24

25 **ABSTRACT:** Organosulfates (OSs) are ubiquitous aerosol components with intense
26 research over years. However, spatial and diurnal variations in OS formation in polluted
27 atmosphere remain poorly understood. In this study, 130 OS species were quantified
28 (or semi-quantified) in ambient fine particulate matter (PM_{2.5}) collected in urban and
29 suburban Shanghai (East China) in summer 2021. Isoprene- and monoterpene-derived
30 OSs were dominant OS groups (averaging 51% and 19% of total quantified OSs,
31 respectively), likely indicating a large biogenic contribution to OS formation in summer.
32 Most OSs peaked during daytime, while monoterpene-derived nitrooxy-OSs (NOS_m)
33 increased during nighttime. Accordingly, OSs were largely produced via daytime
34 formation processes, rather than nighttime chemistry, excepting NOS_m. Additionally,
35 although OS formation in the urban and suburban areas exhibited similar diurnal
36 variations, the average concentrations of biogenic and anthropogenic OSs decreased
37 significantly from the urban site to the suburban site. Furthermore, we concretized
38 daytime OS formation based on the interactions among OSs, ultraviolet (UV), ozone
39 (O₃), and sulfate (SO₄²⁻). Indeed, the concentrations of most OSs were significantly
40 correlated with the values of UV[O₃][SO₄²⁻] during daytime in both urban and suburban
41 Shanghai. In particular, the correlation between major OSs and UV[O₃][SO₄²⁻] was
42 stronger than the correlation of major OSs with O₃ and SO₄²⁻; moreover, there was no
43 significant correlation between major OSs and UV. Thus, higher urban OS events were
44 attributed to the enhanced photochemical processes and sulfate level in the urban area.
45 Overall, this study provides field evidence for the influence of photochemical process
46 and anthropogenic sulfate on OS formation and has important implications for the

47 mitigation of organic particulate pollution.

49

50 **1. Introduction**

51 Organosulfates (OSs) are ubiquitous constituents in secondary organic aerosol
52 (SOA) and can contribute up to ~30% of organic mass in atmospheric fine particles
53 (PM_{2.5}) (Tolocka and Turpin 2012; Surratt et al. 2008; Hettiyadura et al. 2018). OSs
54 affect the formation, hygroscopicity, light-absorbing, and acidity of organic aerosols as
55 well as biogeochemical cycles of sulfur (Estillore et al. 2016; Riva et al. 2019; Fleming
56 et al. 2019), which are tightly associated with air quality, human health, and regional
57 climate (Ramanathan et al. 2001; Menon et al. 2008). Thus, understanding the
58 mechanisms and key influencing factors of OS formation in the ambient atmosphere is
59 of great significance for an effective assessment of environment and climate effects of
60 OSs.

61 Many laboratory studies have suggested that heterogeneous and multiphase
62 reactions involving biogenic and anthropogenic volatile organic compounds (VOCs),
63 their oxidation intermediates, and sulfate or gas-phase sulfur dioxide (SO₂) are
64 important pathways for the formation of OSs (Blair et al. 2017; Riva et al. 2016b; Ye et
65 al. 2018). For example, the formation of 2-methyltetrol sulfate ester (2-MT-OS) and 2-
66 methylglyceric acid sulfate ester (2-MGA-OS) can be attributed to the reactive uptake
67 of isoprene epoxydiols (IEPOX) and isoprene-derived hydroxymethyl-methyl- α -
68 lactone (HMML) by acidic particles, respectively (Surratt et al. 2010; Nguyen et al.

69 2015). The ozonolysis of α -pinene and limonene in the presence of SO₂ can contribute
70 to the production of monoterpene-derived OSs (e.g., C₉H₁₅O₇S⁻ and C₁₀H₁₇O₇S⁻) (Ye
71 et al. 2018). Chamber experiments by Riva et al., (Riva et al. 2015) showed that the
72 photooxidation of C₁₀–C₁₂ alkanes is associated with the formation of aliphatic OSs.
73 More recently, the aliphatic OSs have been identified based on the uptake experiments
74 of SO₂ by oleic acid and other unsaturated fatty acids (Shang et al. 2016; Passananti et
75 al. 2016). In addition, the gas-phase oxidation of polycyclic aromatic hydrocarbons was
76 found to be an important source of aromatic OSs (Riva et al. 2015).

