22 **Abstract**

23 In the autumn of 2019, a five-day long-lasting dust event was observed using a  
24 synergy of field measurement techniques in Shanghai. This particular dust event stood

25 out from others due to its unique characteristics, including low wind speed, high relative  
26 humidity, elevated levels of gaseous precursors, and contrasting wind patterns at  
27 different altitudes. During this event, three distinct dust stages were identified. The first  
28 stage was a typical dust invasion characterized by ~~with~~ high concentrations of  
29 particulate matters but relatively short duration. In contrast, the second stage exhibited  
30 an unusual enhancement of ozone, attributed to compound causes of weak synoptic  
31 system, transport from the ocean, and subsidence of high-altitude ozone down drafted  
32 by dust. Consequently, gas phase oxidation served as the major formation pathway of  
33 sulfate and nitrate. In the third stage of dust, a noteworthy phenomenon known as dust  
34 backflow occurred. The dust plume originated from the Shandong Peninsula and slowly  
35 drifted over the Yellow Sea and the East China Sea before eventually returning to  
36 Shanghai. Evidence of this backflow was found through the enrichment of marine  
37 vessel emissions (V and Ni) and increased solubility of calcium. Under the influence of  
38 humid oceanic breezes, the formation of nitrate was dominated by aqueous processing.  
39 Additionally, part of nitrate and sulfate were directly transported via sea salts,  
40 evidenced by their co-variation with  $\text{Na}^+$  and confirmed through thermodynamic  
41 modeling. The uptake of  $\text{NH}_3$  on particles, influenced by the contributions of alkali  
42 metal ions and aerosol pH, regulated the formation potential of secondary aerosol. By  
43 developing an upstream-receptor relationship method, the amounts of transported and  
44 secondarily formed aerosol species were separated. This study highlights that the  
45 transport pathway of dust, coupled with environmental conditions, can significantly  
46 modify the aerosol properties, especially at the complex land-sea interface.

47

## 48 1. Introduction

49 Dust serves as a significant natural source of aerosols, constituting approximately  
50 half of the tropospheric aerosols (Zheng et al., 2016). Dust aerosols play crucial roles  
51 in environmental and climatic changes by affecting the radiation balance (Feng et al.,  
52 2020; Nagashima et al., 2016; Goodman et al., 2019). The optical properties of dust  
53 aerosols are influenced by various parameters of iron oxides, including refractive  
54 indices, size distributions, and mineralogical compositions. Consequently, these factors  
55 introduce potential uncertainties regarding the role of dust in climate forcing (Zhang et  
56 al., 2015; Jeong, 2008). Furthermore, dust aerosols have important impacts on  
57 tropospheric chemistry by participating in heterogeneous and photolysis reactions in  
58 the atmosphere (Wang et al., 2014; Liu et al., 2018). During transport, dust can mix  
59 with gaseous pollutants, toxic metals, and soot, thereby affecting air quality  
60 immediately and potentially posing public health hazards (Liu et al., 2021; Wang et al.,  
61 2021). Moreover, Barkley et al. (2021) found that iron-containing aerosols transported  
62 from Africa to the equatorial North Atlantic Ocean provided plentiful nutrients to algae  
63 in the ocean and accumulated inside algae.

64 The irregular shapes of dust particles provide an efficient medium for  
65 heterogeneous reactions with  $\text{NO}_2$ ,  $\text{O}_3$ ,  $\text{SO}_2$ , and  $\text{NH}_3$ , thereby altering the particle size  
66 spectrum, hygroscopicity, and radiative properties (Hsu et al., 2014; Tian et al., 2021;  
67 Jiang et al., 2018). Jiang et al. (2018) observed a significant increase in nitrate and  
68 sulfate concentrations during a dust period in March 2010 in Shanghai. This elevation  
69 was attributed to the presence of moderate to high levels of relative humidity and  
70 gaseous precursors, implying that dust can efficiently promote the formation of sulfate  
71 and nitrate. Previous studies have revealed that  $\text{HNO}_3$  formed through the reactions of  
72  $\text{NO}_2$  with hydroxyl radical or  $\text{N}_2\text{O}_5$  hydrolysis preferentially reacts with mineral dust

73 particles and produce nitrate, which serves as the primary source of nitrate during dust  
74 episodes (Tang et al., 2016; Wu et al., 2020). Improvements in the simulation of sulfate  
75 were achieved by employing various parameterization schemes for the heterogeneous  
76 uptake of SO<sub>2</sub> on natural dust surfaces in the presence of NH<sub>3</sub> and NO<sub>2</sub> under different  
77 relative humidity conditions (Zhang et al., 2019). Wang et al. (2018) simulated that  
78 heterogeneous reactions on dust accounted for the majority of nitrate over the Yellow  
79 Sea and the East China Sea during the dust long-range transport. Tang et al. (2017)  
80 conducted a comprehensive review on the effect of dust heterogeneous reactions on the  
81 tropospheric oxidation capacity. They proposed that high RH (> 80%) and a wider range  
82 of temperature should be considered in the laboratory studies of heterogeneous  
83 reactions of mineral dust. Additionally, more comprehensive kinetic models should be  
84 developed to understand the complex multiphase reactions.

85 Controversies have arisen regarding the mixing of dust and anthropogenic aerosols.  
86 Zhang et al. (2005) found that anthropogenic aerosols separated with dust during a dust  
87 event in Qingdao, China. Coincidentally, a time-lag between dust and anthropogenic  
88 aerosols was observed in Japan and South Korea downstream of the dust transport.  
89 Single particle analysis revealed that sulfate in fine particles appeared 12 hours before  
90 the dust arrival in Japan. Wang et al. (2013) also observed a lag of 10 - 12 hours between  
91 dust and anthropogenic aerosols on a dust day in Shanghai (Wang et al., 2013).  
92 Furthermore, Huang et al. (2019) documented vertical differences in long-transported  
93 aerosols during a pollution event in Taiwan. Dust from the Gobi Desert in Inner  
94 Mongolia and China existed at the altitudes of 0.8km and 1.90km, respectively, while  
95 biomass burning aerosols from South Asia were present at higher altitudes of 3.5km.  
96 Coastal regions often experience a mixture of inland anthropogenic emissions and

97 releases from the ocean, making regional pollution complex in these areas (Wang et  
98 al.; Hilario et al., 2020; Patel and Rastogi, 2020; Perez et al., 2016; Wang et al., 2017).  
99 The eastern coast of China, bordering the East China Sea and the Yellow Sea, is  
100 particularly influenced by the Asian monsoon and high emissions from inland industries,  
101 resulting in highly intricate meteorological and pollution conditions (Hilario et al.,  
102 2020). Furthermore, the marine boundary layer in this region exhibits significant  
103 seasonal and diurnal variations in , relative humidity and temperature further impacting  
104 photochemical processes and heterogeneous reactions on aerosol surfaces (Zhao et al.,  
105 2021). Sea and land breezes play a crucial role in this coastal area. During the night,  
106 land breezes carry pollutants from the land to the sea. Subsequently, during the day,  
107 these land breezes transform into sea breezes, bringing the pollutants back over the sea.  
108 This phenomenon leads to an increase in air pollutants over the land (Zhao et al., 2021).  
109 For instance, Wang et al. (2022b) found that during the ozone pollution in Shanghai in  
110 2018, the presence of O<sub>3</sub> at high altitudes at night was transported vertically downward  
111 during the daytime and high O<sub>3</sub> over the ocean was transported horizontally to the land,  
112 jointly contributing to regional O<sub>3</sub> pollution in Shanghai. Also, one dust episode in 2014  
113 was observed over Shanghai via detouring from northern China due to the blocked north  
114 Pacific subtropical high-pressure system (Wang et al., 2018).

115 Previous studies have shown that about 70% of Asian dust traverses the eastern  
116 coast of China before moving towards the Korean Peninsula, the Sea of Japan, and  
117 eventually reaching the Pacific Ocean. The eastern coast of China serves as a crucial  
118 route for Asian dust transport to the Pacific Ocean (Arimoto et al., 1997; Huang et al.,  
119 2010<sup>a</sup>). Most previous research has focused on typical dust events characterized by  
120 strong intensities, high wind speed, low humidity, and low oxidants (Li et al., 2017; Ma

121 et al., 2019; Xu et al., 2017; Xie et al., 2005). In contrast, this study aims to depict an  
122 atypical dust event that was observed in Shanghai, a coastal mega-city in Eastern China.  
123 The unusualness of the meteorological conditions, transport pathways, and air  
124 pollutants during the particular dust event was explicitly described. The study involves  
125 categorizing the dust event into three stages and comparing the aerosol chemical  
126 compositions between these stages. By focusing on the second and third stages, the  
127 different formation mechanisms of nitrate and sulfate were investigated. The amounts  
128 of major aerosol species from transport and secondary formation were estimated based  
129 on a simplified method of relating the upstream and receptor simultaneous  
130 measurements.

131

## 132 **2. Methodology**

### 133 **2.1. Observational sites**

134 At Shanghai Pudong Environmental Monitoring Station (31°13' N, 121°32'E),  
135 comprehensive measurements of various atmospheric parameters were conducted.  
136 All the instruments were installed on the top floor of a building, about 25m above  
137 the ground level. As shown in Figure S1, the sampling site is situated at the eastern  
138 tip of Shanghai, close to the coastal line. During November, the mean temperature  
139 and relative humidity in Shanghai were recorded as 17.3°C and 72% respectively.  
140 In autumn and winter, air pollutants originating from upstream urban regions often  
141 undergo transport to Shanghai via high-pressure systems. Additionally, air  
142 pollutants in Shanghai tended to linger at the sea/land boundary regions due to the  
143 sea-land breeze (Shen et al., 2019).

