We thank the reviewers for their comments and suggestions on the manuscript. We outline below responses to the points raised by each referee and summarize the changes made to the revised manuscript. We also provide a revised version of the manuscript with highlighted modifications.

Reponses to Referee #1

> 1. *Before digging into the reason for the difference between modeled and measured composition, one need be sure that the difference is minimally influenced by the measurement artefacts. Is this possible that small compounds, particularly those less oxygenated C1-C4 compounds in particle-phase, are fragment of parent products or decomposition during heating in CHARON? It is surprising to see these compounds in the particle-phase due to their high volatility. It would helpful to elaborate the method used to exclude the artefacts and/or discuss their influence on the measured chemical composition.*

Thermal decomposition is typically not observed in CHARON PTR-ToF-MS instruments (except for hydroperoxides and labile sugars). It has, however, been shown in previous work (*e.g.*, Gkatzelis et al., 2018; Leglise et al. 2019) that at the conditions used in this study ($E/N = 105$ Td) scission of the C-C bond may indeed occur. Therefore a fraction of the low C compounds found in the particle phase may thus be measurement artifacts.

> 2. *In Fig. 2, no oligomers ($C > 7$) compounds were shown. Are there any oligomers ($C > 7$) detected? Can CHARON PTR MS see them?*

Oligomers can be observed with CHARON PTR-ToF-MS instruments. It is, however, likely that at the operating conditions used in this study (E/N = 105 Td) oligomers fragment upon protonation.

> 3. *I suggest adding a figure of reaction schemes of toluene+OH reaction highlight the new reaction mechanisms added to the model in SI so that readers can better follow.*

The suggested figure was added to SI (Fig. S6) and is now mentioned in the text.

> 4. *L167, which data does this statement based on?*

According to Jenkin et al. (2019) SAR, the RO₂ + RO₂ reactions mainly lead to the formation of alkoxy radicals as RO₂ + NO reactions. Under atmospheric conditions, the RO₂ + CH₃O₂ (the most abundant RO₂ in atmosphere) reaction represents about 10 % of the RO₂ reactivity (Lannuque et al., 2018). If we have here decided to not consider all RO₂ + RO₂ reactions it is to limit the already relatively large size of our mechanisms. We are aware that this means ignoring the formation of certain minor secondary compounds, notably C_{>7}. This choice was made considering (1) the high NO_x levels limiting the importance of RO₂ + RO₂ reactions and (2) the absence of detection of such compounds in our experiments.

> 5. *L236, what does “long range interactions” mean? It would be helpful to briefly explain it.*

Middle- and long-range interactions correspond to interactions between the organic compounds and charged molecules (especially inorganic ions, the only considered here) in water phase. This term is used by opposition of the interactions between the different uncharged organic molecules which occur at a shorter range.

> 1. *L35, it is not clear that what the “enhanced” is compared with.*

It is compared to a reference mechanism using MCM and GECKO-A. It is now specified in the text.

> 2. *L287, “as” should be “and”?*

The text was modified.

> 3. *L407, “cercles” should be “circles”. Also it would helpful to clarify that it is the diameter or area of circles that denotes the mass in Fig. 3.*

The area of the circles has been used. The text was modified and the legend of Fig. 3 was detailed.

> *In the caption of Fig. 3, there are no “pie charts”. Please check.*

The mention to pie charts was removed.

> 1. *L451, the “of” after “24 %” should be deleted.*

The text was modified.

> 2. *L505, “47%”, is this correct or should it be 28%?*

You are right, the mistake was corrected and 47% was replaced by 30% (28 + 2 %).

> 3. *L545, a comma is missing after “(a).*

> 4. *L482, a space is missing after “distribution”.*

The text was corrected.

Reponses to Referee #2

> *Line 98: Additional experimental details such as the rate and residence time of the gas flow in the OFR and the initial concentrations of toluene should be provided in the experimental section.*

Experiments were carried out using a total flow varying from 1.3 to 1.8 L/min corresponding to a residence time of approximately 10-13 minutes. These details have been introduced in the experimental section.

> *Line 132: Have any experiments been done to verify that all the organics in SOA are thermally desorbed at a temperature of 413 K in the CHARON inlet? Was the fragmentation of organic compounds during the thermal desorption of SOA significant?*

It has been shown in the literature that at the temperatures used in this study SVOCs, LVOCs and even ELVOCs are vaporized (*e.g.*, Piel et al., 2021). It is important to note that vaporization is affected on the walls of the thermal desorption unit at reduced at reduce pressure (few mbar). Piel et al. (2021) also mention that certain types of thermal decomposition such as the decarboxylation of organic acids does not occur at the temperatures used in this study. The same authors found evidence for the thermal decomposition of hydroperoxides in the CHARON inlet.

