## Abstract

Many studies have shown that emission inventories are one of the input with the most critical influences on the results of air quality modeling. Comparing emission inventories among themselves is therefore essential to build confidence in emission estimates. In this work we extend the approach of Thunis et al. (2022) to compare emission inventories by building a benchmark that serves as reference for comparisons. This benchmark is an ensemble that is based on three state-of-the-art EU-wide inventories: CAMS-REG, EMEP and EDGAR. The ensemble-based methodology screens differences between inventories and the ensemble. It excludes differences that are not relevant and identifies among the remaining ones, those that need special attention. We applied the ensemble-based screening to both a EU-wide and a local (Poland) inventory.

The EU-wide analysis highlighted a large number of inconsistencies. While the origin of some differences between EDGAR and the ensemble can be identified, their magnitude remains to be explained. These differences mostly occur for SO<sub>2</sub>, PM and NMVOC, for the industrial and residential sectors, and reach a factor 10 in some instances. Spatial inconsistencies mostly occur for the industry and other sectors.

At the local scale, inconsistencies relate mostly to differences in country sectorial shares that result from different sectors/activities being accounted for in the two types of inventories. This is explained by the fact that some emission sources are omitted in the local inventory due to lack of appropriate geographically allocated activity data. We identified sectors and pollutants for which discussion between local and EU-wide emission compilers would be needed in order to reduce the magnitude of the observed differences (e.g. in the residential and industrial sectors).

43 The ensemble-based screening proved to be a useful approach to spot inconsistencies by  
44 reducing the number of necessary inventory comparisons. With the progressive resolution of  
45 inconsistencies and associated inventory improvements, the ensemble will improve. In this sense,  
46 we see the ensemble as a useful tool to motivate the community around a single common  
47 benchmark and monitor progress towards the improvement of regional and locally developed  
48 emission inventories.

52 ensemble

## 53 1. Introduction

54 Many studies have shown that emission inventories are one of the inputs with the most critical  
55 influences on the results of air quality modeling (Kryza et al., 2015, Zhang et al., 2015). Even  
56 more concerning, certain studies have shown that important uncertainties affect emission  
57 inventories, which may impeach conclusions based on air quality model results (Trombetti et al.,  
58 2018, Markakis et al., 2015). These uncertainties result from the need to compile a wide variety  
59 of information to develop an emission inventory. For the many pollutants and activity sectors to  
60 cover, the spatial and temporal distribution of emissions is typically based on proxies that can be  
61 estimated through different methods.

62  
63 In Thunis et al. (2022), we showed that comparing emission inventories is an effective way to  
64 detect inconsistencies when differences are very large. A methodology was designed to compare  
65 two emission inventories, one against the other. This methodology identifies disparities between  
66 the two inventories by assessing country totals, their sectorial share and the proportion of the  
67 country emissions attributed to the urban areas. In this work, we adhere to the same principle of  
68 analyzing differences while introducing a novel ensemble concept to facilitate the simultaneous  
69 comparison of a larger number of inventories.

70  
71 Ensemble of models have widely been used in climate (Kotlarski et al., 2014) and air quality  
72 modelling fields throughout the world (Stevenson et al., 2006; Vautard et al, 2009; Marecal et al.  
73 2015; Brasseur et al., 2019) as they generally provide better and more robust results. While in  
74 some instances, reference values (e.g., measurements) exist against which models can be  
75 compared, this is unfortunately not the case for emissions, and hence the emission ensemble is  
76 not necessarily better than any of its members. The emission ensemble is therefore not a more  
77 accurate inventory. This is, however, not an issue as the ensemble is used here as a common  
78 benchmark for comparison. Moreover, our focus is on differences between emission estimates  
79 rather than on their absolute values, for which accuracy and robustness is of secondary  
80 importance. The underlying concept is that above a certain threshold, differences are so large that  
81 one or both inventories can be considered wrong. The choice of this vocabulary, i.e. wrong is  
82 intentional and is meant here to foster the process of reviewing the data when differences exceed  
83 a given threshold. In other words, a factor 100 difference between inventories for a given  
84 sector/pollutant most likely reveals one or more significant errors (or inconsistencies) which are  
85 relatively straightforward to identify and must be addressed in either one or both inventories.  
86 The methodology screens differences between inventories, excludes differences that are not

87 relevant (i.e., large differences on low emission values are disregarded) and identifies among the  
88 remaining ones, those that need special attention.

89  
90 In addition to this key advantage, several other objectives are pursued by introducing the  
91 ensemble for EU wide emission inventories, namely (1) to create a unique common benchmark  
92 to monitor and quantify the current level of agreement among the ensemble members; (2) to  
93 identify and characterize the largest mismatches in terms of pollutant, sector among them; (3) to  
94 foster interactions between EU wide emission inventory developers around identified  
95 inconsistencies and (4) to allow for comparing additional inventories (e.g. bottom-up ones) with  
96 the ensemble. A comparison of the ensemble with local (intended here as national or sub-  
97 national) inventories can be indeed helpful, as they are independent estimates, which methods  
98 are based on local knowledge and understanding of the activities and processes that result on  
99 emissions.

100  
101 The work is structured as follows. In Section 2, we review the screening methodology proposed  
102 in Thunis et al. (2022) and discuss the construction of the ensemble in the frame of this screening  
103 approach. In Section 3, we apply the ensemble-based screening approach to one European-wide  
104 inventory whereas in Section 4 we illustrate how this ensemble can then be compared to local  
105 inventories in a bilateral manner. For the latter, a local inventory developed for Poland is used. In  
106 Section 5, we discuss the main findings from both type of comparisons and conclude in Section  
107 6.

108

## 109 2. Description of the methodology

### 110 2.1 Overview of the screening methodology

111  
112 In this section, we provide a brief summary of the screening method detailed in Thunis et al.  
113 (2022). The approach aims at comparing two emission inventories over a series of urban areas  
114 over which the consistency is assessed for all sectors and pollutants. Based on gridded annual  
115 emissions detailed in terms of pollutants (“ $p$ ”) and sectors of activity (“ $s$ ”), the data required for  
116 each pollutant and sector ( $[p,s]$  couple) are twofold and consist of (1) emissions aggregated over  
117 specific urban areas (lowercase notation  $e_{p,s}$ ) and country scale emissions (uppercase notation  
118  $E_{p,s}$ ).