144 In addition to the measurements taken in Shanghai, data from environmental  
145 monitoring stations in Qingdao and Lianyungang are also incorporated into this  
146 study.

147

## 148 2.2. Instrumentation

149 A set of online instruments was set up at the Pudong observational site. Inorganic ions  
150 ( $\text{NO}_3^-$ ,  $\text{SO}_4^{2-}$ ,  $\text{Cl}^-$ ,  $\text{Na}^+$ ,  $\text{NH}_4^+$ ,  $\text{K}^+$ ,  $\text{Mg}^{2+}$ ,  $\text{Ca}^{2+}$ ) in  $\text{PM}_{2.5}$  and soluble gases ( $\text{NH}_3$ ,  $\text{HNO}_3$ ,  
151  $\text{HCl}$ ,  $\text{HONO}$ ) were measured by an online ion chromatography (IC, MARGA-1S,  
152 Metrohm). It operated at a flow rate of 16.7 L/min with a time resolution of one hour.  
153 Briefly, air was drawn into a  $\text{PM}_{2.5}$  cyclone inlet and passed through a wet rotating  
154 denuder (gases) and a steam jet aerosol collector (aerosols). Subsequently, the aqueous  
155 samples were analyzed with ion chromatography. More details can be found in (Xu et  
156 al., 2020). Hourly trace metals (Si, Ca, Cu, Fe, K, Co, Mn, Cr, Zn, Pb, As, Cd, V, Ni) in  
157  $\text{PM}_{2.5}$  were measured by using the Xact 625 multi-metals monitor (Cooper  
158 Environmental, Beaverton, OR, USA). Particles were collected onto a Teflon filter tape  
159 at a flow rate of 16.7 L/min, and then transported into the spectrometer where the  
160 particles were analyzed with an X-ray fluorescence. Organic carbon and elemental  
161 carbon were measured by an in situ Semi-Continuous Organic Carbon and Elemental  
162 Carbon aerosol analyzer (RT-4, Sunset Laboratory, Beaverton, Oregon, USA). [Samples](#)  
163 [were collected for 40 min and then analyzed in the following 20 min.](#) The concentration  
164 of mineral aerosols is calculated by summing the major mineral elements with oxygen  
165 for their normal oxides, i.e.,  $[\text{Minerals}] = (2.2 * \text{Al} + 2.49 * \text{Si} + 1.63 * \text{Ca} + 2.42 * \text{Fe} + 1.94 * \text{Ti})$   
166 (Malm et al., 1994). The concentration of OM (organic matters) is estimated by  
167 multiplying OC with a factor of 2.

168 The concentrations of particles and gaseous pollutants were measured by a set of  
169 Thermo Fisher Scientific instruments, including PM<sub>2.5</sub> (Thermo 5030i), PM<sub>10</sub> (Thermo  
170 5030i), SO<sub>2</sub> (Thermo Fisher 43i), NO<sub>x</sub> (Thermo Fisher 42i), O<sub>3</sub> (Thermo Fisher 49i),  
171 and CO (Thermo Fisher 48i-TLE). These parameters were measured at the temporal  
172 resolution of 5min. Meteorological parameters (ambient temperature, relative humidity,  
173 wind speed, and wind direction) were obtained by a Vaisala Weather transmitter  
174 (WXT520) at the temporal resolution of 1min. ~~Other supplementary parameters such~~  
175 ~~as~~ The height of planetary boundary layer (PBL) was retrieved from a ceilometer  
176 (CL31, Vaisala) at the temporal resolution of 30 min. ~~Vertical profiles of ozone and~~  
177 aerosol optical properties extinction were obtained by an aerosol lidar (AGJ, AIOFM)  
178 at the temporal resolution of 30 min and vertical resolution of 7.5 m, respectively.  
179 ~~ceilometer (CL31, Vaisala), Vertical profiles of ozone were obtained by an ozone~~ lidar  
180 (LIDAR-G-2000, WUXIZHONGKE) at the temporal resolution of 15 min and vertical  
181 resolution of 7.5 m, respectively, ~~and aerosol lidar (AGJ, AIOFM), respectively.~~ All  
182 instruments are routinely maintained and calibrated to ensure the quality of data.

183

### 184 2.3. Thermodynamic simulation of aerosol pH and aerosol liquid water content

185 The ISORROPIA II model is subject to the principle of minimizing the Gibbs energy  
186 of the multi-phase aerosol system, leading to a computationally intensive optimization  
187 problem (Song et al., 2018). The model can predict the physical state and compositions  
188 of atmospheric inorganic species (NH<sub>4</sub><sup>+</sup>, Na<sup>+</sup>, K<sup>+</sup>, Mg<sup>2+</sup>, Ca<sup>2+</sup>, SO<sub>4</sub><sup>2-</sup>, NO<sub>3</sub><sup>-</sup> and Cl<sup>-</sup>)  
189 with their gas- and particle-phase concentrations and meteorological parameters  
190 (relative humidity and temperature) as model inputs. The model includes two modes,  
191 i.e., reverse and forward mode. The reverse mode calculates the equilibrium

192 partitioning based on aerosol-phase concentrations only, while the latter uses both  
193 aerosol-phase and gas-phase concentrations as inputs. Moreover, particles can be  
194 assumed as “metastable” with liquid-phase but no solid participating while “stable”  
195 with the liquid and solid phases or both. The ISORROPIA running in the forward mode  
196 at the metastable state was applied in this study. Aerosol pH was calculated based on  
197 the equilibrium particle hydronium ion concentration and aerosol liquid water content  
198 (ALWC) obtained from model results. ISORROPIA II calculates the aerosol pH, ALWC  
199 (aerosol liquid water content) and compositions of ammonia sulfate nitrate chloride  
200 sodium calcium potassium magnesium in the thermodynamic equilibrium with gas  
201 phase precursors. The performances and advantages of ISORROPIA over the usage of  
202 other thermodynamic equilibrium codes has been assessed in numerous studies (Nenes  
203 et al., 1998; West et al., 1999; Ansari and Pandis, 1999; Yu et al., 2005). ~~The~~  
204 ~~ISORROPIA running in the forward mode at the metastable state was applied in this~~  
205 ~~study.~~

#### 207 **2.4. Hybrid Single-Particle Lagrangian Integrated Trajectory Model**

208 The HYSPLIT (Hybrid Single-Particle Lagrangian Integrated Trajectory) was  
209 used to compute the backward trajectories of the air parcels during the dust events. It is  
210 a widely used model that computes dispersion following the particle or puff. The  
211 advection of a particle or puff is computed from the average of the three-dimensional  
212 velocity vectors for the initial position and the first-guess position (Draxler  
213 and Hess, 1998). Turbulent velocity components are expressed as a function of the  
214 velocity variance, a statistical quantity derived from the meteorological data, and the  
215 Lagrangian time scale. The calculation of air mass trajectories can be used to depict the

216 [airflow patterns for interpreting the transport of air pollutants over various spatial and](#)  
217 [temporal ranges \(Stein et al., 2015\)](#). In this study, the HYSPLIT model was driven by  
218 meteorological data outputs from the Global Data Assimilation System (GDAS) (Su et  
219 al., 2015), which is available at <ftp://arlftp.arlhq.noaa.gov/pub/archives/gdas1>. Air mass  
220 trajectories were launched at different heights from the ground and a total duration of  
221 48 hours simulation was conducted.

222

### 223 2.5. Calculation of uptake coefficient of NH<sub>3</sub> (γ<sub>NH3</sub>) on particles

224 NH<sub>3</sub>, being the most abundant alkaline species in the atmosphere, plays a crucial  
225 role in acid neutralization and secondary aerosol formation. To assess the gas-particle  
226 partitioning of NH<sub>3</sub>, the uptake coefficient of NH<sub>3</sub> (γ<sub>NH3</sub>) on particles is calculated as  
227 below. Initially, the quasi-first-order reaction rate constant for heterogeneous  
228 conversion from NH<sub>3</sub> to NH<sub>4</sub><sup>+</sup> (k<sub>het</sub>, s<sup>-1</sup>) is calculated ~~is calculated by Eq. (1) according~~  
229 ~~to~~ (Liu et al., 2022).

$$230 \quad k_{\text{het}} = \frac{2(C_{\text{NH}_4^+, t_2} - C_{\text{NH}_4^+, t_1})}{(C_{\text{NH}_3, t_2} + C_{\text{NH}_3, t_1})(t_2 - t_1)} \quad (1)$$

231 k<sub>het</sub> is only valid when c<sub>NH4+</sub> increases, while c<sub>NH3</sub> decreases assuming a constant  
232 emission rate from t<sub>1</sub> to t<sub>2</sub> (1 h in this study). Then, the uptake coefficient of NH<sub>3</sub> (γ<sub>NH3</sub>)  
233 on particles can be calculated as below (Liu et al., 2022; Wang and Lu, 2016).

$$234 \quad \gamma_{\text{NH}_3} = \frac{4k_{\text{het}}}{S\omega} = \frac{4k_{\text{het}}}{S \sqrt{\frac{8RT}{\pi M}}} \quad (2)$$