77 Furthermore, OSs have been identified in different ambient atmospheres, including
78 suburban, rural, urban, marine, polar, and forest areas (Kristensen and Glasius 2011;
79 Hettiyadura et al. 2017; Hawkins et al. 2010; Stone et al. 2012; Hettiyadura et al. 2018;
80 Hansen et al. 2014; Glasius et al. 2018). Owing to different levels of precursors and
81 atmospheric pollution, the abundance and formation pathways of OSs change
82 substantially in temporal and spatial scales (Wang et al. 2021; Ding et al. 2022; Jiang
83 et al. 2022; Nozière et al. 2010; O'brien et al. 2014). Patently, field observations are
84 valuable for verifying the mechanistic understanding of OS formation obtained in the
85 laboratory studies. The importance of atmospheric oxidants and sulfate (or SO₂) in the
86 OS formation was proposed in field observations according to a correlation analysis of
87 OSs with ozone (O₃) (or the sum of O₃ and NO₂ concentrations) and sulfate (or SO₂)
88 (Nguyen et al. 2014; Hettiyadura et al. 2019; Wang et al. 2018). Notably, these
89 observation-based studies also highlighted the role of photochemistry of OS precursors.
90 However, the interactions among ultraviolet (UV), O₃, and sulfate have not been well

91 investigated. In particular, few studies were performed to systematically reveal the
92 difference in the formation processes of OSs in polluted and clean areas, as well as
93 during daytime and nighttime.

94 Shanghai is a megacity in the Yangtze River Delta (YRD) region of China.
95 Locally varied ambient conditions such as O₃, SO₂, and NO_x, relative humidity (RH),
96 and aerosol acidity affect the formation of OSs significantly (Cai et al. 2020; Wang et
97 al. 2021). Here, 130 OS species were quantified (or semi-quantified) in PM_{2.5} samples
98 collected in urban and suburban Shanghai in summer 2021 to investigate the relative
99 influence of photochemistry and nighttime chemistry on OS formation and their
100 linkages with anthropogenic sulfate pollution. In addition, the potential impacts of
101 aerosol acidity and aerosol liquid water (ALW) on OS formation were discussed. This
102 study can help to deepen the understanding of photochemical process and nighttime
103 chemistry of OSs in the atmosphere.

104

105 **2. Materials and Methods**

106 **2.1 Site Description and Sample Collection**

107 Ambient PM_{2.5} samples were continuously collected in the urban center and
108 suburban area in Shanghai from 11 to 23 July 2021 (**Figure S1**). The sampling site in
109 the urban center is located on the roof of a building (~20 m above the ground) in the
110 Xuhui Campus of Shanghai Jiao Tong University. The site is characterized by a typical
111 urban environment with heavy traffic and dense population. The aerosol sampler in the
112 suburban area was placed on the roof of a ~20 m high building in a monitoring station

113 of Pudong Huinan. This site is closer to the coastline than the urban sampling site
114 (**Figure S1**). Thus, the suburban site is expected to be more affected by clean air mass
115 from the sea. PM_{2.5} was sampled onto the prebaked (550°C for ~8 h) quartz fiber filters
116 (8 × 10 in., Whatman) using a high-volume air sampler (HiVol 3000, Ecotech) at a flow
117 rate of 67.8 m³ min⁻¹. The duration of each sample collection in both urban and
118 suburban areas was approximately 11 h during the daytime (8:30–19:30 LT) and 12 h
119 during the nighttime (20:00–8:00 LT). Two blank filter samples were collected at each
120 site during the campaign. A total of 50 filter samples were collected, which were stored
121 at –30°C until analysis.

