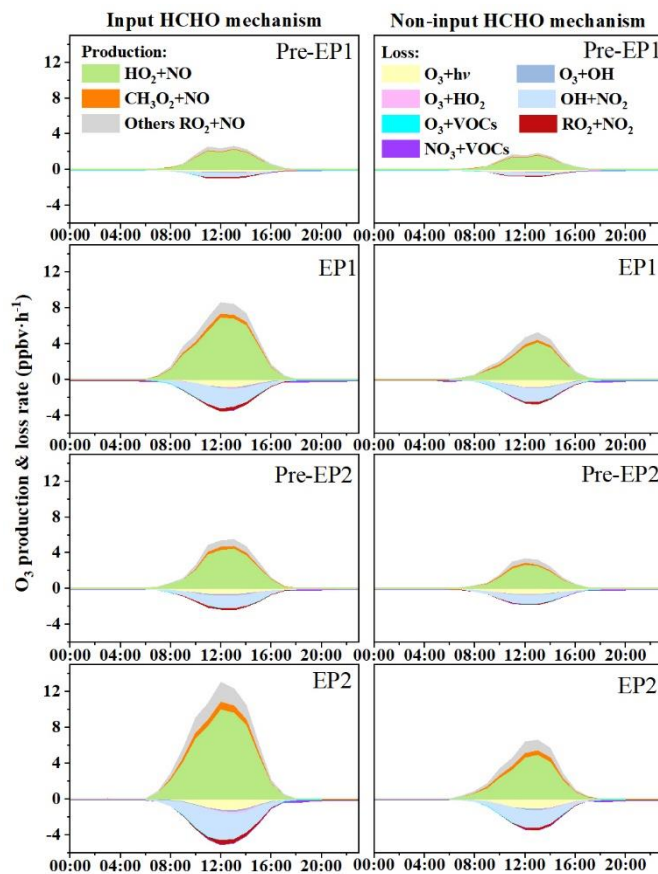

403  
404 **Figure 5. Evolution of HMS (aq) distribution with increasing RH, colored according to**  
405 **aerosol pH.**  
406

### 407 3.5 Effects of HCHO on O<sub>3</sub> formation

408 To investigate the effects of HCHO on O<sub>3</sub> formation during the co-occurring O<sub>3</sub>  
409 and PM<sub>2.5</sub> pollution period, the OBB was used to quantify the detailed O<sub>3</sub> production  
410 and loss pathways in both scenarios: input HCHO (IH) and non-input HCHO (NIH)  
411 (Fig. 6 and Fig. S9). The daytime production rates of HO<sub>2</sub>+NO and RO<sub>2</sub>+NO in the IH  
412 scenario were calculated to be 6.84 and 1.25 ppbv h<sup>-1</sup> for EP1 and 9.91 and 2.17 ppbv  
413 h<sup>-1</sup> for EP2, respectively. Meanwhile, the predominant O<sub>3</sub> loss reaction in this scenario