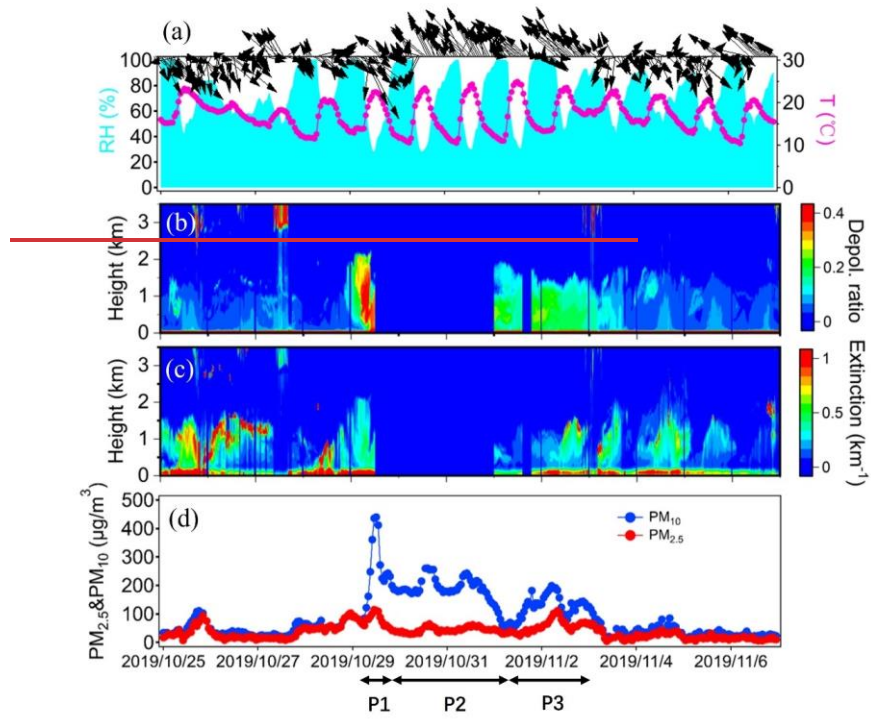

235 where S is the surface area of particles (m<sup>2</sup> m<sup>-3</sup>) measured using SMPS and APS. ω is  
236 the velocity of NH<sub>3</sub> molecules. T is the ambient temperature (K). R is the ideal gas  
237 constant, and M is the molecular weight of NH<sub>3</sub> (kg mol<sup>-1</sup>).

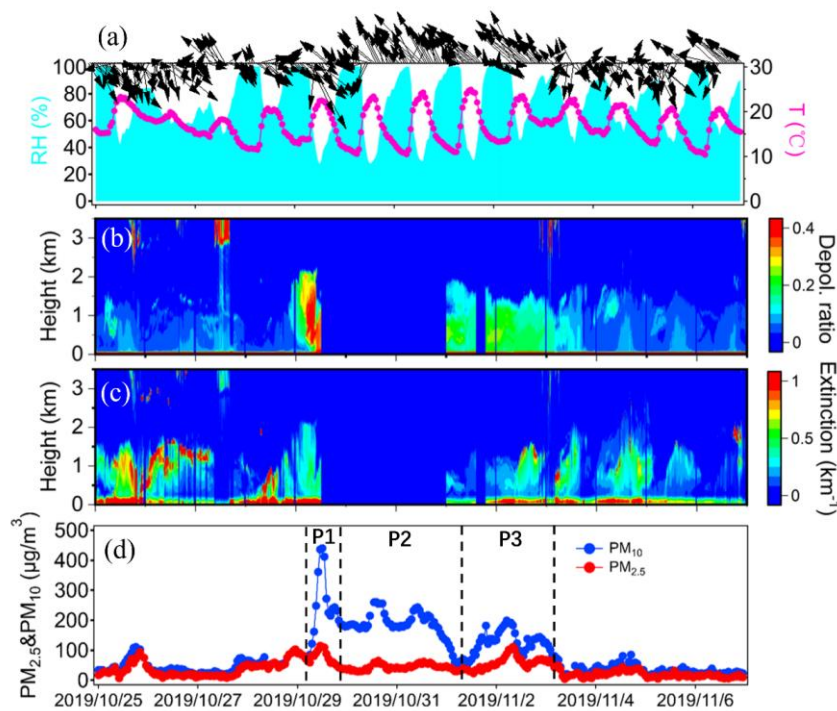

238

## 239 3. Results and Discussion

### 240 3.1. Characteristics of an unusual dust event

241 Figure 1 shows the time series of PM<sub>10</sub>, PM<sub>2.5</sub>, meteorological parameters, as well  
242 as the vertical profiles of aerosol extinction coefficient and depolarization ratio  
243 observed at the Shanghai sampling site from October 25 to November 6, 2019. From  
244 October 25 to 28, the mean wind speed was 0.9±0.72m/s with a peak value of 3.1m/s,  
245 remaining relatively low, and predominantly blowing from the northwest~~remained~~  
246 ~~relatively low of 0.9±0.72m/s with a peak value of 3.1m/s, and predominantly blowing~~  
247 ~~from the northwest.~~ The mean concentrations of PM<sub>2.5</sub> and PM<sub>10</sub> ~~was~~were 34.7 and  
248 44.2 µg/m<sup>3</sup>, respectively. Starting at 4:00 LST on October 29, the concentration of PM<sub>10</sub>  
249 increased sharply and lasted till November 2 (Figure 1d). The aerosol lidar observation  
250 indicated that both the aerosol extinction coefficient and depolarization ratio extended  
251 from the ground to around 2km during the same period. In general, if the particle  
252 depolarization ratio exceeds 10%, the aerosol is identified as mineral dust (Shimizu et  
253 al., 2004) due to the nonsphericity (irregular shapes) and relatively large size of  
254 particles (Mcneil and Carswell, 1975). Notably, the enhanced depolarization ratio (>0.1)  
255 suggested the occurrence of a prolonged dust event in Shanghai. By using the  
256 PM<sub>2.5</sub>/PM<sub>10</sub> mass ratio of 0.4 as a threshold (Fan et al., 2021), the period from October  
257 29 to November 2 was defined as the dust period in this study. The remaining days,  
258 including October 25 to October 28 and November 3 to November 6, were defined as  
259 the non-dust period. Throughout the entire dust period, the mean concentrations of  
260 PM<sub>2.5</sub> and PM<sub>10</sub> reached 53.3 ± 20.5µg/m<sup>3</sup> and 172.4 ± 70.2µg/m<sup>3</sup>, respectively,  
261 yielding a low PM<sub>2.5</sub>/PM<sub>10</sub> ratio of 0.34 ± 0.15. As a comparison, PM<sub>2.5</sub> and PM<sub>10</sub> during  
262 the non-dust period was 38.9µg/m<sup>3</sup> and 49.8µg/m<sup>3</sup>, respectively, exhibiting a relatively  
263 high PM<sub>2.5</sub>/PM<sub>10</sub> ratio of 0.62 ± 0.20.

265

266 Figure 1. Time series of (a) relative humidity, temperature, wind vectors, (b) aerosol  
 267 depolarization ratio, (c) aerosol extinction coefficient, (d) mass concentrations of PM<sub>2.5</sub>  
 268 and PM<sub>10</sub> during the study period. Three dust stages, i.e., P1, P2, and P3 are also marked.  
 269 The missing aerosol lidar data were due to instrument malfunction.

270

271 The occurrences of dust are typically accompanied by low relative humidity and  
 272 strong winds due to the passage of cold fronts (Huang et al., 2010b; Huang et al., 2010a;  
 273 Wang et al., 2013; Wang et al., 2018). However, in this study, relative humidity was  
 274 exceptionally high with the mean value of  $71 \pm 26\%$ . It showed strong diurnal variation,  
 275 reaching its minimum in the daytime and even close to 100% in the nighttime (Figure  
 276 1a). Additionally, wind speed was low of  $0.54 \pm 0.59 \text{ m/s}$  with a maximum of 2.6 m/s.  
 277 This stagnant synoptic condition led to elevated concentrations of main gaseous

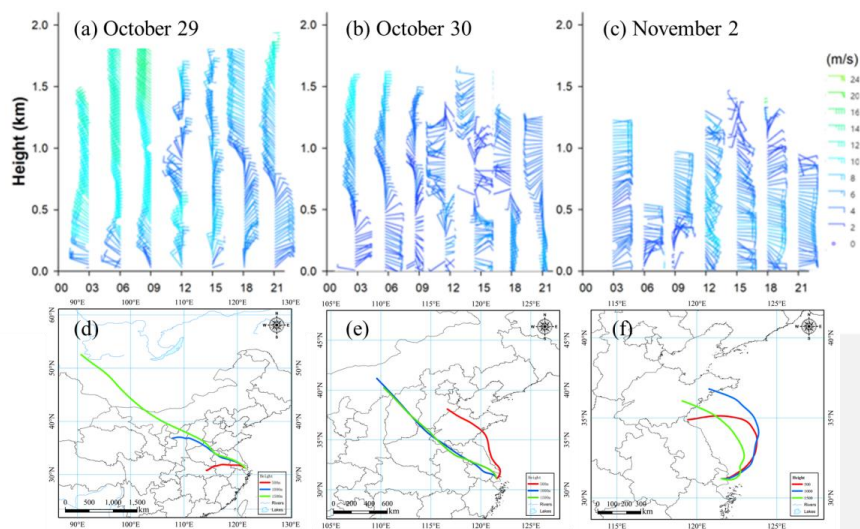

278 pollutants such as O<sub>3</sub>, SO<sub>2</sub>, and NO<sub>2</sub>, with mean values of 86.0±47.8μg/m<sup>3</sup>,  
279 11.8±3.4μg/m<sup>3</sup>, and 63.3±27.9μg/m<sup>3</sup>, respectively, even higher than those during the  
280 non-dust period.