122

123 **2.2 Chemical Analysis and Prediction of Aerosol Acidity and ALW**

124 A portion of the filter (~15.9 cm²) was extracted with 3 mL methanol in an
125 ultrasonic bath for 30 min for two times. The **sodium camphor sulfonate** (1 ppm) was
126 spiked on the filter punches as an internal standard before extracting. The extracts
127 obtained each time were combined and filtered through a 0.22 μm Teflon syringe filter
128 (CNW Technologies GmbH) and then concentrated to 300 μL under a gentle stream of
129 ultra-high-purity nitrogen gas. Subsequently, 300 μL ultrapure water was added into the
130 concentrated samples, followed by centrifugation to get the supernatant for analysis.
131 OSs were analyzed using an Acquity UPLC (Waters, USA) coupled to a Xevo G2-XS
132 **Quadrupole** time-of-flight mass spectrometer (ToF-MS, Waters, USA) equipped with
133 an electrospray ionization (ESI) source operated in the negative ion mode. The
134 chromatographic conditions and analytical procedures were detailed in our recent

135 publication (Wang et al. 2021).

136 A total of 212 OSs were identified by UPLC-MS analysis, in which 130 OS species
137 were quantified (or semi-quantified) (Table 1 and Table S1). The quantified (or semi-
138 quantified) species included isoprene-derived OSs (OS_i), monoterpene-derived OSs
139 (OS_m), C₂-C₃ OSs, aliphatic OSs, and aromatic OSs (Hettiyadura et al. 2019). It is worth
140 noting that most of identified OSs were semi-quantified using surrogate standards
141 because of the lack of authentic standards (Staudt et al. 2014; Hettiyadura et al. 2015).
142 The surrogate OS standards included potassium phenyl sulfate (98%, Tokyo Chemical
143 Industry), methyl sulfate (99%, Macklin), sodium octyl sulfate (95%, Sigma-Aldrich),
144 glycolic acid sulfate (artificial synthesis), lactic acid sulfate (artificial synthesis),
145 limonaketone sulfate (artificial synthesis), and α -pinene sulfate (artificial synthesis)
146 (Olson et al. 2011; Wang et al. 2017; Hettiyadura et al. 2019; Hettiyadura et al. 2017;
147 Wang et al. 2018), as detailed by our previous study (Wang et al. 2021). Considering
148 that OSs with similar structures of carbon backbone typically have similar MS
149 responses (Wang et al. 2021; Wang et al. 2017), the selection of surrogate standard for
150 a given OS was primarily based on the similarities in the carbon chain structure of the
151 standard and targeted OS species (Hettiyadura et al. 2017). Furthermore, the similarities
152 of the sulfur-containing fragment ions in the MS/MS spectra of the standard and
153 targeted OS species have also been adopted (Wang et al. 2021; Hettiyadura et al. 2019).
154 For OSs that have been reported in previous studies, MS/MS can further support their
155 structural identifications (Table 1). However, most of OSs without identified structural
156 information were classified and semi-quantified according to their molecular formulas

157 and correlation analysis with known OSs and unidentified OSs (**Sect. S1**) (Bryant et al.
158 2021; Hettiyadura et al. 2019). Details about the standards used for quantitative OS
159 species as well as about the classification or identification of OSs were shown in Table
160 1, Table S1, and Supplementary Information (**Sect. S1**). We found that most of OSs
161 without identified structural information in previous studies and this study had
162 significantly lower peak intensity compared to those listed in Table 1, implying that
163 these OS compounds have weak impact on total OS abundance in ambient aerosols. In
164 general, the differential ionization efficiencies and fragmentation patterns in the OS
165 measurement may introduce biases (Hettiyadura et al. 2017). Consequently, the OS
166 species shown in Table 1 and Table S1 should not be regarded as an accurate measure
167 of OS compounds, but a best solution in the absence of authentic OS standards
168 (Hettiyadura et al. 2015; Hettiyadura et al. 2017; Hettiyadura et al. 2019; Wang et al.
169 2021). The recoveries of OS standards ranged from 84% to 94% (87%±4%). Thus, we
170 assumed that there is a high extraction efficiency for major OS species in this study, as
171 indicated by previous studies (Wang et al. 2021; Hettiyadura et al. 2015). Detailed data
172 quality control was described in our recent publication (Wang et al. 2021).

173 The mass concentrations of organic carbon (OC) and elemental carbon (EC) were
174 determined via an OC/EC analyzer (DRI Model 2015). The mass concentrations of OC
175 were converted to those of organic matter (OM) using a conversion factor of 1.6 (Turpin
176 and Lim 2001; Wang et al. 2021; Wang et al. 2018). The mass concentrations of
177 inorganic ions in PM_{2.5} samples, including Na⁺, NH₄⁺, K⁺, Mg²⁺, Ca²⁺, Cl⁻, NO₃⁻, and
178 SO₄²⁻, were measured using an ion chromatograph system (ICS-5000+, Thermo, USA).