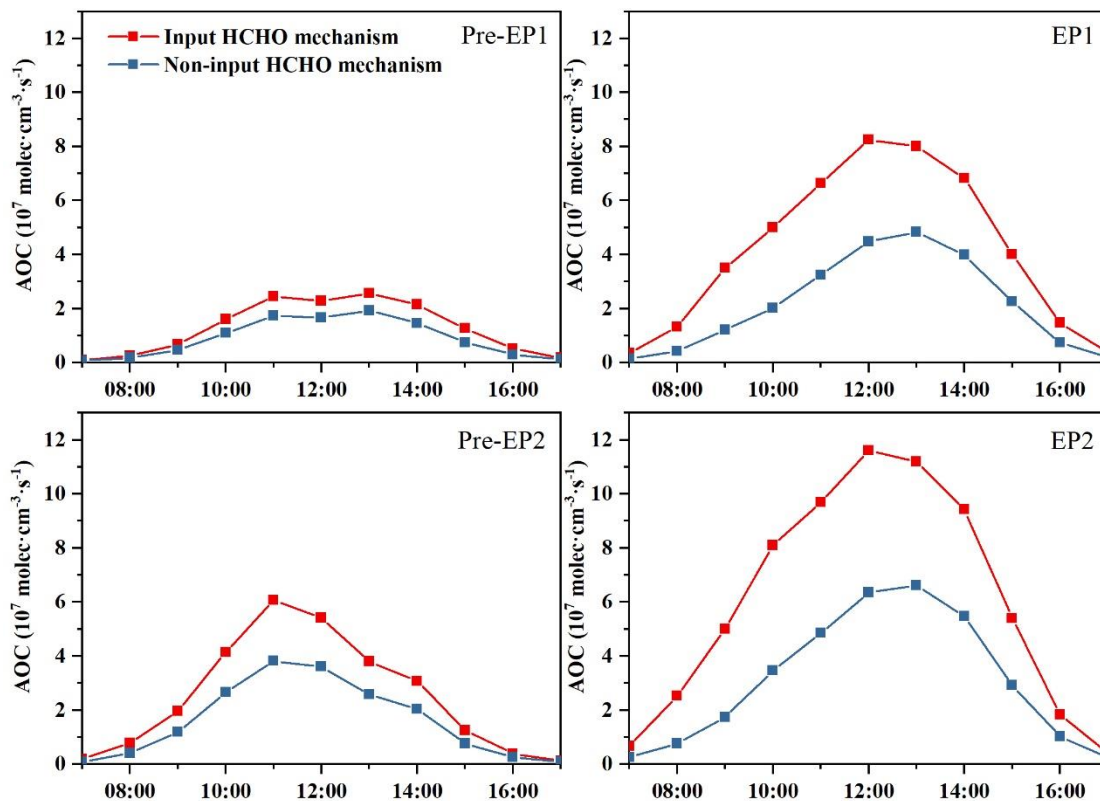

414 was OH+NO<sub>2</sub>, with rates of 2.26 ppbv h<sup>-1</sup> for EP1 and 3.17 ppbv h<sup>-1</sup> for EP2, followed  
 415 by O<sub>3</sub> photolysis with rates of 0.77 ppbv h<sup>-1</sup> and 1.10 ppbv h<sup>-1</sup>. In contrast, the daytime  
 416 production rates of HO<sub>2</sub>+NO and RO<sub>2</sub>+NO in the NIH scenario were 4.03 and 0.85  
 417 ppbv h<sup>-1</sup> for EP1 and 4.86 and 1.29 ppbv h<sup>-1</sup> for EP2, respectively. These results  
 418 indicate that disabling the HCHO mechanism reduced the production rates of HO<sub>2</sub>+NO  
 419 by 41% for EP1 and 51% for EP2. In addition, the average maximum net O<sub>3</sub> production  
 420 rate with the IH scenario was 5.02 ppb h<sup>-1</sup> for EP1 and 7.93 ppb h<sup>-1</sup> for EP2,  
 421 approximately two times higher than the values of 2.48 ppb h<sup>-1</sup> and 3.14 ppb h<sup>-1</sup> with  
 422 the NIH scenario. The results showed that the daytime net O<sub>3</sub> production rates decreased  
 423 by 50–60% when the HCHO mechanism was disabled, probably due to the decrease in  
 424 ROx concentrations and radical propagation rates (Wu et al., 2023; Zhang et al., 2021).

425

426 **Figure 6. O<sub>3</sub> production and loss rates by the OBM with and without the HCHO mechanism**

427 The atmospheric oxidation capacity (AOC) is a critical factor in determining the  
428 production rate of secondary pollutants and atmospheric photochemical pollution (Jia  
429 et al., 2023; Qin et al., 2022). In this study, AOC is calculated as the sum of the oxidation  
430 rates of various primary pollutants (e.g., CO, NO<sub>x</sub>, and VOCs) by major oxidants (i.e.,  
431 OH, O<sub>3</sub>, and NO<sub>3</sub>). The model-simulated AOC, OH, HO<sub>2</sub>, and RO<sub>2</sub> under different  
432 periods are shown in Fig. 7 and Fig. 8. The daily maximum AOC during EP1 and EP2  
433 was  $8.24 \times 10^7$  and  $11.6 \times 10^7$  molecules  $\text{cm}^{-3} \text{s}^{-1}$ , respectively, which were higher than  
434 those ( $2.56 \times 10^7$  and  $5.39 \times 10^7$  molecules  $\text{cm}^{-3} \text{s}^{-1}$ ) in other periods. However, when the  
435 HCHO mechanism was disabled, the daily maximum AOC during different stages  
436 decreased significantly. Especially, HCHO played much important role in AOC during  
437 the co-occurring PM<sub>2.5</sub> and O<sub>3</sub> pollution periods. All these results are comparable to rural  
438 sites in Hong Kong ( $6.2 \times 10^7$ ) and Berlin ( $1.4 \times 10^7$  molecules  $\text{cm}^{-3} \text{s}^{-1}$ ) but lower than  
439 those observed in highly polluted cities, such as Santiago ( $3.2 \times 10^8$  molecules  $\text{cm}^{-3} \text{s}^{-1}$ )  
440 and Shanghai ( $1.0 \times 10^8$  molecules  $\text{cm}^{-3} \text{s}^{-1}$ ) (Li et al., 2018; Xue et al., 2016; Liu et al.,  
441 2022a). These studies have reported that the variations in AOC are related to precursor  
442 concentrations/types and photochemical conditions.