281 We further divided the dust event into three stages based on the temporal  
282 characteristics of PM<sub>10</sub> and the transport patterns of air masses. As shown in Figure 1d,  
283 PM<sub>10</sub> quickly climbed from 4:00 on October 29 and reached a maximum of 436μg/m<sup>3</sup>  
284 after 8 hours. The air masses primarily originated from the semi-arid regions of  
285 northwest China (Figure 2d), which was consistent with both the near surface wind  
286 observation (Figure 1a) and wind lidar observation (Figure 2a). The wind profiles  
287 showed prevailing northwest winds from the surface up to around 2km before noon on  
288 October 29, indicating the presence of a strong synoptic system. Afterwards, PM<sub>10</sub>  
289 quickly decreased to 199 μg/m<sup>3</sup> at 20:00, October 29 within 8 hours. This was primarily  
290 attributed to the shift of wind directions. As shown in Figure 2a, while winds above  
291 700m continued to blow from the northwest, near- surface winds had shifted from the  
292 southeast. Due to Shanghai's coastal location adjacent to the East China Sea, the  
293 relatively clean southeasterlies diluted the local air pollutants, thereby explaining the  
294 quick decline in PM10 concentrations. This initial dust episode occurring from 4:00 -  
295 13:00 on October 29 was defined as Stage P1.

296 Despite the persistent southeasterly winds, the dust event did not come to a  
297 complete halt. Even under these prevailing winds, hourly PM<sub>10</sub> concentrations  
298 remained above 150 μg/m<sup>3</sup> until November 1, gradually decreasing to 65 μg/m<sup>3</sup> at 03:00,  
299 November 1 (Figure 1d). Compared to P1, wind speed during this stage was as low as  
300 0.4 ± 0.5m/s, while RH was moderately high of 70 ± 26%. Although the daytime RH  
301 stayed low between 30% and 50%, it frequently soared above 90% at nighttime. Figure

302 2e shows that although the air masses originated from the Gobi Desert, they also  
303 traversed considerable coastal regions. The wind profiles further indicated that while  
304 northwest winds prevailed at altitudes higher than 500m, east and northeast winds were  
305 dominant below 500m (Figure 2b). Consequently, the relatively high RH during this  
306 period can be attributed to the mixing of dust plumes with coastal sea breezes. This dust  
307 episode from 14:00, October 29 to 3:00 on November 1 was designated as Stage P2.

308 Following P2, PM<sub>10</sub> and PM<sub>2.5</sub> rose again and peaked at 5:00 and 9:00 on  
309 November 2 with the hourly concentration of 199 and 117 μg/m<sup>3</sup>, respectively. Different  
310 from P1 and P2, the air masses during this stage originated from the Shandong  
311 Peninsula and the northern region of Jiangsu province, and then migrated over the  
312 Yellow Sea and the East China Sea (Figure 2f). Typically, dust plumes tend to travel  
313 eastward, impacting the western Pacific region and even distant oceanic regions (Wang  
314 et al., 2018; Nagashima et al., 2016). However, in this case, the air masses evidently  
315 deviated and pushed the dust back towards the mainland. The wind profiles on  
316 November 2 revealed that winds within the detected altitude range predominantly  
317 originated from the eastern and southeastern oceanic regions (Figure 2c). This probably  
318 indicated the mixing between dust plumes and humid oceanic air masses was quite  
319 sufficient, which was also reflected by the highest average RH of 76 ± 24% among the  
320 three stages of the dust event. Moreover, the concentrations of O<sub>3</sub> and NO<sub>2</sub> at this stage  
321 were higher than those of P1 and P2, potentially promoting the formation of secondary  
322 aerosol components and will be discussed later. This rarely observed dust backflow  
323 transport episode from 4:00 on November 1 to 23:00 on November 2 was designated  
324 as Stage P3.

325

326 Figure 2. Wind profiles observed by a wind profiler radar on (a) October 29, (b) October  
 327 30, and (c) November 2. 48-hour backward trajectories simulated at the sampling site  
 328 starting from (d) 4:00 AM, October 29, (e) 9:00 AM, October 30, and (f) 13:00 PM,  
 329 November 2. The red, blue, and green trajectories represented starting altitudes of 100,  
 330 500, and 1500m, respectively.

331

### 332 3.2. Comparisons of aerosol chemical compositions among the three dust stages

333 Figure 3a shows the time-series of hourly aerosol chemical components,  
 334 including SNA ( $\text{NO}_3^-$ ,  $\text{SO}_4^{2-}$ , and  $\text{NH}_4^+$ ), OM, EC, and mineral aerosols in  $\text{PM}_{2.5}$ .  
 335 During P1, the mean concentration of SNA was  $49.9 \pm 31.6 \mu\text{g}/\text{m}^3$ . The mineral  
 336 aerosols reached  $16.4 \pm 14.6 \mu\text{g}/\text{m}^3$ , accounting for 19% in  $\text{PM}_{2.5}$ . The contribution of

337 OM to PM<sub>2.5</sub> was almost identical to that of mineral aerosols (Figure 3b).

338

339

340 Figure 3. (a) Times-series of major chemical components in PM<sub>2.5</sub> during the study  
341 period. (b) The mean proportion of major chemical components in PM<sub>2.5</sub> during the  
342 three dust stages.

343

344 During P2, mineral aerosols increased to  $23.4 \pm 54.1 \mu\text{g}/\text{m}^3$  and accounted for 33%  
345 in PM<sub>2.5</sub>, representing the highest among all three stages (Figure 3b). Due to the  
346 continuous dilution effect of dust on local anthropogenic pollutants, the concentrations  
347 and proportions of SNA in PM<sub>2.5</sub> were the lowest during this stage. For instance, NO<sub>3</sub><sup>-</sup>  
348 only accounted for 10% in PM<sub>2.5</sub>, indicating a suppression of nitrate formation to some  
349 extent. The levels of OM didn't exhibit obvious changes and averaged  $10.1 \pm 2.1 \mu\text{g}/\text{m}^3$ ,  
350 accounting for 21% in PM<sub>2.5</sub>.

351 During P3, mineral aerosols averaged  $11.9 \pm 2.7 \mu\text{g}/\text{m}^3$ , ranking the lowest among  
352 all three stages. The proportion of mineral aerosols in PM<sub>2.5</sub> decreased to 20%,

353 suggesting the dust backflow from the ocean was less enriched in mineral components.  
354 Compared to P2, SNA showed significant increases and much stronger diurnal  
355 variations during P3.  $\text{SO}_4^{2-}$ ,  $\text{NO}_3^-$ , and  $\text{NH}_4^+$  averaged  $6.7 \pm 2.4$ ,  $12.4 \pm 8.9$ , and  $5.4 \pm$   
356  $2.7 \mu\text{g}/\text{m}^3$ , respectively. As shown in Figure 3b, the contribution of nitrate to  $\text{PM}_{2.5}$   
357 increased to 21%, while that of sulfate rose to 12%, the highest among all three stages.  
358 The concentration of OM ( $9.3 \pm 3.2 \mu\text{g}/\text{m}^3$ ) and its proportion (16%) during P3 were  
359 lower than the other two stages, likely due to the unconventional dust backflow  
360 transport pathway.

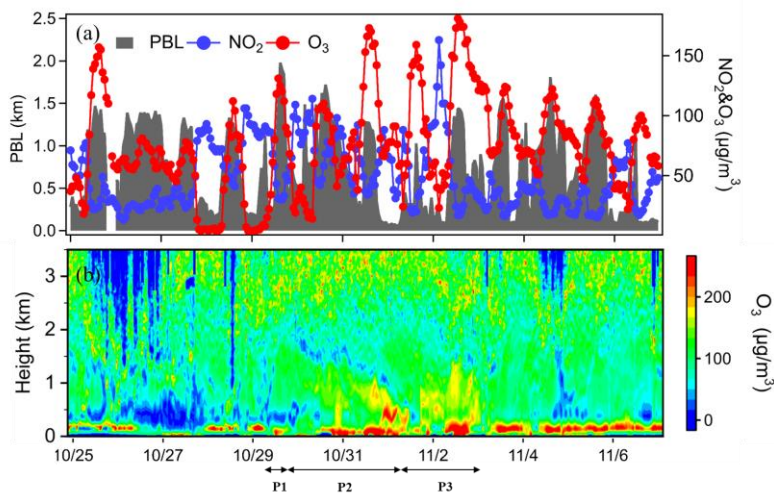

361

### 362 3.3. Unconventional features of the dust episodes

#### 363 3.3.1. Unusually enhanced $\text{O}_3$ during dust

364 Figure 4 shows the hourly near surface ozone concentrations and vertical profiles  
365 of ozone during the study period. Interestingly, a few high  $\text{O}_3$  peaks occurred during  
366 the dust event (Figure 4a).  $\text{O}_3$  averaged  $92.8 \pm 52.8 \mu\text{g}/\text{m}^3$  during the dust, about 50%  
367 higher than the non-dust days. Among the three dust stages,  $\text{O}_3$  substantially increased  
368 from  $35.9 \pm 36.4 \mu\text{g}/\text{m}^3$  during P1 to  $80.7 \pm 41.2 \mu\text{g}/\text{m}^3$  during P2, and further rose to  
369  $104.0 \pm 48.7 \mu\text{g}/\text{m}^3$  during P3. The low  $\text{O}_3$  during P1 can be attributed to the cleansing  
370 effect of the strong dust associated with the cold front, which was consistent with  
371 previous studies that reported reduced oxidant concentrations during intense dust  
372 events (Benas et al., 2013). Regarding the relatively high  $\text{O}_3$  during P2 and P3, several  
373 causes may contribute to this phenomenon. Firstly, the mean wind speed was low of  
374 0.4 and 0.6 m/s during P2 and P3, respectively. ~~Consequently, this weak synoptic~~  
375 ~~system exerted a weak dilution effect on the local air pollutants.~~ OneA numerical  
376 study conducted during the similar period suggested that the low wind speed caused

377 ~~the~~ reduction of boundary layer height and the warming of the lower atmosphere, thus  
 378 ~~accelerating~~ the ozone formation by  $\sim 1$  ppbv/h (Wang et al., 2020). Consequently,  
 379 this weak synoptic system was favorable for the accumulation of ozone ~~exerted a weak~~  
 380 dilution effect on the local air pollutants. Secondly, since the dust plume travelled  
 381 mostly over the coastal and oceanic areas, a portion of  $O_3$  could be transported from  
 382 the high ozone oceanic areas (Wang et al., 2022b). Thirdly, the ozone lidar also  
 383 detected high  $O_3$  stripes during P2 and P3. As shown in ~~Figure 5b~~ Figure 4b, the high  
 384  $O_3$  profiles extended from the surface to around 1 km and the profile structure was  
 385 similar to that of aerosol depolarization ratio. The subsidence of dust particles likely  
 386 contributed to downward transport of high-altitude  $O_3$ , thereby influencing the  
 387 elevated  $O_3$  near the ground (Yang et al., 2022).