119  
120 The consistency between emissions in both inventories is assessed around three aspects: (1) the  
121 total pollutant emissions assigned at country level; (2) the way these country emissions are  
122 distributed across sector and 3) the way country emissions are distributed spatially, and  
123 therefore, allocated to main urban areas. To address these three aspects, we decompose the ratio  
124 of the known pollutant-sector emissions for each city as follows:

125

$$\frac{e_{p,s}^1}{e_{p,s}^2} = \frac{e_{p,s}^1}{E_{p,s}^1} * \frac{E_{p,s}^1}{E_p^1} * \frac{E_p^1}{E_p^2} * \frac{E_p^2}{E_{p,s}^2} \tag{1}$$

126  
 127  
 128  
 129  
 130  
 131  
 132  
 133  
 134  
 135  
 136

where  $\bar{E}_p$  represents the country scale emissions summed over all sector for a given pollutant. Superscripts refer to the two inventories used for the screening. Equation (1) is an identity where all terms are known from input quantities, i.e. the city and country scale emissions detailed in terms of pollutants and sectors. The three terms on the right-hand side of the identity provide information on spatial distribution (*FAS*, Focus Area Share), on the country sectorial share (*LSS*, Large Scale Sectorial share) and on the country pollutant totals (*LPT*, Large scale Pollutant Total).

For convenience, we rewrite equation (1) in logarithm form as:

$$\log\left(\frac{e_{p,s}^1}{e_{p,s}^2}\right) = \log\left(\frac{\frac{e_{p,s}^1}{\bar{E}_{p,s}^1}}{\frac{e_{p,s}^2}{\bar{E}_{p,s}^2}}\right) + \log\left(\frac{\frac{\bar{E}_{p,s}^1}{\bar{E}_p^1}}{\frac{\bar{E}_{p,s}^2}{\bar{E}_p^2}}\right) + \log\left(\frac{\bar{E}_p^1}{\bar{E}_p^2}\right) \quad (2)$$

137  
 138  
 139

Which can be rewritten as equation (3) with simplified notations:

$$\hat{e} = \widehat{FAS} + \widehat{LSS} + \widehat{LPT} \quad (3)$$

140  
 141  
 142  
 143  
 144

where the hat symbol (^) indicates that quantities are expressed as logarithmic ratios. These three quantities form the basis of the screening methodology and serve as input information for a graphical representation that facilitates the interpretation of the results.

145  
 146  
 147  
 148  
 149  
 150  
 151  
 152

As the number of  $[p,s]$  points under screening, equivalent to the product of the number of pollutants and sectors further multiplied by the number of urban areas (i.e.  $N \times N_p \times N_s$ ), may become overwhelming, we adopt a series of steps to concentrate the screening on priority aspects. First, we restrict the screening to emissions that are relevant, i.e. large enough. As shown in Thunis et al. (2022), this exclusion step leads to eliminating a large fraction of the  $[p,s]$  couples from the screening process (between 80 and 90%). Second, we flag, among the remaining emissions, only those for which inventory emission ratios are larger than a given threshold ( $\beta_t$ ).

153  
 154  
 155  
 156  
 157  
 158  
 159  
 160  
 161  
 162

When differences are small, it is not possible to tell whether they originate from methodological choices or from errors. We refer to these small differences as “uncertainty”. Although very large differences may result from methodological choices as well (e.g., inclusion or not of particulate matter condensable emissions for the residential sector), they are more likely to be associated to errors. Given the magnitude of the differences, it will in most cases be possible to identify one best value out of the two inventory estimates, even though the true emissions are unknown. These large differences are named “inconsistencies”. In the proposed screening methodology, a  $\beta_t$  threshold of 2 (free parameter) is introduced to distinguish inconsistencies from uncertainties.

163  
 164  
 165

As a follow-up step, all  $[p,s]$  couples that remain after the relevance test and inconsistency detection steps ( $\beta_{p,s} > \beta_t$ ), are used to calculate an “Emission Consistency Indicator (ECI)” as follows:

$$ECI = \max_{\{\text{relevant emissions}\}} \frac{\log(\beta_{p,s})}{\log(\beta_t)} \quad (4)$$

167 The ECI quantifies the maximum difference among all relevant [p,s], normalized by the  
 168 inconsistency level ( $\beta_t$ ). It therefore quantifies the ratio between the maximum inconsistency and  
 169 the assumed level of uncertainty. A value of ECI less than one means that all differences are  
 170 considered as uncertainty (in other words none of the inventory can be identified as best  
 171 performing). Together with the ECI, which quantifies this maximum difference, we associate the  
 172 percentage of inconsistent [p,s] with respect to the total number of relevant data, to provide  
 173 information on the number of detected inconsistencies.

174  
 175 Finally, we prioritise inconsistencies following the LPT – LSS – FAS hierarchy. In other words,  
 176 if large scale inconsistencies are spotted for LPT, they are flagged as the priority, regardless of  
 177 the magnitude of inconsistencies calculated for LSS and/or FAS. If no inconsistency is flagged  
 178 for LPT, the same holds for LSS regardless of the level of inconsistency calculated for FAS.  
 179 Consequently, the inconsistency flagged as priority might not be the largest inconsistency. This  
 180 hierarchy is motivated by the fact that addressing large scale inconsistencies will lead to  
 181 potentially resolving several issues at once (e.g. all urban areas within a given country).  
 182 Inconsistencies are counted when the individual terms in equation (3) are larger than the  
 183 threshold  $\beta_t$  but also when the indicators sums (i.e.,  $\widehat{FAS} + \widehat{LSS} + \widehat{LPT}$ ,  $\widehat{LSS} + \widehat{LPT}$ ) exceed this  
 184 threshold.

185  
 186 It is important to note that the method follows a bottom-up approach, i.e., we assess the three  
 187 types of inconsistencies for each city, pollutant and sector. This means that the same LPT  
 188 inconsistency is counted for all cities within a given country or for all sectors for a given  
 189 pollutant. Similarly, a LSS inconsistency is counted for each city belonging to the same country.  
 190 While this might be seen as double counting of some inconsistencies, the approach allows  
 191 comparing local vs country scale indicators.

## 192 2.2 Construction of an ensemble as reference

193  
 194 This work aims at applying a novel ensemble concept to extend the Thunis et al. (2022)  
 195 methodology to several inventories. The ensemble is calculated from EU-wide inventories that  
 196 have been developed and regularly updated over several years within the EU<sup>1</sup>. While either the  
 197 mean or the median of these inventories could be used to calculate the ensemble, we choose to  
 198 use the median as it has been shown to be a more robust indicator compared to the mean (Riccio  
 199 et al. 2007). Indeed, if one of the inventories is a strong outlier (i.e., much larger or much smaller  
 200 values), the mean would be strongly influenced by these extreme values and would differ from  
 201 the values of most of the inventories. On the other hand, the median is not affected by extreme  
 202 values and therefore takes a value closer to the values taken by most of the inventories. It  
 203 therefore remains further away from outliers, which become easier to identify.