> *Line 145: Are the C* values calculated from the measured partitioning coefficients using Equation 2? What are the influences of the potential non-equilibrium phase partitioning (for example under low RH conditions) and non-ideality of the condensed phase on such calculations?*

The C^* were calculated using equations 1 and 2. According to Shiraiwa and Seinfeld (2012): the equilibrium time is achieved from seconds to minutes for relatively high volatility organic compounds into liquid particles. However, equilibrium time can increase to hours or days for organic aerosol when the particles are large, semi-solid particles, of low volatility, and low mass loadings. Instantaneous equilibrium partitioning may lead to substantial overestimation of particle mass concentration and underestimation of gas-phase concentration.

In our study most of the identified SOA compounds identified are semi-volatile (Table 1). Moreover, monodispersed seeds+SOA had a size was about 150-216 nm so our particles are quite small to establish an equilibrium with the gas phase. In addition, the total mass concentration was on average $13.9 \pm 3.4 \mu\text{g m}^{-3}$ for the experiments at 295 K and $17.4 \pm 4.9 \mu\text{g m}^{-3}$ for the experiments at 280 K, the mass loading is high enough for the establishment of the equilibrium. Indeed according to Figure 4 of Shiraiwa and Seinfeld (2012), for semi-solid SVOCs with a diameter of 150 nm and organic mass concentration 14-17 $\mu\text{g m}^{-3}$ the equilibrium timescale of SOA partitioning is about 10 min. Given the fact that the residence time in the OFR was about 11-13 minutes we conclude that particle and gas phases were practically in equilibrium. Furthermore, in preliminary modeling tests, gas-particle partitioning was represented using both methods: one considering thermodynamic equilibrium at each time step, and one following a dynamic phase transfer approach. The two methods showed no significant differences in partitioning under our simulation conditions.

The non-ideality, for individual organic compounds in different mixtures is quantified by the activity coefficient γ . Liu et al. (2020) found that the γ of bulk SOA (produced by OH oxidation of a mixture of 1-alkanols) increased from near 1 to 5 as the seeds and the SOA have more differing polarities. A high γ value of 74 was found for a wet ammonium sulfate-SOA system indicating phase separation. Ammonium sulfate is a polar compound. We have to check the polarity of the SOA compounds, if the majority of their mass have polarities close to ammonium sulfate, then we say that γ is around 1 and we are close to ideality. If the polarity is quite different, then the seeds are less hospitable to the condensing vapors and the compounds tend to stay in the gas phase increasing the C^* by up to 5 times (and so $\log C^*$ will increase half an order of magnitude).

Tests on non-ideality carried out in the modeling section clearly show the effect that considering it can have on the partitioning of different compounds. However, these tests highlight the large uncertainties that remain in the calculation of non-ideality, with effects that can be contrary depending on the phases and compounds. The lack of interaction data between the different functional groups adds even more uncertainties. It is partly for this reason that we have chosen not to take non-ideality into account for the experimental C^* in Fig. 3.