388  
 389 Figure 4. (a) Time-series of near surface  $O_3$ ,  $NO_2$  and planetary boundary layer height  
 390 (b) Vertical profiles of ozone observed by the ozone Lidar.

391

### 392 3.3.2. Dust backflows during P3

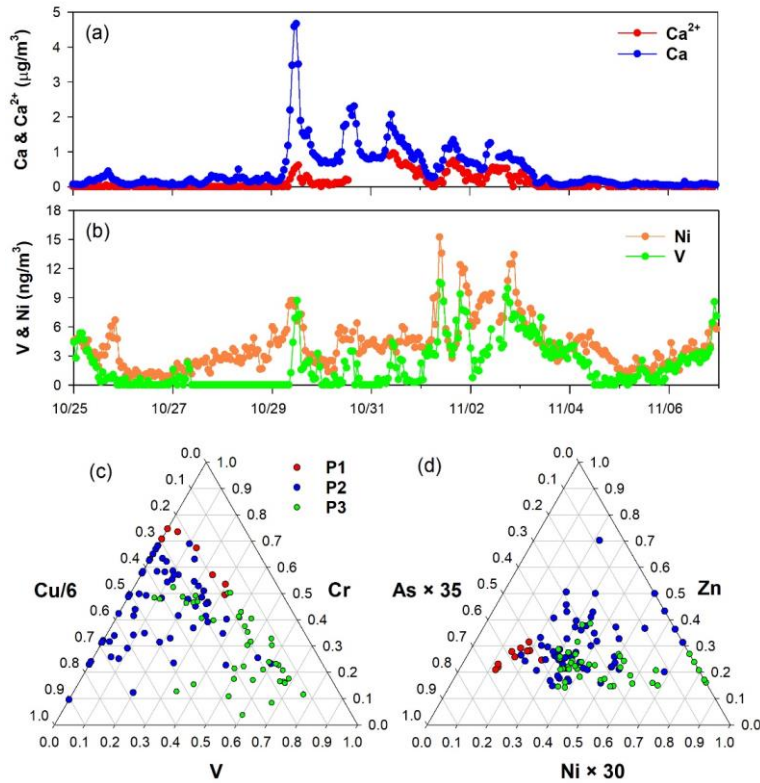

393 The dust during P3 was diagnosed as a backflow transport pathway from the

394 mainland to Shanghai through the Yellow Sea and the East China Sea, as determined  
395 by the backward trajectory analysis (Figure 2f). This unconventional dust transport  
396 route, termed “dust backflow”, was consistent with a similar occurrence in 2014 when  
397 dust from northern China detoured over Shanghai (Wang et al., 2018). In this section,  
398 we have provided further evidences of the dust backflow from various aspects.

399         Figure 2f illustrates that the dust drifted away from the Shandong Peninsula, thus  
400 we selected two coastal sites in Shandong province for supplementary analysis. Figure  
401 S2 compares the time-series of hourly air pollutants at Qingdao, Lianyungang, and  
402 Shanghai. At Qingdao and Lianyungang, high PM<sub>10</sub> concentrations were observed  
403 during October 30 – 31, indicating the invasion of dust in these regions. After about  
404 two days, PM<sub>10</sub> peaked in Shanghai on early November 2. This temporal consistency  
405 aligned with the simulation duration of the backward trajectories, which lasted around  
406 48 hours (Figure 2f). In Figure 9, it can be observed that in the upstream dust regions  
407 (i.e., Qingdao and Lianyungang), PM<sub>10</sub> varied negatively with NO<sub>2</sub> and CO (the  
408 highlighted period in the figure). While in Shanghai, positive correlations between  
409 PM<sub>10</sub> and both NO<sub>2</sub> ( $R^2=0.32$ ) and CO ( $R^2=0.55$ ) indicated that the dust during P3  
410 served as a carrier for gaseous pollutants rather than acting a diluter.

411

412

413

414 Figure 5. Time-series of (a) Ca, Ca<sup>2+</sup>, (b) V, and Ni during the study period. (c)  
 415 Cu-Cr-V ternary diagram and (d) As-Zn-Ni ternary diagram among the P1 – P3 dust  
 416 episodes. Due to substantial concentration differences of various elements, some  
 417 elements are artificially changed to make most scatters appear around the centroid.

418

419 Additional evidence of dust backflows was provided from the perspective of  
 420 aerosol chemical tracers. Figure 5a plots the time-series of Ca and Ca<sup>2+</sup>, representing  
 421 the total calcium and the soluble part of calcium, respectively. It was observed that Ca  
 422 and Ca<sup>2+</sup> didn't exhibit a proportional variation trend, which should be related to the

423 solubility of calcium during different dust stages. During P1, the mean concentration of  
424 Ca reached the highest of  $1.63 \pm 1.53 \mu\text{g}/\text{m}^3$  while  $\text{Ca}^{2+}$  was the lowest of  $0.21 \pm$   
425  $0.20 \mu\text{g}/\text{m}^3$ , thus resulting in the lowest  $\text{Ca}^{2+}/\text{Ca}$  ratio of  $0.10 \pm 0.08$ . As discussed in  
426 Section 3.1, dust during P1 was the strongest and thus it contained higher fractions of  
427 minerals, primarily in the form of insoluble metal oxides. The average concentrations  
428 of  $\text{Ca}^{2+}$  and Ca during P2 were  $0.33 \pm 0.28 \mu\text{g}/\text{m}^3$  and  $1.11 \pm 0.46 \mu\text{g}/\text{m}^3$ , respectively,  
429 resulting in the higher  $\text{Ca}^{2+}/\text{Ca}$  ratio of  $0.27 \pm 0.20$ . As a comparison, the average  
430 concentrations of  $\text{Ca}^{2+}$  and Ca during P3 reached  $0.34 \pm 0.20 \mu\text{g}/\text{m}^3$  and  $0.78 \pm$   
431  $0.27 \mu\text{g}/\text{m}^3$ , respectively, yielding the highest  $\text{Ca}^{2+}/\text{Ca}$  ratio of  $0.38 \pm 0.19$ . The  
432 significantly higher solubility of calcium during P3 should be directly related to the  
433 prolonged presence of dust plumes over the open ocean. The abundant water vapor over  
434 the ocean could accelerate the dissolution of the insoluble components in particles  
435 during the mixing between continental dust and oceanic air masses. Additionally, the  
436 backflow transport pathway facilitated the entrainment of sea salts and contributed to  
437 the increase of soluble calcium.

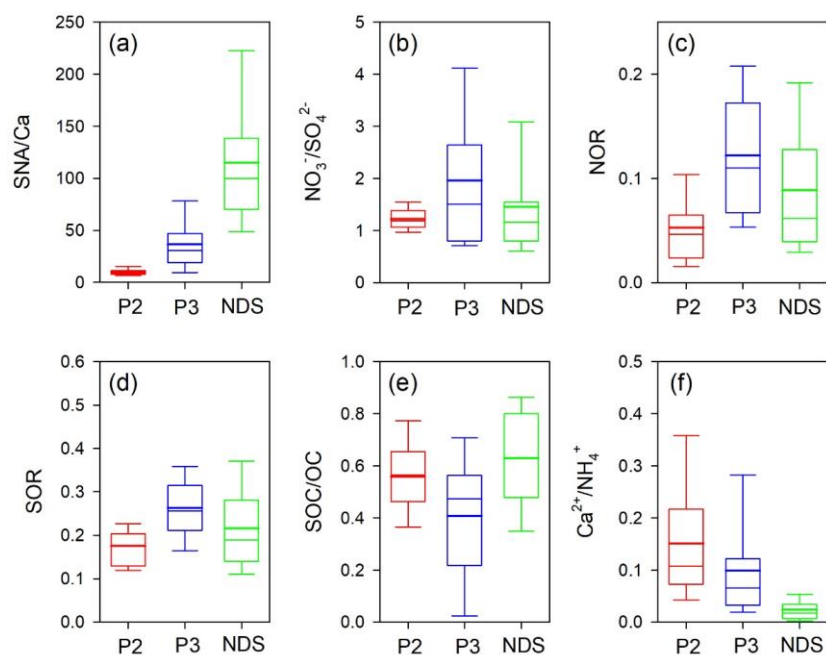

438 Figure 5b provides additional insights by displaying the time-series of V and Ni,  
439 which are typical tracers of oil combustions (Becagli et al., 2012). They varied  
440 significantly during the study period, and the mass concentrations of V and Ni increased  
441 4 and 1.8 times during P3 compared to P2, respectively. Consistently, the enrichment  
442 factors of Ni and V displayed higher values during P3 than P1 and P2 (Figure S3). The  
443 trends are substantiated in the ternary diagrams, which are commonly applied to  
444 illustrate the relative abundances of three components and infer the source variations  
445 (Bozlaker et al., 2019; Cwiertny et al., 2008; Laskin et al., 2005). As shown in the Cu-  
446 Cr-V ternary diagram (Figure 5c), the dust samples during P1 were positioned away