---

<sup>1</sup> Note that EDGAR is designed as a global inventory but we consider here its European coverage only in this analysis and refer to it as a European wide inventory

204 In this work, the ensemble is created from three state-of-the-art Europe wide inventories: CAMS-  
205 REG (Copernicus Atmospheric Monitoring Service), EMEP and EDGAR.

206  
207 EDGAR is a comprehensive global emission inventory providing country and sector specific  
208 greenhouse gas and air pollutant emissions from 1970 up to date. EDGAR is becoming a global  
209 reference for anthropogenic emissions, in particular contributing to the IPCC AR6 (Sixth  
210 Assessment Report) and to the annual UNEP emissions gap reports (UNEP2023) tackling global  
211 climate change issues. In the context of air pollution, EDGAR is also widely used by air quality  
212 modellers, playing an important role as gap-filling inventory in the Hemispheric Transport of Air  
213 Pollution mosaic compilation. Emissions are computed using a consistent methodology for all  
214 world countries, following the IPCC Guidelines (IPCC 2006, 2019) and EMEP/EEA Guidebook  
215 (EMEP/EEA, 2016, 2019) for greenhouse gases (GHGs) and air pollutants, respectively.  
216 Emissions are calculated for all anthropogenic sectors outlined by the IPCC excluding Land Use,  
217 Land Use Change and Forestry. This computation utilizes international statistics and default  
218 emission factors complemented with state-of-the-art information. Subsequently, annual  
219 emissions specific to each sector and country are downscaled globally at 0.1x0.1 degree  
220 employing a multitude of spatial proxies. Comprehensive insights into the EDGAR methodology  
221 and the underlying assumptions regarding the spatial data used for downscaling national  
222 emissions are available in several scientific publications (Janssens-Maenhout et al. 2015, 2019;  
223 Crippa et al. 2018, 2021; Crippa et al. 2020; Oreggioni et al. 2022). Additionally, the yearly  
224 emission data are further disaggregated into monthly emissions to further support atmospheric  
225 modellers in capturing the seasonality of anthropogenic emissions (Crippa et al. 2020).

226  
227 CAMS-REG version 5.1 is an emission inventory developed as part of CAMS to support  
228 European scale air quality modelling (Kuenen et al. 2022). The inventory builds on the officially  
229 reported emission data to EMEP in the year 2020, which are complemented by other sources  
230 where reported data are not available or deemed of insufficient quality. The data are spatially  
231 distributed consistently across the entire domain at a resolution of 0.05x0.1 degrees (latitude-  
232 longitude). The spatial distribution takes into account specific point source emissions as reported  
233 in the European Pollutant Release and Transfer Register (EPTR2022) to correctly represent point  
234 source emissions to the extent possible. The emissions are provided in GNFR (Gridded  
235 Nomenclature For Reporting) format. The emission dataset is used in support of the CAMS  
236 regional modelling activities, but is also publicly available to support air quality assessment at  
237 European level. CAMS-REG-v5.1 is an update of version 4.2 that includes official national  
238 emission submissions for the year 2020.

239  
240 The EMEP-GNFR emissions (Mareckova et al., 2017), based on 2017 reporting, are compiled  
241 within the “UNECE co-operative programme for monitoring and evaluation of the long-range  
242 transmission of air pollutants in Europe”, or also known as EMEP. EMEP is a scientifically  
243 based and policy driven programme under the Convention on Long-range Transboundary Air  
244 Pollution (CLRTAP) for international co-operation, that has the final aim of solving  
245 transboundary air pollution problems. Emissions are built from officially reported data provided  
246 to CEIP (Centre of Emission Inventory and Projection by the Member States in Europe) and  
247 follow the EMEP/EEA guidebook guidelines (EMEP/EEA 2019) to define the annual totals. The  
248 emissions are gap-filled with gridded TNO data from CAMS and EDGAR. The dataset consists  
249 of gridded emissions for SO<sub>x</sub>, NO<sub>x</sub>, NMVOC, NH<sub>3</sub>, CO, PM<sub>2.5</sub>, PM<sub>10</sub> and PM<sub>coarse</sub> at 0.1° x

250 0.1° resolution. More information on the emissions and where to download can be found in the  
251 User Guide (<https://emep-ctm.readthedocs.io/en/latest/>) and in Mareckova et al., (2017). The  
252 EMEP domain covers the geographic area between 30°N-82°N latitude and 30°W-90°E  
253 longitude.

254  
255 Based on these three inventories, the ensemble is defined on a yearly basis (here 2018). Urban  
256 ( $e_{p,s}$ ) and country emissions ( $E_{p,s}$ ) for the selected year are required as input. Independent  
257 ensemble values for  $E$  and  $e$  are defined for each pollutant-sector couple [p,s] as the median of  
258 the three inventory values. For a given area, the urban and country scale emission ensembles for  
259 a given year read as:

$$\begin{aligned} e_{p,s}^{ens} &= \text{median} \{e_{p,s}^{CAMS}, e_{p,s}^{EMEP}, e_{p,s}^{EDGAR}\} \\ E_{p,s}^{ens} &= \text{median} \{E_{p,s}^{CAMS}, E_{p,s}^{EMEP}, E_{p,s}^{EDGAR}\} \end{aligned} \quad (5)$$

261  
262 Note that this calculation implies that  $e_{p,s}^{ens}$  and  $E_{p,s}^{ens}$  might not belong to the same inventory for a  
263 given area and pollutant-sector couple [p,s]. It is also worth mentioning that should one  
264 inventory pollutant-sector value behave as an outlier; its value will not be selected in the  
265 ensemble.

266  
267 As the three emission inventories are characterised by different grid resolutions and sector  
268 aggregations, harmonisation is required to construct the ensemble. This is done in 2 steps:

- 269
- 270 - by grouping the initial emission categories into common categories based on the GNFR  
271 classification (NFR-I, 2023 and Table 1 in supplementary material). The original GNFR  
272 sectors have been aggregated in 5 categories: road transport (F), residential (C), power  
273 plants (A), industry (B) and others. The latter category includes fugitive emissions (D),  
274 solvents (E), shipping (G), aviation (H), off-road transport (I), waste (J) and agriculture  
275 (K-L).
  - 276 - by aggregating gridded emissions on common polygons that delineate the area covered  
277 by an urban area or by a country. Urban area emissions ( $e_{p,s}$ ) are calculated over  
278 functional urban areas (FUA, OECD 2012), composed of a core city plus its wider  
279 commuting zone, consisting of the surrounding travel-to-work areas. About 150 FUAs  
280 across Europe are selected for this screening. Details on these urban areas are provided in  
281 Thunis et al. (2018). The larger scale emissions ( $E_{p,s}$ ) are defined at country level, level  
282 at which emissions are initially reported for these emission inventories.