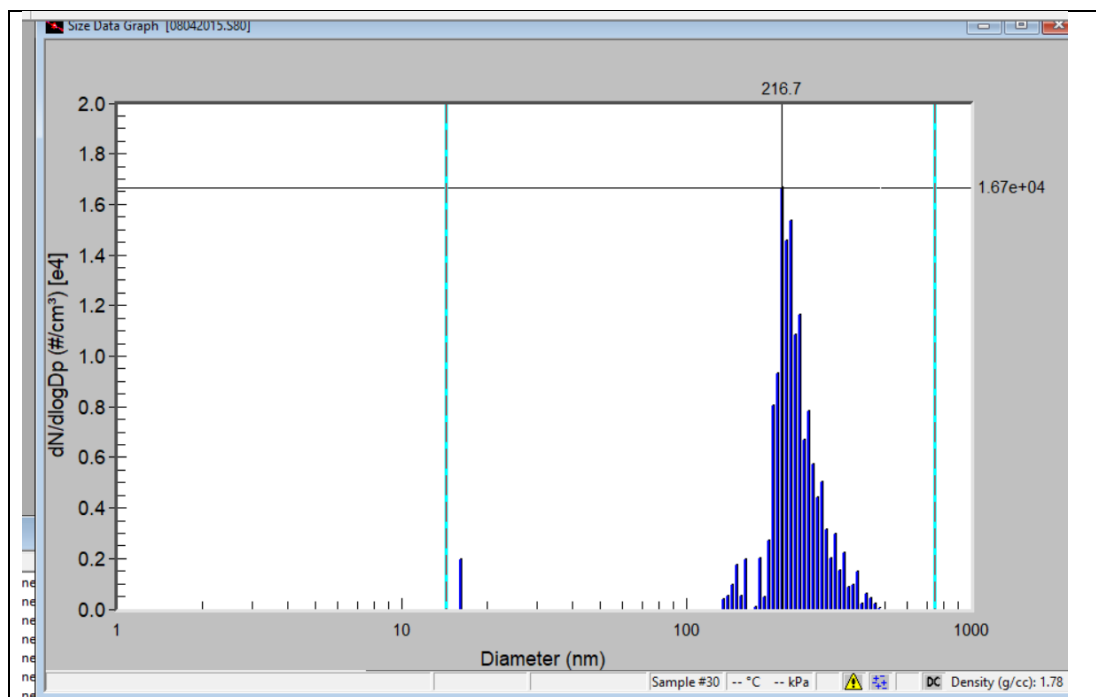

> *Line 210-214: The formation pathways of highly oxygenated organic molecules (HOMs) from toluene photooxidation are also included in the newly developed mechanism. Do they make a significant difference to the speciation of the gaseous and particulate organic species, especially for those with high oxygen numbers?*

In our study, the species referred as “HOMs” correspond to stable species that have undergone at least two successive autoxidation steps after the addition of a first OH radical. Other highly oxygenated compounds (which could have higher oxygen number than these “HOMs”) are formed in a more conventional way by successive oxidation with OH, O_2 and then NO or HO_2 . “HOMs” are negligible in our simulations. This observation is not discussed too much in the article, as it could be due to the high concentrations of radicals (NO and HO_2) in our experimental conditions, which are unfavorable to successive autoxidation pathways. In line with this, recent use of the mechanism in simulations under atmospheric conditions shows that “HOMs” are not negligible in SOA formation when there are few radicals (which is not, however, the most common case for toluene, generally emitted at the same time as many NOx).

> Line 280: What are the size distributions of toluene SOA formed under typical experimental conditions? Are the formed SOA particles monodispersed as assumed here? Given the low pre-existing seed aerosol concentrations ($\sim 9 \mu\text{g}/\text{m}^3$), I would expect that there is significant nucleation and new particle formation during toluene photooxidation. As a result, polydispersed aerosols are likely generated, e.g., a larger particle mode comprised of inorganic-organic mixed particles and a smaller particle mode primarily with pure SOA particles. If this is the case, how would it affect the phase partitioning behaviors of organic compounds as well as the irreversible uptake of small species such as methylglyoxal.

Typically monodisperse seeds were injected ranging from 120 to 170 nm (mobility diameter). As a function of the experimental conditions more or less condensed organics were formed in the particle phase. The bottom plots show SMPS size distribution before and during photooxidation of toluene. Yes, some nucleation is observed at the beginning of the oxidation, after few minutes as the surface condensation increases nucleation is suppressed at least under our experimental conditions. Below size distribution (SMPS) for seeds and during toluene photooxidation. Partitioning has been calculated during stable periods in absence of nucleation events.

> Line 287: These parameters are expected to significantly impact the gas-phase oxidation chemistry, phase partitioning, and/or particle-phase chemistry (e.g, irreversible uptake of methylglyoxal), but it is found in the present study that they have little impact on the overall speciation of the oxidation products. The authors only present the data obtained at different temperatures in the manuscript. I suggest also providing the data obtained for other parameters in the SI.

We agree that RH, initial seeds, toluene and IPN (i.e. OH radical) concentrations can impact phase partitioning. Seed impact has been shown in the SI section (Figure S2). The figure shows as increased sees surface favors SOA formation. But it also clearly suggests that experimental temperature has a stronger impact on SOA mass loading with respect to seed concentration. Therefore, temperature variation has been considered a key parameter. Other parameters have not been extensively investigated in this work. Under our experimental conditions, however, we did not observe a significant impact on gaseous chemistry and therefore overall speciation (i.e. in both phases). This is reflected in the identification of the same m/z (with different intensities), whatever the experimental conditions.