179 A thermodynamic model (ISORROPIA-II) was used to predict the mass
180 concentration of ALW and pH (Guo et al. 2015; Hennigan et al. 2015). The model was
181 operated with particle-phase concentrations of Na^+ , SO_4^{2-} , NH_4^+ , NO_3^- , Cl^- , Ca^{2+} , K^+ ,
182 and Mg^{2+} , as well as ambient temperature (T) and RH as the inputs. Moreover, the
183 forward mode with the thermodynamically metastable state was selected. The detailed
184 descriptions on ALW and pH predictions were shown in our previous studies (Wang et
185 al. 2021; Xu et al. 2020). In particular, we compared different outputs of the pH values
186 calculated by ISORROPIA-II between the cases with and without considering OSs as
187 additional sulfates to investigate potential impact of OSs on pH prediction (Riva et al.
188 2019). The pH values predicted from these two cases (2.55 ± 0.93 vs 2.65 ± 0.94 at the
189 urban site and 2.17 ± 0.68 vs 2.23 ± 0.74 at the suburban site) have an insignificant
190 difference. Thus, OSs were expected to have a considerably small contribution to pH
191 prediction in this study.

192

193 2.3. Auxiliary Data and Data Analysis

194 The transport trajectories of air masses arriving at the sampling sites during the
195 sampling period were created using the database of NOAA's Air Resources Laboratory
196 (NOAA's Air Resources Laboratory, USA) and MeteoInfoMap software coupled with
197 TrajStat program (Chinese Academy of Meteorological Sciences, China). The data of
198 T, RH, wind speed, and UV irradiation as well as the concentrations of NO, NO₂, O₃,
199 SO₂, and PM_{2.5} at the urban and suburban sites were obtained from the environmental
200 monitoring stations of Xuhui (~4 km away from the sampling site) and Pudong Huinan

201 (~10 m away from the sampling site), respectively. The ventilation coefficient (VC) can
202 be used to characterize the state of atmospheric dilution in pollutant concentrations
203 (Gani et al. 2019). The VC value can be expressed as a product of wind speed and
204 planetary boundary layer height (PBLH).

205

206 **3. Results and Discussion**

207 **3.1. Molecular compositions and concentrations of OSs**

208 The mass concentrations and mass fractions of the OS species in PM_{2.5} collected
209 in Shanghai were shown in **Figure 1**, with a focus on their spatial and diurnal
210 differences. On average, isoprene-derived OSs (i.e., OS_i) were the dominant
211 components at both urban and suburban sites (**Figures 1a,d**), which accounted for 53.9
212 ± 0.1% and 48.1 ± 0.1% of the total OS masses, respectively. The mass fractions and
213 concentrations of C₅H₁₁O₇S⁻ were the highest among all kinds of OS_i. In contrast, OS_i
214 containing nitrogen atoms only accounted for a small proportion of OS_i in both urban
215 and suburban areas (**Figures 1a,d** and **Table S2**). Monoterpene-derived OSs (OS_m)
216 were the second most abundant OS components, whose concentrations averaged 30.6
217 ± 46.4 ng m⁻³ and 19.3 ± 25.7 ng m⁻³ in the urban and suburban areas, respectively.
218 Moreover, the abundance of OS_m was also less controlled by nitrogen-containing OS_m.
219 On average, the OS species with two or three carbon atoms (C₂-C₃ OSs) and
220 anthropogenic OSs (OS_a) together contributed to 26.8% and 33.1% of total OS
221 concentrations in the urban and suburban areas, respectively (**Figures 1a,d** and **Table**
222 **S3**). A similar pattern in the relative abundance of different groups of OSs was also