283 In terms of pollutants, we consider NO<sub>x</sub>, NMVOC, PM<sub>2.5</sub>, PM<sub>co</sub> (coarse PM, calculated as the  
284 difference between PM<sub>10</sub> and PM<sub>2.5</sub> emissions), SO<sub>2</sub> and NH<sub>3</sub>.

285  
286 The approach then consists in comparing a given inventory with the ensemble to identify  
287 inconsistencies. It is important to note that while the approach likely highlight errors in the  
288 inventory under screening, it is however not possible to exclude that the inconsistency originates  
289 from the ensemble (i.e., be present in all other inventories). Despite this inconveniency, the  
290 method remains an efficient way to identify, among the large amount of data from several

291 inventories, those that are most likely to be problematic and therefore need to be verified in  
292 priority.

### 293 3. Application to EU-wide inventories

294  
295 The first objective of the ensemble-based screening is to systematically monitor and quantify  
296 existing uncertainties and inconsistencies within EU-wide inventories. It aims to identify the  
297 sources of discrepancies in terms of pollutant, sector and location. To perform this task, we  
298 compare bilaterally each of the three inventories to the ensemble and present the findings in  
299 Figure 1 (left). This figure provides for all ensemble members an overview of existing  
300 inconsistencies, i.e. for emissions that are relevant (i.e., large enough values) and that differ from  
301 the ensemble by more than a factor 2 ( $\beta_t = 2$ ). Each inconsistent emission [p, s] is represented  
302 by a point that has larger-scale emissions ( $\widehat{LSS} + \widehat{LPT}$ ) as abscissa and spatial distribution of  
303 emissions ( $\widehat{FAS}$ ) as ordinate. The sum of these two terms is equal for points that lie on “-1”  
304 slope diagonals. The diamond shape (in the middle of the diagram) delineates the inconsistency  
305 limits. Therefore, each [p, s] point lying outside this shape is an inconsistency. In this diamond  
306 diagram, shapes are used to differentiate activity sectors, while colors indicate pollutants. The  
307 size of the symbol is proportional to the relevance of the emission contribution. Finally, we use  
308 symbol filling to distinguish the type of inconsistencies (i.e., LPT, LSS, and FAS). We refer to  
309 Thunis et al. (2021) for details.

310  
311 The summary report (bottom part of Figure 1) provides overview information about  
312 inconsistencies. More than 21% (number within brackets beside the ECI indicator) of the  
313 relevant emission ratios show inconsistencies. The ECI indicator is equal to 132, meaning that  
314 the largest inconsistency is more than two orders of magnitude larger than the level associated to  
315 uncertainties. The EDGAR inventory is flagged for two thirds of them (the total number of  
316 inconsistencies, denoted as NI is 227 out of 357), with the largest part of them associated to  
317 industry for SO<sub>2</sub> and PM<sub>co</sub> (see numbers within brackets besides the sectors/pollutants in the  
318 bottom legend: Figure 1). Most of the inconsistencies are obtained within the allocation of  
319 emissions at urban scale (218), although an important number of them also occur at country scale  
320 (LSS+LPT=80+59). The diagram also shows that EDGAR reports larger residential and  
321 industrial emissions at country level (yellow squares on the right of the X-axis). It is important to  
322 remember that flagging one particular inventory does not necessarily indicates that this inventory  
323 is the problematic one. But this flagging means that this inventory and/or the others show an  
324 important inconsistency for that city, pollutant and sector which requires further checking.

325  
326 In addition to providing a useful summary that details the current state of variability, the diagram  
327 can also serve as basis to monitor progress, through the ECI indicator and associated percentage.  
328

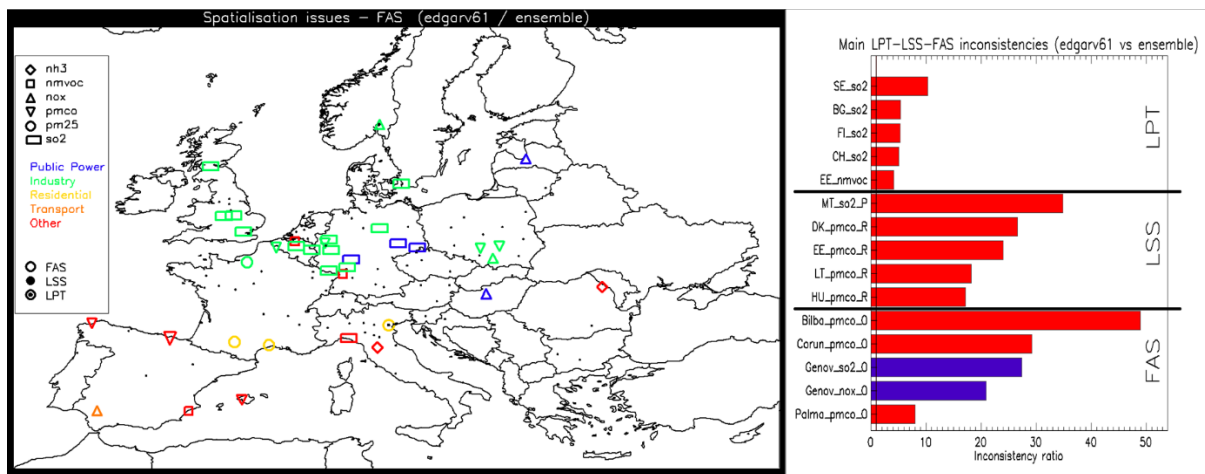

329  
 330 *Figure 1: Overview diamonds. The left diagram shows the comparison of the three ensemble members (CAMSV51, EDGAR,*  
 331 *EMEP) with the ensemble for 2018. The right picture isolates the bilateral comparison between EDGAR and the ensemble.*  
 332 *Symbols and colours are as specified in the legend. Please note that symbols/colors differ between the right and left figures. In*  
 333 *both diagrams, only inconsistencies are displayed. For visualization purposes, we limit the axis to a factor 2 in terms of*  
 334 *magnitude (from -2 to 2) and bound the ECI to 100 (e.g. values of ECI larger than 100 are plotted with a value of 2). Numbers*  
 335 *within bracket in the bottom legend are the total number of inconsistencies for a given pollutant, sector or type.*

336 The ensemble-based screening methodology also serves as a benchmark to compare individual  
 337 inventories. It is applied here (Figure 1 - right) to one of the three state of the art inventories  
 338 used to build the ensemble, EDGAR v.6.1 (Crippa et al. 2022). Results for the two other  
 339 ensemble members: CAMSV51 and EMEP (2022 gridding) are discussed in the  
 340 supplementary material (Section 1).