447 from the V-apex. As a comparison, the dust samples during P2 exhibited greater  
448 scattering, manifesting enhanced anthropogenic contributions, e.g., from chrome  
449 plating industries (Hammond et al., 2008). Compared to P2, the dust samples during P3  
450 moved toward the V-apex, indicating a higher contribution from oil combustions  
451 (Becagli et al., 2012). A similar pattern was observed in the As-Zn-Ni ternary diagram  
452 (Figure 5d). The majority of dust samples during P2 spanned across the diagram,  
453 reflecting contributions from mixed anthropogenic sources. Reciprocally, P3 was closer  
454 to the Ni-apex. These lines of evidences collectively confirmed that the dust had mixed  
455 with pollutants from marine vessel emissions over one of the busiest international  
456 shipping trade routes (Fan et al., 2016) and was subsequently transported back to  
457 Shanghai.

458

### 459 **3.4. Formation of secondary aerosols during the dust long-range transport**

#### 460 **3.4.1. Comparison of typical chemical tracers**

461  
 462 Figure 6. Box plots of (a) SNA/Ca, (b) NO<sub>3</sub><sup>-</sup>/SO<sub>4</sub><sup>2-</sup>, (c) NOR, (d) SOR, (e) SOC/OC,  
 463 and (f) Ca<sup>2+</sup>/NH<sub>4</sub><sup>+</sup> during P2, P3, and NDS, respectively.

464  
 465 To delve deeper into the formation characteristics of secondary aerosols in  
 466 different stages, a variety of chemical tracers was investigated. The P1 dust stage was  
 467 excluded from statistical analysis due to its short duration and limited data availability.  
 468 Figure 6a shows the comparison of SNA/Ca ratios during P2, P3 and non-dust days  
 469 (NDS). The SNA/Ca ratio can be used to assess the relative changes between secondary  
 470 production and primary dust emission by eliminating the impact of meteorological  
 471 conditions among different periods (Zheng et al., 2015). Compared to the two dust  
 472 episodes, the SNA/Ca ratio is significantly higher during NDS. This can be attributed  
 473 to the much lower concentrations of mineral aerosols during NDS, thus resulting in the

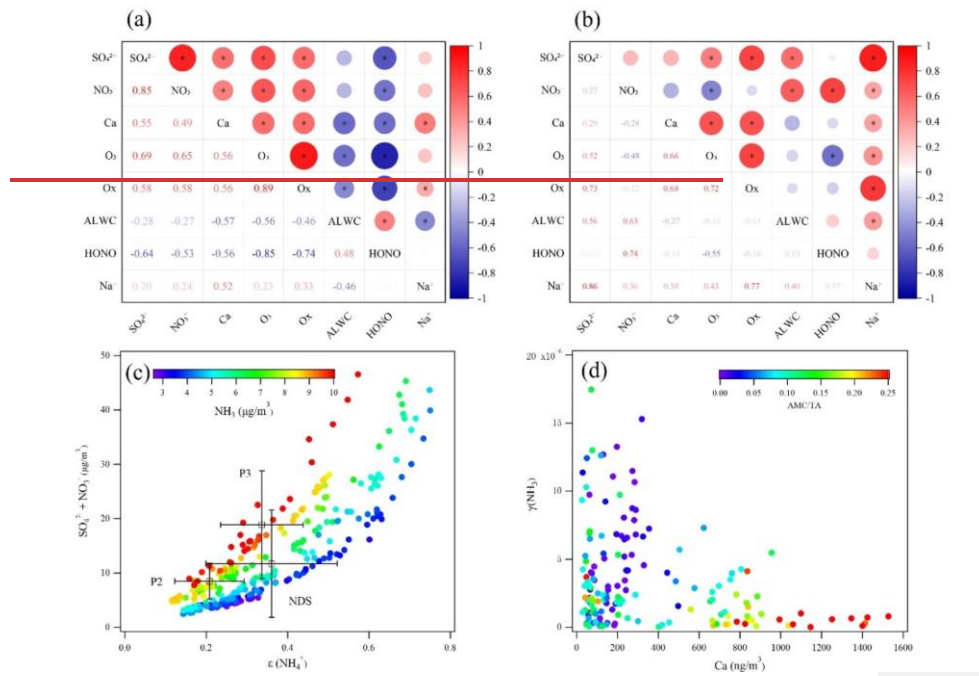

474 higher SNA relative to Ca. In terms of comparing P2 and P3, the average SNA/Ca ratio  
475 during P3 was 3 times that of P2, indicating that the formation of secondary inorganic  
476 aerosols was more prominent during the dust backflow. Regarding the  $\text{NO}_3^-/\text{SO}_4^{2-}$  ratios  
477 (Figure 6b), they were close between NDS and P2, with  $\text{NO}_3^-$  slightly exceeding  $\text{SO}_4^{2-}$ .  
478 The range of  $\text{NO}_3^-/\text{SO}_4^{2-}$  was the largest during P3 with a mean value of around 2,  
479 suggesting that the dust backflow was more conducive to the accumulation of nitrate.  
480 The nitrogen oxidation ratio ( $\text{NOR} = \text{NO}_3^-/(\text{NO}_3^- + \text{NO}_2)$ ) and the sulfur oxidation ratio  
481 ( $\text{SOR} = \text{SO}_4^{2-}/(\text{SO}_4^{2-} + \text{SO}_2)$ ) were further used to gauge the extent of nitrate and sulfate  
482 formation, both showing trends of  $\text{P3} > \text{NDS} > \text{P2}$  (Figure 6c & 6d). It should be noted  
483 that NOR and SOR cannot be used to realistically characterize the extent of nitrogen  
484 and sulfur oxidation during transport-dominated pollution cases, as upstream aging  
485 aerosols can significantly increase the above ratios (Ji et al., 2018). In the following  
486 discussion, we will focus on the formation mechanism of SNA during different dust  
487 stages.

488 The results of SOC/OC ratios differed from the above analysis that SOC/OC was  
489 lower during P3 than during P2 and NDS (Figure 6e), suggesting that the formation of  
490 secondary organic aerosols was not favored via the dust backflow. This may be due to  
491 its maritime transport pathway as the emission intensity of volatile organic compounds  
492 from the ocean is much lower than that from land sources. Consequently, the lacking of  
493 organic aerosol precursors could be the main cause for the lower SOC/OC ratios during  
494 P3. Finally, the  $\text{Ca}^{2+}/\text{NH}_4^+$  ratio was employed to assess the relative contributions of  
495 alkaline chemical components (Figure 6f). As expected, this ratio during the two dust  
496 stages was much higher than that of NDS, indicating the important contribution of dust  
497 to alkaline metal ions. The  $\text{Ca}^{2+}/\text{NH}_4^+$  ratio was higher during P3 (0.15) than during P2

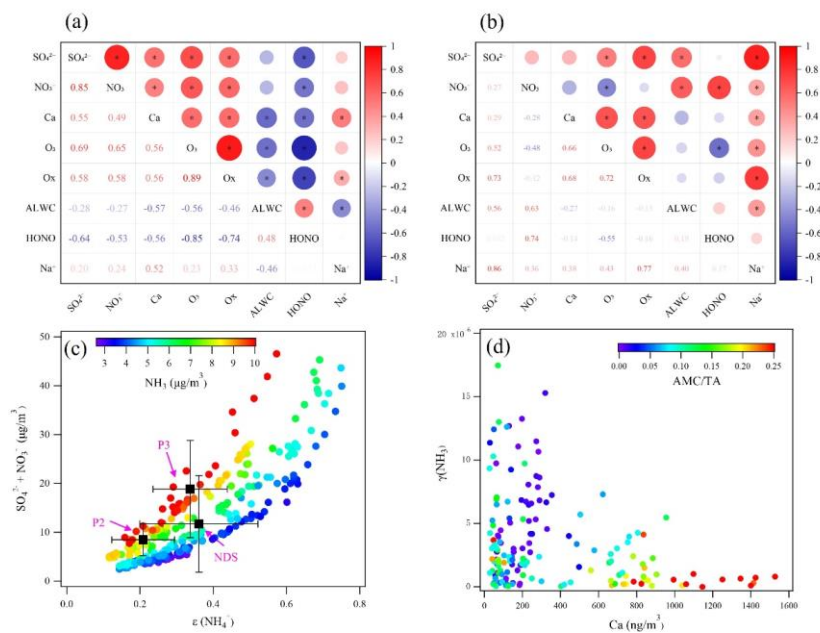

498 (0.10), which aligned with the findings presented in Section 3.2.