223 observed at the same sites in summer 2020 (**Figure S2**). The predominance of OS_i was
224 well documented by many previous observations in Beijing, China (Wang et al. 2018),
225 Guangzhou, China (Bryant et al. 2021), and Atlanta, Georgia, USA (Hettiyadura et al.
226 2019), Hong Kong, China (Wang et al. 2022), Copenhagen, Denmark (Nguyen et al.
227 2014), Centreville, AL, USA (Hettiyadura et al. 2017), Zion, Illinois, USA (Hughes et
228 al. 2021). A reasonable explanation for these cases is that there is a large biogenic
229 emission of isoprene, particularly during summer days with higher temperature than in
230 other seasons (Bryant et al. 2021). Interestingly, we found that the mass concentrations
231 of all types of OSs (i.e., total OS_i, OS_m, C₂-C₃ OSs, and OS_a) tended to decrease from
232 the urban area to the suburban area. This spatial difference in OS concentrations can be
233 attributed to varied atmospheric oxidation capacity and aerosol properties (e.g., sulfate,
234 acidity, and ALW) (Wang et al. 2021), which will be discussed in detail below.

235 **Table S4** gives an overview of OSs in PM_{2.5} in different regions around the world.
236 The concentrations of total OSs in our study (more than 102.3 ng m⁻³) were higher than
237 those in Copenhagen, Denmark (75.7 ng m⁻³) (Nguyen et al. 2014), and Beijing, China
238 (27.4 ng m⁻³) (Wang et al. 2018). However, the OSs showed a lower concentration in
239 Shanghai compared to the observations in Guangzhou (486.4 ng m⁻³) (Wang et al. 2022)
240 and Atlanta, USA (Hettiyadura et al. 2019) (1249.4 ng m⁻³). The concentrations of OS_i
241 in this study were lower than those observed in summertime Atlanta, USA (1123.0 ng
242 m⁻³) (Hettiyadura et al. 2019), Guangzhou, China (460.2 ng m⁻³) (Wang et al. 2022),
243 and Hongkong, China (163.2 ng m⁻³) (Wang et al. 2022), but higher than Copenhagen,
244 Denmark (11.3 ng m⁻³) (Nguyen et al. 2014). For OS_m and C₂-C₃ OSs, their

245 concentrations also showed a variable **range** in different regions (**Table S4**). The
246 concentrations of OS_a in this study were much higher than those in previous
247 observations (Hettiyadura et al. 2017; Kanellopoulos et al. 2022), which is likely
248 explained by more OS_a species being quantified or higher air pollution level in this study.
249 **It should be noted that these spatial comparisons for OS levels mentioned above**
250 **involved more or less uncertainty due to the lack of authentic standards for precise**
251 **quantification of OSs. However, our semi-quantitative data provides at least literature**
252 **reference for future research on these OSs. At the same study site, the abundances of**
253 **biogenic OSs (OS_i + OS_m) were typically higher than those of other types of OSs,**
254 **particularly during the summertime when vegetation grows vigorously (Table S4).**
255 Thus, the yield of summertime OSs in the investigated areas largely depends on the
256 emission level of biogenic VOCs and the air pollution status.

257 We found that the contributions of total OSs to OM were $1.3 \pm 0.5\%$ and $1.9 \pm 0.5\%$
258 at urban and suburban sites in summer 2021, respectively. These proportions of total
259 OSs in OM were larger than those observed in Beijing, China (0.3%) (Wang et al. 2018)
260 and Centreville, USA (0.2%) (Hettiyadura et al. 2017). However, significant higher
261 contribution of total OSs to OM was observed in Atlanta, USA (10.3%) (Hettiyadura et
262 al. 2019) where the formation of OSs was dominated by the oxidation of biogenic VOCs.
263 In particular, total OSs contributed to $1.2 \pm 0.8\%$ of OM in summer 2015 and $1.1 \pm 0.8\%$
264 of OM in summer 2019 in urban Shanghai (Wang et al. 2021). Thus, although
265 anthropogenic emission reduction has been vigorously promoted by the local
266 government in recent years (Guo et al. 2022; Pei et al. 2022), the contribution of SOA

267 to OM in Shanghai has not decreased significantly as expected (Wang et al. 2021).