341 The ECI (>100) indicates that the maximum inconsistency is at least a factor 100 larger than the  
 342 estimated level of uncertainty. Moreover, about 41% of the relevant emission points show an  
 343 inconsistency. As indicated in the overview table, these 41% amount to 227 inconsistencies (NI)  
 344 which are shared into about 35% within the spatial distribution of emissions (FAS=84) and 65%  
 345 at country scale (LPT+LSS=83+80). Most of the inconsistencies are identified, as for SO<sub>2</sub>, PM<sub>co</sub>  
 346 and PM<sub>2.5</sub> from the industry sector, in line with the findings of De Meij et al. (2023). There are  
 347 also an important number of inconsistencies related to the other (46), residential (35) and public  
 348 power sectors (32). In general, for all inconsistencies, EDGAR estimates are larger than those  
 349 represented by the ensemble (all points on the right and/or top of the diagram).

350  
 351 To prioritize the inconsistency analysis, Figure 2 (right side) shows the largest differences for  
 352 LPT (country pollutant total), LSS (country sectorial share) and FAS (spatial distribution), which  
 353 are also identified on the map (left on Figure 2).

354  
 355 *Figure 2: Left: Main inconsistencies spotted at urban scale for EDGAR when compared to the ensemble. Only the main spatial*  
 356 *inconsistency (FAS) for each city is plotted. See explanation of symbols on the top left of the figure. Right: Major LPT (top 5), LSS*  
 357 *(middle 5) and FAS (lower 5) inconsistencies. The two first letters indicate the country code for LSS and LPT whereas the 4 first*  
 358 *city letters are given for FAS. Red shading indicates an overestimation and blue shading an underestimation for the EDGAR*  
 359 *inventory*

360 The following main issues can be extracted from Figure 2 for EDGAR:  
 361

- 362 • Inconsistencies in SO<sub>2</sub> country totals (LPT) are notably observed in Sweden (factor 10),  
 363 Bulgaria, Finland and Switzerland (factor 5). In the case of Sweden and Finland, we could  
 364 identify that the main difference comes from the industry sector, particularly the pulp, paper  
 365 and print sub-sector, for which the inclusion of black liquor use for energy purposes in  
 366 EDGAR need to be revised. For Bulgaria, the SO<sub>2</sub> total is dominated by the public power  
 367 sector for which the activity data, sourced from IEA energy balances, subject to regular  
 368 updates, influence the magnitude of the differences. According to the Bulgarian Informative  
 369 Inventory Report (IIR) of emissions in 2022, SO<sub>2</sub> emissions are regularly updated with  
 370 measurements, which is not the case for the EDGAR emissions estimates, explaining part of  
 371 the differences. Work is in progress to update SO<sub>2</sub> abatement measures in EDGAR. Another  
 372 issue that can explain these inconsistencies relates to the different emission factors applied  
 373 for SO<sub>2</sub> that are based on the sulphur content of fuels, usually not reported regularly by  
 374 countries, values which are integral to CAMS-REG and EMEP<sup>3</sup>. As a follow-up of this  
 375 analysis, the SO<sub>2</sub> emission factors for the power sector in EDGAR have been revised taking  
 376 into account the limits established by the implementation of the large Combustion Directive  
 377 (Directive 2001/80/EC).  
 378
- 379 • A larger sectorial share (LSS) at the country level for SO<sub>2</sub> in Malta for Public Power (factor  
 380 30), for residential PMco emissions in Denmark, Estonia (above a factor 20) and Lithuania  
 381 and Hungary (about a factor 10) is found. The large differences in the residential sector is  
 382 related to biomass burning emissions, both in terms of technology allocation and emission

<sup>3</sup> The default EMEP/EEA Guidebook 2019 emission factor for SO<sub>2</sub> are w/o abatements and only for 1% mass sulphur content for coal and oil and 0.01 g/m<sup>3</sup> for gas (EMEP/EEA guidebook 2019).

383 factors applied. Given the large differences with the ensemble, the review of the EDGAR  
384 methodology led to the indication that EDGAR estimates needed to be updated, especially in  
385 terms of technology allocation. This adjustment is important to accurately reflect the current  
386 technological structure within that sector. Although the filter on low emission values  
387 (relevance test) is applied, it is not effective in the case of Malta because it is a small country  
388 where national totals are composed of few power plants only. The large LSS ratios obtained  
389 there are not significant as the values estimated for the power plant sector appear to be very  
390 small.

391

- 392 • A few large inconsistencies also appear at the local scale (FAS) due to the use of different  
393 proxies to spatially distribute emissions. The largest inconsistencies occur for the other sector  
394 (likely originating from the waste treatment installations). This can probably be explained by  
395 the approach followed in EDGAR for the waste sector for which all emissions are distributed  
396 over a few locations only, using E-PRTR locations for landfilling and incineration and  
397 population in case of missing information. This results in large differences with other  
398 inventories due to the proportion of the emissions being placed within the city area (see  
399 Figure 7 and following in supplementary material, section 3). A similar issue appears in  
400 many north west European cities for SO<sub>2</sub> for public power (green rectangles in the left  
401 Figure). Work is in progress to update the spatial allocation of the public power and waste  
402 sectors emissions (personal communication M. Crippa 2023).

403

404 The ensemble-based comparison highlights an important number of inconsistencies at country  
405 level. While the two other ensemble members (EMEP and CAMS-REG) use (but to different  
406 extents) officially reported emissions and therefore rely on similar total emissions per country,  
407 EDGAR estimates emissions in an independent bottom-up approach, starting from activity levels  
408 and emissions factors from international agencies and bodies (Crippa et al., 2018, Oreggioni et  
409 al. 2022). This difference in approach can explain a large number of inconsistencies identified  
410 for EDGAR but some of them are very large, especially for SO<sub>2</sub> and PM in the industrial sector.  
411 For this particular sector, estimates mostly come from the LPS and E-PRTR databases in  
412 EMEP/CAMS-REG, with emissions being mostly based on measurements or facility-level  
413 estimates. Such information is not used in EDGAR, where estimates are based on fuel  
414 consumption and emission factors that are very general and not plant specific.

## 415 4. Application to local inventories: a case-study over Poland

### 416 4.1 The high resolution Poland emission inventory

417 The ensemble-based screening methodology also serves as a benchmark to compare local  
418 inventories. In this section, it is applied to the inventory for Poland.

419

420 The Central Emission Database (CED) is a local emission inventory designed for Polish national  
421 air quality modelling. The CED is based on source location and provides accurate resolution-free  
422 data, which can be gridded depending on the requested target resolution for different  
423 computational grid configurations over Poland (typically 2.5 km over the entire country and 0.5

424 km for agglomeration zones). The majority of data is processed with respect to its exact  
425 geographical location. Priority is given to the most critical sectors, like residential combustion  
426 (described in detail in Gawuc et al., 2021) and road transport. The road transport data presented  
427 in this paper (relative to 2019) was based on traffic models for the major roads in the country.  
428 Emissions on minor roads were distributed using the residue values taken from subtracting  
429 emission on major roads from the national totals. The current methodology is based on  
430 smartphone car navigation app which provides GPS data on road traffic and annual average car  
431 speed.