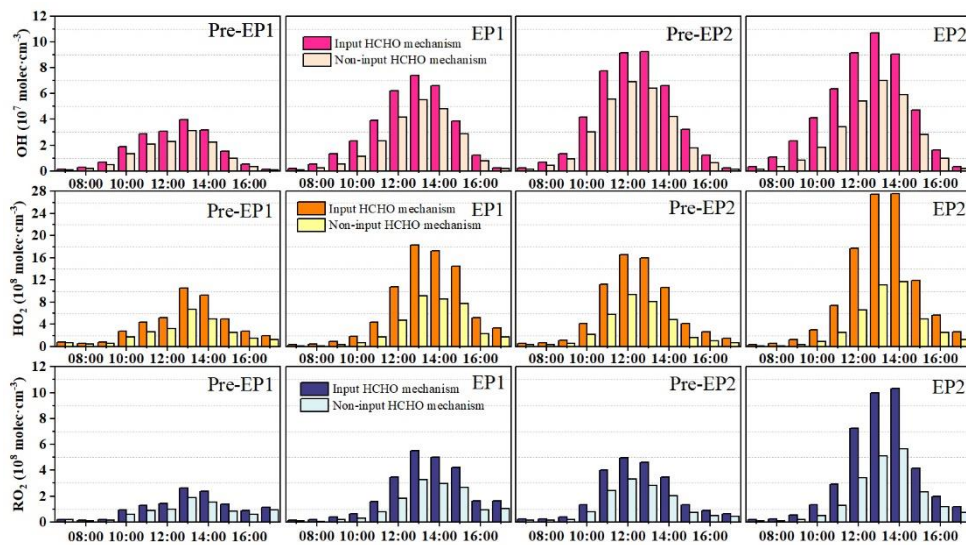

443

444 **Figure 7. Atmospheric oxidation capacity (AOC) calculated by the OBM with and without**  
 445 **the HCHO mechanism.**

446 In addition, the maximum daily concentrations of OH, HO<sub>2</sub>, and RO<sub>2</sub> exhibited a  
 447 similar pattern to that of AOC in both the IH and NIH scenarios (Fig. 8). Therefore, the  
 448 O<sub>3</sub> production rate during EP1 and EP2 was consistent with the maximum daily values  
 449 of AOC, OH, HO<sub>2</sub>, and RO<sub>2</sub>. The differences in RO<sub>x</sub> levels between the IH and NIH  
 450 model scenarios were also calculated (Fig. S10). In this study, disabling the HCHO  
 451 mechanism led to decreased RO<sub>x</sub> concentrations, affecting the O<sub>3</sub> formation. These  
 452 results highlight the significance of HCHO in the photochemical reactions occurring in  
 453 the coastal city during the co-occurring O<sub>3</sub> and PM<sub>2.5</sub> pollution events.

454

455

456

457

458

459

## 460 **Conclusions**

461 A wintertime co-occurring O<sub>3</sub> and PM<sub>2.5</sub> pollution event was selected to investigate  
462 the synergistic effects between PM<sub>2.5</sub> and O<sub>3</sub> in a coastal city in southeast China. The  
463 results demonstrated a positive correlation between PM<sub>2.5</sub> and MDA8 O<sub>3</sub>  
464 concentrations during the whole periods, indicating the enhancement of atmospheric  
465 oxidation capacity (AOC) during cold seasons. The result of positive matrix  
466 factorization (PMF) analysis suggested that the contribution of secondary formation to  
467 PM<sub>2.5</sub> increased during the pollution events, implying that the elevated AOC promoted  
468 the oxidation of SO<sub>2</sub>, NO<sub>x</sub>, and VOCs, leading to the formation of secondary inorganic  
469 and organic components. We also found the significant correlations ( $R^2 = 0.415\text{--}0.477$ )  
470 between HCHO, Fe, Mn, and sulfate concentrations, suggesting the influence of  
471 catalyzed oxidation in the coastal city. Through OBM analysis, we demonstrated that  
472 high concentrations of precursors (SO<sub>2</sub> and HCHO), high RH, and moderately acidic  
473 pH conditions enhanced the heterogeneous formation of hydroxymethanesulfonate  
474 (HMS). Meanwhile, we verified that the input HCHO mechanism increased the  
475 concentrations of RO<sub>x</sub> and net O<sub>3</sub> production rates. Moreover, the production rates of  
476 HO<sub>2</sub>+NO and RO<sub>2</sub>+NO were enhanced, indicating that HCHO affected O<sub>3</sub> formation  
477 by controlling the efficiencies of radical propagation. This study highlighted the  
478 influence of the HCHO mechanism on photochemical reactions and the formation of  
479 HMS in PM<sub>2.5</sub> in coastal cities and was beneficial for improving air quality and  
480 protecting public health.