268 **Figures 1b,e** show diurnal differences in the mass concentrations and mass
269 fractions of the OS components in PM_{2.5} collected at the urban site. The OS_i was the
270 dominant sulfur-containing species regardless of in daytime and nighttime. However,
271 the concentrations of OS_i exhibited a significant decrease from the daytime ($117.8 \pm$
272 148.1 ng m^{-3}) to the nighttime ($43.9 \pm 62.0 \text{ ng m}^{-3}$), except for isoprene-derived
273 nitrooxyorganosulfates (NOS_i). Moreover, the variations in OS_i mass concentrations
274 (~ 2 times) were much larger than those in OS_i mass fractions (< 1.2 times). These
275 results indicate that the production of major OS_i (e.g., C₅H₁₁O₇S⁻, C₅H₉O₇S⁻ and
276 C₅H₇O₇S⁻) was weakened during the nighttime. In contrast, the higher concentration
277 for these OS_i in the daytime can be attributed to the increased levels of precursors (e.g.,
278 isoprene) (Bryant et al. 2021) and oxidants (e.g., O₃) (**Table S5**) as well as the strong
279 photochemistry in the daytime. Although the average fraction of NOS_i was higher in
280 the nighttime than in the daytime, their concentration was similar between the daytime
281 and nighttime. This is because that several special NOS_i (e.g., C₅H₁₀NO₉S⁻,
282 C₅H₈NO₁₀S⁻, C₄H₈NO₇S⁻, and C₅H₈NO₇S⁻) peaked in the daytime, although
283 C₅H₉N₂O₁₁S⁻ showed maximum in the nighttime (**Table S2**). Previous laboratory
284 studies have suggested that the formation of C₅H₁₀NO₉S⁻ is mainly related to •OH
285 oxidation processes (Hamilton et al. 2021). Thus, a strong photochemical oxidation
286 during daytime can be responsible for the increases in concentrations of these NOS_i
287 (particularly C₅H₁₀NO₉S⁻) from the nighttime to the daytime. Overall, the diurnal
288 variations of other OSs including OS_m, C₂-C₃ OSs, and OS_a were similar to that of OS_i,

289 with a higher level in the daytime than in the nighttime excepting for NOSs (**Figure 1**
290 and **Tables S2** and **S3**). It is noteworthy that the fractions and concentrations of
291 monoterpene-derived NOSs (NOS_m) were higher in the nighttime than in the daytime
292 (**Table S2**). This case can be attributed to NO₃•-related nighttime chemistry (Wang et
293 al. 2018). Thus, these findings further emphasize the importance of photochemistry for
294 daytime OS formation and nighttime chemistry for NOS (in particular NOS_m)
295 formation in urban Shanghai.

296 The concentrations of various types of OSs at the suburban site were lower than
297 those at the urban site in both daytime and nighttime (**Figures 1b,c**). However, the
298 characteristics of diurnal difference in various OSs at the suburban site were similar to
299 those observed at the urban site, which showed a substantially higher OS level in the
300 daytime. A similar case was also found in Beijing in 2016 (Wang et al. 2018) and
301 Shanghai in 2017 (Cai et al. 2020). Clearly, the aerosol OS abundance in Shanghai was
302 mainly controlled by the OS formation process in the daytime rather than in the
303 nighttime.

304

305 **3.2. Time series of the major OSs**

306 **Figures 2a-2h** compare the time series of the major OS species and inorganic ions
307 in PM_{2.5} collected at urban and suburban sites. The OS_i concentrations peaked during
308 daytime on July 11 and 12, with maximum values of 479.8 ng m⁻³ and 309.5 ng m⁻³ at
309 urban and suburban sites, respectively. Owing to the high proportion of OS_i in total OSs,
310 total OS concentrations also showed maximum values during July 11 and 12. The mass

311 concentrations of total OSs, OS_i, and C₅H₁₁O₇S⁻ (a major OS_i component) decreased
312 from July 11 to July 14 (period A; i.e., relatively polluted period) in both urban and
313 suburban areas, whereas their concentrations exhibited a quite small fluctuation after
314 July 14 (period B; i.e., clean period). As a result, the mean concentrations of total OSs
315 and OS_i were ~4 times higher in the period A than in the period B. The temporal
316 variations in the concentrations of OS_m, C₈H₁₃O₇S⁻ (a major component of OS_m)
317 (Schindelka et al. 2013), OS_a, and C₂-C₃ OSs were similar to those of total OSs and OS_i.
318 However, the dissimilarities in the diurnal variations of OSs in period A and period B
319 suggest that the sources or levels of precursors and oxidants associated with OS
320 formation differed between these two periods. This consideration was further supported
321 by decreasing O₃ and NO₂ levels from period A to period B (**Table S5** and **Figures 2i,j**).