432  
433 One of the essential components of CED is the “National database on greenhouse gases and  
434 other substances emission” (so-called national database – NB). NB consists of information on  
435 installations and sources' location responsible for emission into the atmosphere. NB has  
436 similarities to E-PRTR, but unlike it, it covers all emission sources regardless of type, power or  
437 production level. Registered NB users provide information on emission volumes resulting  
438 directly from the exploitation of their installations, as well as ancillary processes, which may  
439 cause fugitive emissions. To be applied for CED and air quality modelling, the reported data is  
440 categorized into SNAP (Selected Nomenclature for Air Pollution) and converted to GNFR if  
441 needed (Table 1, supplementary material).

442 NB is a basis for GNRF A (public power), B (industry), D (fugitive), E (solvents), and J (waste)  
443 emission estimations contributing to CED. Two approaches are applied to evaluating CED data.  
444 Firstly, as part of each modelling stream (i.e., operational air quality forecast, annual air quality  
445 assessment, station representativeness analysis), a comprehensive evaluation is undertaken  
446 (station-by-station time series for over 100 monitoring sites for each pollutant). Moreover, spatial  
447 patterns of the increments calculated in the assimilation procedure let to identify and improve the  
448 assumptions behind CED. The database is updated every year and there is a continuous attempt  
449 to improve emission estimates both – for total load and spatial distribution of sources. Modelling  
450 results helped to identify missing sources (e.g. resuspension, underestimated agriculture sector,  
451 domestic water heating). All sectors in CED are constantly improved using the best available  
452 activity data.

453  
454 Note that the CED reference year (2019) differs from the ensemble one (2018). Inconsistencies  
455 are however generally large enough to justify explanations other than those originating from the  
456 difference in terms of reference year.

## 457 4.2 Comparison of the CED inventory to the ensemble

458  
459 The ensemble-based screening applied to Poland is performed for 14 cities (see city locations in  
460 Figure 5), 5 sectors and 6 pollutants, leading to 420 emission ratios being tested.

461  
462 Before proceeding with the screening of the local data, we first analyse the level of consistency  
463 among EU-wide inventory over Poland (Figure 3 is a zoom of Figure 1 over Poland). Among the  
464 420 available data, 84 remain after the relevance test ( $\gamma_t > 0.5$ ). These 84 [p,s] points serve as  
465 basis to identify inconsistencies ( $\beta_t > 2$ ). Inconsistencies occur for about 13% of the relevant  
466 [p,s] points, with a maximum inconsistency (ECI) 2.5 times larger than the assumed level of  
467 uncertainty. As seen from the overview table, most of the issues are related to the EDGAR (20)  
468 and EMEP (6) inventories, in particular to the residential sector for EDGAR, to the industry

469 sector for CAMS-REG and to the other sector for EMEP. Additional details are provided in the  
 470 supplementary material (Section 2).

471  
 472  
 473 *Figure 3: Overview diamonds. The diagram shows the comparison of the three ensemble members (CAMS-REG, EDGAR, EMEP)*  
 474 *with the ensemble inventory over Poland. Symbols and colours are as specified in the legend. In all diagrams, only*  
 475 *inconsistencies are displayed.*

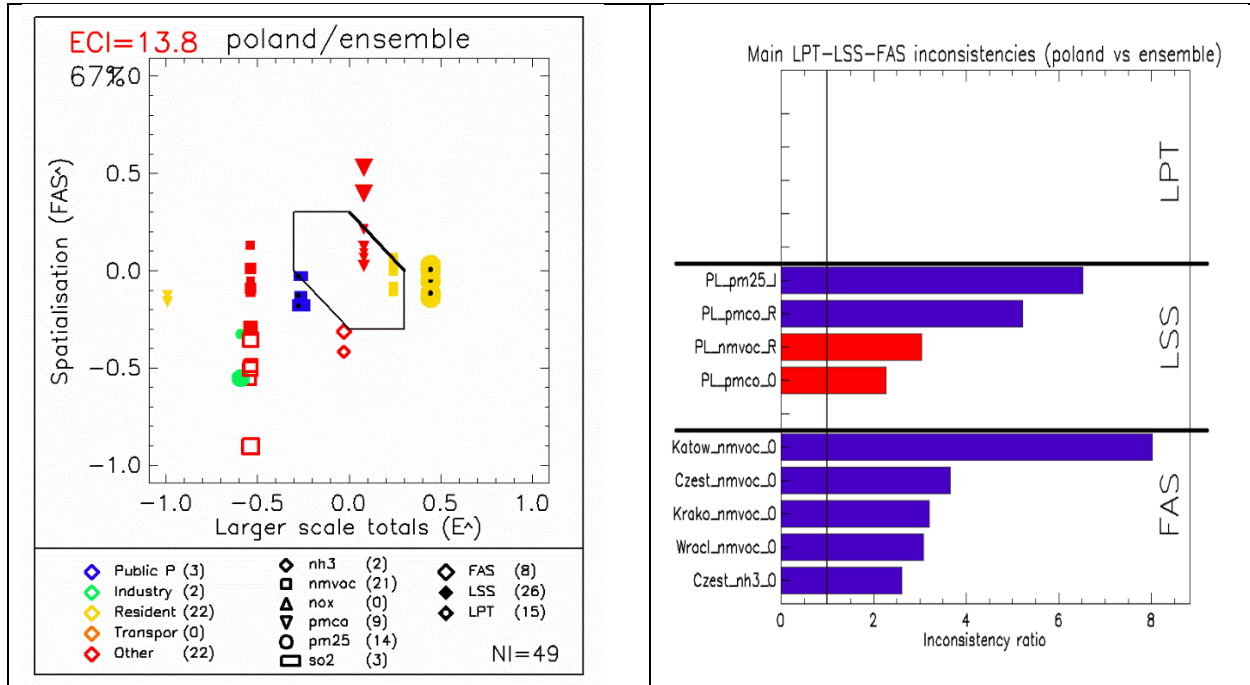

477 The overview diamond diagram (Figure 4 - left) shows the comparison of the CED local  
 478 inventory with the ensemble. It indicates that out of the 420 emission ratios being tested, only 73  
 479 are associated to relevant emissions among which 49 (i.e. 67%) are identified as inconsistencies.  
 480 The consistency indicator (ECI) is around 14, indicating that the maximum inconsistency is  
 481 larger than the assumed level of uncertainty by a factor 14. The summary table (at bottom of the  
 482 diamond, Figure 4) points to the residential and other sectors as the main issues with NMVOC  
 483 and PM<sub>2.5</sub> in terms of pollutants. Most inconsistencies originate at country level, and mostly  
 484 related to the country sectorial share.