The core of the modeling work was to reproduce the global speciation of secondary compounds before reproducing and analyzing their partitioning. As particle-phase chemistry was not represented, this work consisted in developing new chemical mechanisms for gaseous oxidation, on which RH and the initial concentrations of toluene, seeds and IPN had no impact. Only experiments at two different temperatures were therefore reproduced.

The most debatable choice is probably not to reproduce experiments at two different RHs, but as the RH range covered during the experimental campaign was restricted (from 24 to 40%) and the artifacts generated by its variations in the tube little analyzed (e.g. RH-dependent wall condensation), this choice was made. Regarding the impact of RH on methylglyoxal partitioning, as mentioned in the article, the parameterization is very simplified. It is based mainly on field data where temperature and RH are dependent, and leads to potential discrepancies by not integrating either temperature or OH concentrations in its calculation. In this respect, the test is mainly exploratory.

Now that an oxidation mechanism has been proposed, an analysis based on a new campaign of experiments focusing on the partitioning of compounds as a function of conditions should be envisaged, in particular to reduce the uncertainties associated with the processes considered.

> *Line 356: In addition to losing a H₂O molecule, how likely do the toluene oxidation products fragment via C-C scission during PTR-MS measurements? How would it affect the discrimination between parent and fragment ions?*

Yes, it has been shown in the literature (Gkatzelis et al., 2018; Leglise et al., 2019) have shown that at the conditions used in this study (E/N = 105 Td) scission of the C-C bond may occur. Part of the low C compounds found in the particle phase may thus be measurement artifacts.

> *Line 401-402: Please clarify what type of heterogeneous reactions on the reactor wall can produce these small molecules.*

Typical reaction occurring on the wall of OFR or chamber give rise to HONO, HCHO, HCOOH formation. In general adsorbed molecules on the chamber or OFR tube can undergo chemical reaction and produce such small molecules (Doussin et al., 2023).

> *Line 405: Although the authors are able to determine the gas-particle partitioning coefficients (K_p) of the toluene oxidation products, they did not present such data in the manuscript. As the K_p can offer additional insights into the phase partitioning behaviors of the oxidation products, I suggest the authors add an analysis of those data as well as their measurement-model comparisons in the manuscript.*

The experimentally derived K_p are now in table S3.

Concerning modeled K_p , we chose not to detail or represent their comparison with experimental data for several reasons: the uncertainty of partitioning according to the processes considered, and the impossibility of calculating a K_p for (1) many major compounds of the modeled SOA due to their total transfert in the condensed phase, or (2) compounds whose K_p is measured experimentally but present only in the gas phase in the simulations (i.e. light compounds). A bubbles plot comparison figure would have compared different species that do not necessarily represent the major part of the secondary mass produced.

> *Line 413: It seems that some content is missing before the sentence "Other 20 ions were detected...". Please check.*

Nothing is missing but the sentence was not clear, text was modified.

> *Line 425: Figure 3 does not include any pie charts described in the figure caption. Also, there are no descriptions/discussions regarding the comparisons between organic compounds measured by CHARON PTR-MS and the SOA mass measured by AMS in the text. Please double check.*

The mention to pie charts was removed.

> *Line 430-431: The volatility is affected not only by the oxidation state, but also by the molecular size. Therefore, a trend for OSc versus C^* may be observed if the data are further discriminated by the carbon number. In addition, Fig. S6 should be Fig. S5.*

The numbering error was corrected.

> *Line 608: Why does the inclusion of the wall loss parameterization lead to the reduction of the concentration of all m/z values in the particle phase but only the heavier compounds in the gas phase?*

Wall losses of compounds depend on their volatility, whatever their m/z . It's therefore logical to see compounds in the particulate phase (i.e. the least volatile) all impacted to a greater or lesser extent.

Here, the impact on the gas phase is minimal in all cases. It is concentrated on two types of compounds: (1) those of low volatility, which are present in both phases (the decrease in particulate concentration goes hand in hand with the decrease in gas concentration) and (2) compounds formed after several oxidation steps, whose parent species have seen their concentrations decrease due to wall losses (these compounds are potentially the heaviest due to the successive addition of functions). This does not mean that there is no effect on other gaseous compounds, but it is negligible.

> In addition, the following language errors should be corrected.

Line 91: produced -> produce

Line 249: wall losses -> wall loss effects

Line 273: Delete "controlled".

Line 287: as -> as well as

Line 298: as -> such as

Line 346: by -> followed by

Line 407: cercles -> circles

Line 442: that -> than

Line 443: Delete either of "only".

The text was modified.