322 Sulfate showed a temporal variation similar to total OSs, OS_i, and OS_m
323 concentrations in most days (**Figures 2g,h**). We observed several abnormally high
324 sulfate events during period B (from the evening of the 17th to 18th). The transport
325 distance of air mass on July 18 was found to be shorter than that in other days (**Figure**
326 **S3**); moreover, VC value was lower on July 18 than on other days (**Figure S4**). Thus,
327 this high sulfate case can be partly attributed to the special meteorological conditions
328 on July 18. In general, sulfate concentrations showed a strong correlation with total OSs,
329 OS_i, and OS_m concentrations at both sites ($P < 0.01$, $r = 0.76-0.78$). These results
330 indicate that the abundances of OSs in these two study areas were tightly associated
331 with sulfate-related particle-phase chemistry (Surratt et al. 2008).

332 The concentrations of total OSs, OS_i, and OS_m exhibited a distinct diurnal

333 variation during period A at both sites, with a higher concentration in the daytime. The
334 diurnal variation pattern of OSs was similar to those of O₃ and sulfate. These findings
335 imply an important role of atmospheric oxidation capacity and sulfate in daytime OS
336 formation. Exceptionally, although a clear diurnal pattern was also observed for NOS_m,
337 their concentrations peaked in the nighttime, suggesting that the formation of NOS_m
338 was highly affected by the NO₃•-related nighttime chemistry (Iinuma et al. 2007;
339 Surratt et al. 2008). In the period B, the concentrations of various OSs showed a weak
340 diurnal variation, with a slightly higher level in the daytime.

341 As mentioned above, the ambient levels of oxidants (e.g, O₃ and NO₂) and sulfates
342 showed a significant difference in period A and period B, which were tightly associated
343 with the formation of OSs (Wang et al. 2021). Cluster analysis of backward trajectories
344 showed that air masses arriving at both urban and suburban sites in the period A mainly
345 originated from the continental region, with significant influences of anthropogenic
346 emissions (e.g., NO_x and SO₂) from southern YRD. Furthermore, considering the
347 distinct and similar diurnal variation of O₃, NO₂, SO₂, sulfate, and OSs during period A
348 at both sites, aerosol OSs can be assumed to be mainly formed in local areas. In contrast,
349 these two sampling sites were primarily affected by air masses transported from the
350 East China Sea in the period B. Moreover, the average VC value in the period A was
351 two times lower than that in the period B (**Table S5**), implying relatively weaker
352 diffusion and dilution of air pollutants in the period A. These factors can be partly
353 responsible for the higher oxidant and sulfate concentrations in the period A than in the
354 period B. Similarly, since the suburban site is closer to the East China Sea with a

355 decreased influence from anthropogenic emissions (**Figure 3**), the levels of O₃, NO_x,
 356 and sulfate were higher at the urban site than at the suburban site (**Figure 2** and **Table**
 357 **S5**). The differences in the concentration of oxidants and sulfate might provide an
 358 explanation for the difference in the concentrations of OSs between periods A and B as
 359 well as between urban and suburban sites.

360

361 **3.3. Formation mechanisms of OSs**

362 **3.3.1 Isoprene-derived OSs**

363 Previous laboratory studies have suggested that isoprene can react with •OH to
 364 form IEPOX in the gas phase under low NO_x conditions (Fabien et al. 2009). In the
 365 daytime, ambient O₃ can be rapidly photolyzed to generate •OH under the influence of
 366 UV (Kourtchev et al. 2015). Thus, O₃ and UV could serve as a proxy of •OH.
 367 Considering a significant role of photochemistry and sulfate-related heterogeneous
 368 chemistry in the formation of OSs, OS_i production is expected to be closely associated
 369 with isoprene, O₃, UV, and sulfate. Specifically, the simplified pathways leading to the
 370 formation of OS_i in the atmosphere can be derived as follows.