485  
 486 PM residential emissions are systematically larger in CED than in the ensemble for PM<sub>2.5</sub>,  
 487 whereas smaller for PM<sub>co</sub>. This can be partially explained by the inclusion of condensable in  
 488 CED (not included in EU-wide ensemble). Note that including or not condensable results more  
 489 than doubles total PM<sub>2.5</sub> emissions over Poland due to the importance of residential wood  
 490 combustion emissions. Note that in this case, the CED inventory likely performs better than the  
 491 ensemble, highlighting the fact that ensemble estimates are not necessarily more accurate.  
 492 Despite this, inconsistencies are flagged and paths for improvements are identified.

493  
 494 Relatively less important but yet about a factor between 2 and 5, low values occur for SO<sub>2</sub>  
 495 emissions from power-generation sector (blue rectangles, Figure 4). As none of the three Europe-  
 496 wide inventory shows an inconsistency for this sector/pollutant, this indicates a general issue  
 497 between local and EU-wide inventories. This might be explained by the fact that CED is solely

498 based on NB, supplied directly with users' data, while Europe wide inventories (EMEP) likely  
 499 include additional emissions as they are based on overall fuel sales. In addition, point source  
 500 emissions from E-PRTR may be different from point source emissions used in national  
 501 inventories.

502  
 503 The transport and industry sectors show the lowest number of inconsistencies, which is observed  
 504 by few points related to those sectors in the diagram (Figure 4 left). While this is expected for  
 505 transport which is a diffuse source, this is surprising for the industry as this sector was the main  
 506 source of inconsistencies at Europe wide level (see Figure 3).  
 507

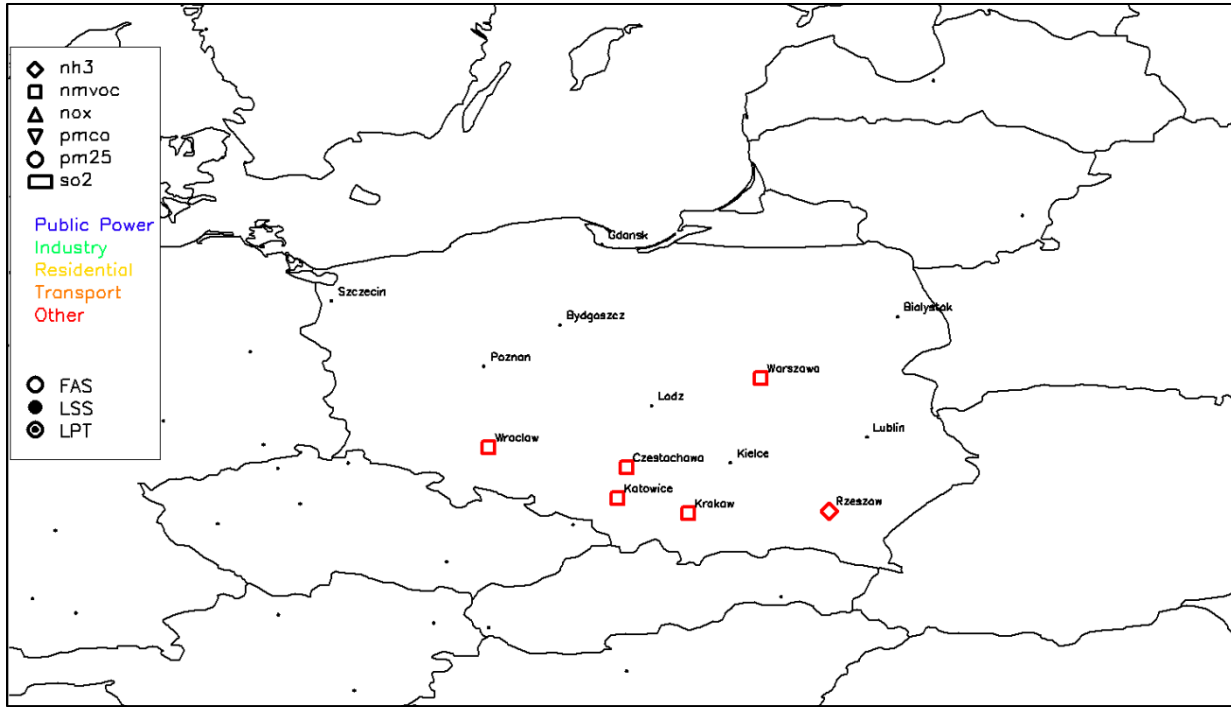

508  
 509 *Figure 4: Diamond comparison of the local Polish vs ensemble inventory (left) and comparison of the ensemble top-down*  
 510 *members vs the ensemble restricted to the Polish territory.*

511 Figure 4 (right) highlights the priorities for the analysis. At country scale, the largest  
 512 inconsistency occurs for the industrial share of PM2.5 (factor 6 larger in the Polish inventory,  
 513 LSS, Figure 4), for PMco and NMVOC from the residential sector by a factor 5 lower and 3  
 514 larger in the Polish inventory, respectively, as well as for PMco from the other sector (factor 3  
 515 lower in the Polish inventory). In the case of PM2.5, the difference can be explained by the fact  
 516 that the reports provided to NB are based on user-specific permits which specify the list of  
 517 pollutants to be reported whereas in EU wide inventories, emissions are generally calculated  
 518 using official EMEP/EEA emission factors. A comparison of EMEP and CED country totals per  
 519 pollutant and GNRf sector is available in Table 2 of supplementary material.

520  
 521 At the local scale (Figure 5), the spatial allocation of NMVOC emissions for the other sector  
 522 leads to important differences in cities like Katowice (factor 8, Figure 4 – right), Czestochowa  
 523 and Krakow. A similar situation is found for PM in Kielce. We see from Figure 4 that this issue  
 524 occurs for many cities in the southern part of Poland. The large differences spotted in some cities

525 (e.g. Kielce) are likely caused by emissions from heaps and excavations. While in CED,  
 526 emissions from these sources are accounted for, only emissions from brown coal excavations  
 527 (part of NFR 1B1a) are included in the EMEP inventory. Hence, including all heap and  
 528 excavations emissions in EU-wide inventories would be advisable.  
 529

530  
 531  
 532 *Figure 5: overview of inconsistencies for the comparison between local emission inventory in Poland and the Europe wide*  
 533 *emission inventory ensemble*

534 In conclusion, the comparison of the Polish inventory with the ensemble mostly spots issues that  
 535 are related to a difference in terms of sectorial share at country level, explained by the  
 536 accounting of different sources in the two types of inventories. A similar argumentation can  
 537 explain part of the large discrepancies observed in some cities. Most of the issues occur for the  
 538 residential and other sectors and mostly for PM and NMVOC. Although the number of  
 539 inconsistencies may seem large, many of these are similar for all cities.  
 540 Inconsistencies in the spatial distribution of the emissions are relatively minor. This is due to the  
 541 fact that EMEP reports for Poland, used in two out of three EU-wide inventories in the ensemble,  
 542 are gridded by Polish experts, utilizing spatial proxies based on CED activity data for several  
 543 sectors like stationary combustion, road transport and livestock (last updated in 2021,  
 544 Bebkiewicz et al. 2022).