499

515

Figure 7. Correlation heatmaps during (a) P2 and (b) P3. The size of dot corresponds to the value of the correlation coefficient. The black star inside the dot means the correlation is significant ( $p < 0.05$ ). (c) The mass concentrations of  $\text{SO}_4^{2-}$  and  $\text{NO}_3^-$  as a function of  $\epsilon(\text{NH}_4^+)$ , with dots colored by the concentration of  $\text{NH}_3$ . The mean states of P2, P3, and NDS are added. Error bars denote one standard deviations. (d) The uptake coefficient of  $\text{NH}_3$  ( $\gamma_{\text{NH}_3}$ ) on particles as a function of Ca, with dots colored by the AMC/TA molar ratios. AMC and TA denote the total molar concentrations of  $\text{Na}^+$ ,  $\text{K}^+$ ,  $\text{Mg}^{2+}$ , and  $\text{Ca}^{2+}$  and the total molar concentrations of anions, respectively.

In this section, we further analyze the formation mechanism and key influencing factors of secondary components during P2 and P3. Figure 7a & 7b compare the correlation heatmaps of  $\text{SO}_4^{2-}$  and  $\text{NO}_3^-$  with various parameters. During P2, both  $\text{SO}_4^{2-}$

516 and  $\text{NO}_3^-$  displayed the most significant correlations with  $\text{O}_3$  and Ox ( $\text{O}_3 + \text{NO}_2$ ), while  
517 even negatively correlated with ALWC. In regard of the obvious ozone enhancement  
518 phenomenon as discussed in Section 3.3.1, the photochemistry pathway for the  
519 secondary aerosol formation (e.g.,  $\text{S(IV)} + \text{O}_3(\text{aq}) \rightarrow \text{S(VI)}$ ) should overwhelm over  
520 the aqueous phase pathways, e.g., oxidation by  $\text{H}_2\text{O}_2$ , catalysis by tracer metals, and  
521 oxidation by  $\text{NO}_2$  photochemistry should be the main pathway for the secondary aerosol  
522 formation rather than the liquid phase processing. In addition,  $\text{SO}_4^{2-}$  and  $\text{NO}_3^-$  also  
523 showed moderate correlations with elemental Ca, suggesting that dust acted as a carrier  
524 to transport these salts, which can be derived from background minerals in dust (Wu et  
525 al., 2022) and dust heterogeneous reactions during the transport (Huang et al., 2010a).

526 As for P3, it showed a distinctly different correlation heatmap from P2. While  
527  $\text{SO}_4^{2-}$  still demonstrates a correlation with  $\text{O}_3$ , the relationship between  $\text{NO}_3^-$  and  $\text{O}_3$   
528 (as well as Ox) disappeared. On the contrary, both  $\text{SO}_4^{2-}$  and  $\text{NO}_3^-$  show significant  
529 correlations with ALWC. During P3, the average RH reached 76%, providing favorable  
530 conditions for liquid-phase reactions. Furthermore, by relating  $\text{NO}_3^-$  and the  
531 multiplication of ALWC and  $\text{NO}_2$ , the correlation coefficient ( $R^2 = 0.41$ ) was further  
532 improved (Figure S4a). Similar results were observed by relating  $\text{NO}_3^-$  to the  
533 multiplication of ALWC and  $\text{NO}_2 * \text{O}_3 * \text{NO}_2$  (a proxy of  $\text{N}_2\text{O}_5$ , (Huang et al., 2021))  
534 (Figure S4b), confirming the dominant reaction pathway of nitrogen oxides to nitrate  
535 via the aqueous phase reactions. As a result,  $\text{NO}_3^-$  was also strongly correlated with  
536 HONO (Figure S4c), typically deriving from the heterogeneous reactions of  $\text{NO}_2$  on  
537 the surface of moist particles (Alicke et al. (2002)).

538 In addition, unlike P2, both  $\text{SO}_4^{2-}$  and  $\text{NO}_3^-$  showed moderate to significant  
539 correlations with  $\text{Na}^+$ , a tracer of sea salts (Figure 7b). Since neither  $\text{SO}_4^{2-}$  nor  $\text{NO}_3^-$

540 correlated with Ca, it can be inferred that sea salts played a more important role in the  
541 transport of air pollutant during the dust backflow over the ocean. To assess whether  
542 dust or sea salts participated in the heterogeneous reactions of secondary aerosol during  
543 P3, the ISORROPIA II model was run with different scenarios. Figure S5 shows the  
544 model performance for  $\text{SO}_4^{2-}$ ,  $\text{NO}_3^-$ ,  $\text{NH}_4^+$ , and  $\text{NH}_3$  based on the  
545  $\text{SO}_4^{2-}$ - $\text{NO}_3^-$ - $\text{NH}_4^+$ - $\text{Cl}^-$ - $\text{NH}_3$ - $\text{HCl}$ - $\text{HNO}_3$  system. After adding  $\text{Ca}^{2+}$  into this  
546 thermodynamic equilibrium system, the correlations between the simulations vs  
547 observations for all four species were lowered with different extents (Figure S6). If  $\text{Na}^+$   
548 was added into the thermodynamic equilibrium system, the model performance was  
549 slightly improved (Figure S7). This corroborated that the heterogeneous reactions on  
550 dust were very limited while sea salts were intensively involved in the formation of  
551 secondary inorganic aerosols during the dust backflow.

552 To further explore the influencing factors affecting the formation of secondary  
553 inorganic aerosols, we examined the role of  $\text{NH}_3$  in different stages, representing by the  
554 relationship between the gas-particle partitioning of ammonia ( $\varepsilon(\text{NH}_4^+)$ ), defined as the  
555 ratio between particle phase ammonia ( $\text{NH}_4^+$ ) and total ammonia ( $\text{NH}_x = \text{NH}_3 + \text{NH}_4^+$ )  
556 and the total acids ( $\text{SO}_4^{2-} + \text{NO}_3^-$ ). As shown in Figure 7c, it is obvious that the total  
557 acids strongly co-varied with  $\varepsilon(\text{NH}_4^+)$ . Higher  $\varepsilon(\text{NH}_4^+)$  resulted in higher  
558 concentrations of secondary aerosols. Moreover, under similar  $\varepsilon(\text{NH}_4^+)$  conditions,  
559 higher  $\text{NH}_3$  promoted stronger formation of secondary aerosols. Thus, both  $\text{NH}_3$  and  
560  $\varepsilon(\text{NH}_4^+)$  collectively determined the aerosol formation potential. The mean states of  
561 P2, P3, and NDS are compared in Figure 7c. P2 had the lowest  $\varepsilon(\text{NH}_4^+)$  with the mean  
562 value of 0.21, despite the relatively high concentrations of  $\text{NH}_3$  during this period ( $7.9$   
563  $\pm 1.0 \mu\text{g}/\text{m}^3$ ). The relatively low gas-particle partitioning of ammonia limited the

564 neutralization of the acidic components. In contrast,  $\text{NH}_3$  during P3 was the highest  
565 during the study period ( $9.8 \pm 1.8 \mu\text{g}/\text{m}^3$ ), and  $\varepsilon(\text{NH}_4^+)$  (0.34) was only slightly lower  
566 than that during NDS, thus effectively fostering the formation of secondary inorganic  
567 aerosols.

568 To explain this phenomenon, the uptake coefficient of  $\text{NH}_3$  ( $\gamma_{\text{NH}_3}$ ) on particles,  
569 which is one of the important parameters affecting the gas-particle partitioning of  
570 ammonia, was calculated. Figure 7d shows the decreasing trend of  $\gamma_{\text{NH}_3}$  with the  
571 increase of dust intensity (using Ca as an indicator). This coincided with a multi-year  
572 observational study in Beijing and Shijiazhuang, where  $\gamma_{\text{NH}_3}$  obviously increased due  
573 to significant decline in alkali earth metal contents from the dust emission sources  
574 during 2018 – 2020 (Liu et al., 2022). Thus, this partially explained why  $\varepsilon(\text{NH}_4^+)$  was  
575 relatively low during P2, which was ascribed to the reduced uptake capacity of  $\text{NH}_3$  on  
576 particles.

577 The ion balance calculation indicated that the total anions and cations are in ideal  
578 equilibrium (Figure S8, regression slope = 0.99,  $R^2 = 0.99$ ), indicating that both  $\text{NH}_4^+$   
579 and alkali metal cations (including  $\text{Na}^+$ ,  $\text{K}^+$ ,  $\text{Mg}^{2+}$ , and  $\text{Ca}^{2+}$ ) contributed to the  
580 neutralization of acids to varying degrees. The ratio of alkali metal cations/total anions  
581 (AMC/TA) was used to color the data points in Figure 7d, showing an opposite trend  
582 between AMC/TA and  $\gamma_{\text{NH}_3}$ . During P2, the mean value of AMC/TA reached 21%,  
583 implying that the neutralization of acids by  $\text{NH}_3$  had been significantly suppressed, thus  
584 explaining the decrease in the  $\text{NH}_3$  uptake coefficient at high dust intensity. In contrast,  
585 the AMC/TA ratio decreased to 11% during P3, indicating a reduced competition  
586 between  $\text{NH}_3$  and the alkali dust components. Finally, we also compared the aerosol pH  
587 at different stages, which was 3.2, 3.0, and 2.8 during P2, P3, and NDS, respectively.

588 The relatively high aerosol acidity at P3 and NDS favored the uptake of alkaline gases  
589 (Liu et al., 2022), which also contributed to the higher ( $\gamma_{\text{NH}_3}$ ) at these two stages.

590

### 591 **3.5. Estimation of transported and secondarily formed particles during P3**

592 As discussed in previous sections, the aerosols observed during P3 could originate  
593 from both aged aerosols transported via the dust backflows and secondary formation.  
594 In this section, we aimed to estimate the contribution of transport and secondary  
595 formation to the main aerosol species, respectively, based on the simultaneous  
596 measurements at the Pudong site and the Lianyungang site. As discussed in Section  
597 3.4.1, Lianyungang acted as an upstream region where dust drifted away from the  
598 mainland. The duration of dust observed at Lianyungang was approximately from 5:00  
599 on October 30 to 16:00 on October 31, about 46 hours ahead of the dust invasion  
600 observed at Pudong (Figure S2).