## 545 5. Added value and limitations of the ensemble approach

546  
 547 European wide inventories are not totally independent of each other. Interlinkages between the  
 548 CAMS-REG, EDGAR and EMEP inventories exist. For example, the link between EMEP and  
 549 CAMS-REG is that (1) both inventories rely on country reported data and may use the same  
 550 spatial proxies when country do not report. EMEP is also linked to EDGAR as it uses in some  
 551 cases EDGAR distribution as a proxy for gridding in case a Party is not reporting (CEIP2022).

552 Consequently, these interlinkages hide some of the inconsistencies, when all inventories behave  
553 similarly. It is however expected that repeated screenings lead to improvements and to a  
554 progressive convergence among inventories, hence reducing the number of flagged  
555 inconsistencies.

556  
557 In our work, the number of members of the ensemble is limited to three. This would be an issue  
558 if the goal were to obtain more accurate and robust results with the ensemble. In such a case, the  
559 more members, the more robust the results of the ensemble. Our goal is however different and  
560 consists in creating a benchmark for comparison. Rather than looking at absolute values, we  
561 assess differences (between an inventory and the ensemble), for which the accuracy and  
562 robustness of the absolute values is of secondary importance.

563  
564 As emission inventories are characterized by different grid resolution and sector aggregations,  
565 harmonization is required prior to the screening process for a meaningful comparison.  
566 Conversion to a common grid resolution might result in point sources shifted by one grid cell and  
567 be in the urban area in one inventory and not in another, although having the same geographical  
568 coordinates in both inventory. However, city specific diamond diagrams can be used to check if  
569 this issue occurs.

570  
571 While it is more effective for inventory teams to meet and compare approaches in detail to  
572 understand and correct differences between inventories, this can be challenging at times,  
573 especially in the absence of a specific project to support the work. It must however be noted, that  
574 in many instances the reporting of an inconsistency, especially when it is very large, leads to a  
575 generally straightforward identification of the underlying cause without requiring too detailed  
576 information regarding the inventories.

577  
578 The settings used in this work, e.g. the choice of 150 urban areas or the way sectors are  
579 aggregated are arbitrarily fixed. The method allows for flexible choices and could be applied to  
580 other areas than urban (e.g. complex industrial areas or intensive agriculture land) to assess the  
581 consistency with respect to other types of emissions. In terms of sectors, a further disaggregation  
582 of the other sector will be performed in future to better understand where inconsistencies  
583 originate from.

## 584 6. Conclusions

585  
586 The approach presented in this work supports the screening and flagging of inconsistencies  
587 among inventories, through the construction of an ensemble benchmark. This ensemble is  
588 created to monitor the status and progress made with the development of Europe-wide  
589 inventories, but also to facilitate the comparison among inventories in a relatively simple  
590 manner.

591  
592 The analysis of the EU-wide ensemble and the comparison with its individual members  
593 highlighted a large number of inconsistencies. While two out of the three inventories constituting  
594 the ensemble behave more closely to each other (CAMs-REG and EMEP), they yet show  
595 inconsistencies in terms of the spatial distribution of emissions. The origin of some differences  
596 between these inventories and EDGAR can be identified but their magnitude remains to be

597 explained. These differences mostly occur for SO<sub>2</sub>, PM and NMVOC, for the industrial and  
598 residential sectors, and reach a factor 10 in some instances. The results of the screening provided  
599 useful information that allowed identifying necessary improvements on the estimation of air  
600 pollutants emissions, in particular for EDGAR, with the PM emissions from the small-scale  
601 combustion sector and SO<sub>2</sub> from the industry and power plant sectors. Spatial inconsistencies  
602 mostly occur for the industry and other sectors. The fact that the largest inconsistencies are found  
603 for sectors where point sources play a major role was expected. Indeed, while a diffuse sector  
604 like transport may be distributed quite differently, outliers would not appear as strongly as for  
605 point sources.

606  
607 The application of the ensemble-screening approach to the local inventory for Poland leads to  
608 identifying another type of inconsistencies. While we would intuitively expect differences  
609 between local and European-wide inventories to be driven mainly by the spatial distribution of  
610 the emissions, this is not always the case in our analysis. Inconsistencies indeed relate mostly to  
611 differences in country sectorial shares that result from different sectors/activities being accounted  
612 for in the two types of inventories. This can be explained by the fact that some emission sources  
613 are omitted in the local inventory due to lack of appropriate geographically allocated activity  
614 data. We identified sectors and pollutants for which discussion between local and EU-wide  
615 emission compilers would be needed in order to reduce the magnitude of the observed  
616 differences (e.g. in the residential and industrial sectors mostly for NMVOC, PM<sub>2.5</sub> and PM<sub>10</sub>).

617  
618 It is also interesting to note that the comparison at local and European-wide scale lead to  
619 different types of inconsistencies. While the comparison to one local inventory is presented in  
620 this work as an example, these comparisons can be systematized to improve the quality of the  
621 ensemble.

622  
623 The ensemble is not meant to be a static entity. It will evolve as inconsistencies are progressively  
624 discussed and solved and emission inventories get improved. The ensemble is therefore  
625 associated with reference inventory versions as well as with a reference year. In this sense the  
626 ensemble represents a useful tool to motivate the community around a single common  
627 benchmark and monitor progress towards the improvement of regional and locally developed  
628 emission inventories. It also ensures that improvements become permanent, as forgotten  
629 improvements would indeed be flagged again by the system.

666 **Code and data availability.**

667 Supporting data and source code are available at: “Philippe Thunis. (2023). Supporting data for

668 the publication "Emission ensemble approach to improve the development of multi-scale

669 emission inventories" [Data set]. Zenodo. <https://doi.org/10.5281/zenodo.7940402>”

670 .

671

672 **Author contributions.**

673 PT and AC contributed to the study conception and design. Material preparation, data collection

674 and analysis were performed by PT, EP, ADM, JK, MB, LG, KS, and AC. All authors reviewed

675 the manuscript. All authors read and approved the final manuscript.

676

677 **Competing interests.** The authors declare that they have no conflict of interest.