601 To assess the extents of transported air pollutants, black carbon (BC) was used as  
602 a reference aerosol component. As shown in Figure S9, one BC pollution episode on  
603 October 30 at Lianyungang was observed. Correspondingly, another BC pollution  
604 episode emerged at Pudong on November 2 after about 46 hours. Since the air mass  
605 trajectory from Lianyungang to Pudong predominantly traversed over the ocean, and  
606 considering that BC has no secondary sources, it can be reasonably assumed that the  
607 differences of BC concentrations between these two sites were ascribed to the removal  
608 processes of particles.

609 To determine the removal fractions of aerosols during dust transport, we first  
610 defined the average concentrations of various aerosol components during the preceding  
611 five hours of the dust at Pudong as their background concentrations. Then, a coefficient

612  $k$  was derived to calculate the removal fractions of aerosols during the dust transport as  
613 below.

$$614 \quad k = \frac{AV_{LYG,BC} - (AV_{PD,BC} - BKG_{PD,BC})}{AV_{LYG,BC}} \quad (3)$$

617  $AV_{LYG,BC}$  and  $AV_{PD,BC}$  represent the average concentration of BC at Lianyungang  
618 and Pudong during their respective dust period.  $BKG_{PD,BC}$  represents the background  
619 concentration of BC at Pudong. Assuming that other aerosol species were removed with  
620 a similar efficiency as BC, the amounts of transported aerosol species from  
621 Lianyungang to Pudong can be estimated as below.

$$622 \quad TP_{PD,i} = AV_{LYG,i} \times (1 - k) \quad (4)$$

623  $TP_{PD,i}$  represents the transported amounts of aerosol species  $i$ .  $1 - k$  represents the  
624 transport fraction of aerosols. Then, the secondarily formed aerosol species  $i$  at Pudong  
625 can be calculated as below.

$$626 \quad SF_{PD,i} = AV_{PD,i} - BKG_{PD,i} - TP_{PD,i} \quad (5)$$

627 Figure 8 shows the results of the transported and the secondarily formed aerosol  
628 species during P3. It was calculated that the secondarily formed and transported  $\text{NO}_3^-$   
629 averaged  $6.8 \mu\text{g}/\text{m}^3$  and  $4.7 \mu\text{g}/\text{m}^3$ , accounting for about 45% and 31% of its total mass  
630 concentration, respectively. This was consistent with the earlier analysis that a  
631 considerable portion of nitrate was formed through the aqueous phase secondary  
632 formation. In contrast, it was calculated that the transported  $\text{SO}_4^{2-}$  accounted for about  
633 42% of its total mass concentration, while the secondarily formed  $\text{SO}_4^{2-}$  was almost  
634 negligible. This was also consistent with the phenomenon that  $\text{SO}_4^{2-}$  correlated  
635 significantly with  $\text{Na}^+$  (Figure 6b). As for  $\text{NH}_4^+$ , it exhibited a similar apportionment as  
636  $\text{NO}_3^-$ , with the secondarily formed and transported  $\text{NH}_4^+$  accounting for about 35% and

Formatted: Font: Italic

Formatted: Font: Not Italic, Not Superscript/  
Subscript

637 28% of its total mass concentration, respectively. Compared to  $\text{NO}_3^-$  and  $\text{NH}_4^+$ , OM was  
 638 more dominated by transport (57%) while its secondary formation only accounted for  
 639 about 13%. It should be noted that the simple method devised in this study may have  
 640 inherent uncertainties. Considering the prolonged duration of the dust event, it is  
 641 possible that certain dust particles lingered over the open ocean. Consequently, the  
 642 contributions attributed to aerosol transport should be considered as a conservative  
 643 estimate or lower bound, rather than an exhaustive assessment.  
 644

647  
 648 Figure 8. The apportioned concentrations of the major aerosol species during P3.

649  
 650 **4. Conclusion**

651 During October 29 to November 2, 2019, a long-lasting dust event was observed in  
 652 Shanghai based on a synergy measurement of near surface air pollutants, aerosol lidar,  
 653 wind profiling lidar, and air masses trajectory modeling. During the whole dust period,  
 654 the mean concentrations of  $\text{PM}_{2.5}$  and  $\text{PM}_{10}$  reached  $53.3 \pm 20.5 \mu\text{g}/\text{m}^3$  and  $172.4 \pm$   
 655  $70.2 \mu\text{g}/\text{m}^3$ . Different from most dust events, this dust event was characterized of  
 656 exceptionally high relative humidity, ( $71 \pm 26\%$ ) and low wind speed, and relatively

657 ~~high concentrations of gaseous pollutants.  $-(0.54 \pm 0.59\text{m/s})$ . Due to this stagnant~~  
658 ~~synoptic condition, the mean concentrations of main gaseous pollutants such as  $\text{O}_3$ ,  $\text{SO}_2$ ,~~  
659 ~~and  $\text{NO}_2$  reached  $86.0 \pm 47.8\mu\text{g}/\text{m}^3$ ,  $11.8 \pm 3.4\mu\text{g}/\text{m}^3$ , and  $63.3 \pm 27.9\mu\text{g}/\text{m}^3$ ,~~  
660 ~~respectively, even higher than those during the non-dust period.~~

661 The dust event was divided into three stages from P1 – P3. P1 was a short dust episode  
662 ~~when wind profiles showed dominant northwest winds from the ground to the altitudes~~  
663 ~~of around 2km, indicating the presence of a due to the strong cold fronts synoptic system.~~  
664 P2 was a dust episode when RH was moderately high of  $70 \pm 26\%$  and the  
665 southeasterlies prevailed with partial air masses from coastal regions. P3 was a rarely  
666 observed dust backflow transport episode. The air masses originated from the Shandong  
667 Peninsula and the northern region of Jiangsu province, and then migrated over the  
668 Yellow Sea and the East China Sea. RH reached the highest of  $76 \pm 24\%$  among the  
669 three stages of the dust event.

670 During P2, ~~mineral aerosols accounted for 33% in  $\text{PM}_{2.5}$ , the highest among all~~  
671 ~~three stages. A~~ abnormally high  $\text{O}_3$  concentrations were observed, ~~much higher than the~~  
672 ~~non-dust days. This was partially~~ which could be due to the weak synoptic system as  
673 well as that exerted weak dilution effect on the local air pollutants. The ozone lidar  
674 ~~observed that the subsidence of dust particles probably~~ down drafted high-altitude  $\text{O}_3$   
675 along with the subsidence of dust particles ~~and also contributed to the high  $\text{O}_3$  near the~~  
676 ~~ground. As a result,~~ Sulfate and nitrate moderately correlated with  $\text{O}_3$  while had  
677 almost no correlation with ALWC, indicating that the formation of secondary aerosols  
678 during P2 should be mainly promoted via the gas-phase oxidations. -

679 During P3, a special phenomenon of dust backflow was observed and confirmed  
680 by various evidences. ~~Two upstream sites (Qingdao and Lianyungang) showed dust~~

Formatted: Indent: First line: 0 ch

681 ~~occurrences about 48 hours ahead that of Shanghai, consistent with the transport~~  
682 ~~duration of the dust backflow from the Shandong Peninsula to Shanghai over the Yellow~~  
683 ~~Sea and the East China Sea. As a result,~~ The highest  $\text{Ca}^{2+}/\text{Ca}$  ratio was observed due  
684 to that the lingerer of dust plumes over the open ocean. Moreover, contributions of V  
685 and Ni significantly increased, indicating the mixing between dust and marine vessel  
686 emissions. Different from P2, nitrate significantly correlated with ALWC but not with  
687  $\text{O}_3^-$ , indicating its aqueous-phase reaction pathway. Also, sulfate and nitrate exhibited  
688 moderate to strong correlations with  $\text{Na}^+$ , suggesting sea salts as a medium for the  
689 heterogeneous reactions.

690 By analyzing various chemical tracers, the formation extent of SNA was found  
691 much stronger during P3 than during P2. Both  $\text{NH}_3$  and  $\varepsilon(\text{NH}_4^+)$   
692 ( $\text{NH}_4^+ / (\text{NH}_3 + \text{NH}_4^+)$ ) determined the concentrations of SNA. To explain the relatively  
693 high  $\varepsilon(\text{NH}_4^+)$  values during P3, the uptake coefficient of  $\text{NH}_3$  ( $\gamma_{\text{NH}_3}$ ) on particles is  
694 calculated.  $\gamma_{\text{NH}_3}$  negatively varied with the intensity of dust, which were attributed to  
695 two factors. Higher contributions of alkali metal components suppressed the  
696 neutralization capacity of  $\text{NH}_3$  on acids, thereby lowering  $\gamma_{\text{NH}_3}$  during P2. Also,  
697 relatively high aerosol pH during P2 didn't facilitate the uptake of  $\text{NH}_3$  and the  
698 subsequent aerosol formation.

699 Based on a simplified method, the amounts of transported and secondarily formed  
700 particles during P3 were quantified. It was calculated that about 45% and 31% of  $\text{NO}_3^-$   
701 was contributed by secondary formation and transport, respectively. In contrast, the  
702 transported  $\text{SO}_4^{2-}$  accounted for about 42% of its total mass concentration while the rest  
703 was from its background concentration with negligible secondary formation. OM was  
704 dominated by transport (57%) while its secondary formation only accounted for about