376 Where J_{O_3} is the photolysis rate constant, k_{1-4} is the second-order rate coefficient, M is

377 N₂ or O₂, and X represents the potential products (e.g., IEPOX and HMML) of isoprene
 378 oxidation by •OH.

379 Assuming the concentrations of O(¹D) and •OH are in the steady state, we can
 380 derive the following equations (H. and Seinfeld 2016).

$$381 \quad [O(^1D)] = \frac{J_{O_3}[O_3]}{k_1[H_2O] + k_2[M]} \quad (6)$$

$$382 \quad [•OH] = 2\tau_{OH}k_1[O(^1D)][H_2O] \quad (7)$$

383 Where τ_{OH} is the average lifetime of •OH. In general, J_{O_3} is linearly dependent on the
 384 UV radiation, i.e., $J_{O_3} = \phi UV$, where ϕ is the slope of the linear fitting between J_{O_3} and
 385 UV radiation (Li et al. 2022). Combining equation (6) and (7), the steady-state •OH
 386 concentration can be expressed as:

$$387 \quad [•OH] = \frac{2\tau_{OH}k_1[H_2O]J_{O_3}[O_3]}{k_1[H_2O] + k_2[M]} = \alpha\phi\tau_{OH}UV[O_3] \quad (8)$$

$$388 \quad \alpha = \frac{2k_1[H_2O]}{k_1[H_2O] + k_2[M]} \quad (9)$$

389 Also, assuming a steady-state to the oxygenated organic intermediates (i.e., X),
 390 we can derive:

$$391 \quad [X] = k_3\tau_X[Isoprene][OH] = \alpha\phi k_3\tau_X\tau_{OH}[Isoprene]UV[O_3] \quad (10)$$

392 Where τ_X is the average lifetime of X in the atmosphere.

393 During the strong formation of OS_i via the heterogeneous reactions of X on acidic
 394 sulfate, the change in the abundance of OS_i is expected to be proportional to its
 395 formation rate:

$$396 \quad \frac{d[OS_i]}{dt} \propto k_4[SO_4^{2-}][X] \propto \alpha\phi k_3 k_4 \tau_X \tau_{OH} [Isoprene] UV [O_3] [SO_4^{2-}] \quad (11)$$

397 It should be noted that the above equations are derived based on the assumption
 398 that the reaction between O(¹D) and H₂O is a major source of summertime •OH in the

399 studied areas. Given that a linear relationship was observed between atmospheric •OH
400 and $J_{O(^1D)}$ in different atmospheres (Stone et al., 2012), such an assumption seems to
401 be reasonable. When isoprene is in a steady state in the atmosphere, OS_i production is
402 expected to be proportional to the product of O₃, UV, and sulfate.

$$403 \quad \frac{d[OS_i]}{dt} \propto UV[O_3][SO_4^{2-}] \quad (12)$$

404 It should be noted that equation (12) did not consider the influences of aerosol
405 acidity, ALW, and other factors (e.g., •OH production from the photolysis of nitrous
406 acid and aldehydes during the daytime). However, the deduction can at least suggest
407 that the secondary production of OS_i is positively correlated with the value of
408 $UV[O_3][SO_4^{2-}]$. Indeed, the concentrations of daytime OS_i and major OS_i species
409 showed a linear positive relationship with the value of $UV[O_3][SO_4^{2-}]$ at both urban and
410 suburban sites ($r = 0.84\text{--}0.92$, $P < 0.01$) (**Figure 4a-c**). We found that the correlation
411 between major OS_i species and $UV[O_3][SO_4^{2-}]$ was stronger than the correlation of
412 major OS_i species with O₃ and SO_4^{2-} ($r < 0.82$, $P < 0.01$); moreover, there was no
413 significant correlation between major OSs and UV ($P > 0.05$). Thus, our results provide
414 field evidence that the formation of daytime OS_i in these two study areas was mainly
415 controlled by •OH oxidation of isoprene; moreover, the higher concentration of OS_i in
416 the urban area can be attributed to the stronger atmospheric oxidation capacity (i.e.,
417 higher $UV[O_3]$ value) and more serious anthropogenic sulfate pollution (particularly
418 during period A). We also observed that the OS concentrations did not significantly
419 increase in several high sulfate events in the period B. One possible explanation is that
420 these abnormal high sulfate events resulted in excessive SO_4^{2-} in the formation of OSs.

421 2-MT-OS and 2-MGA-OS have been identified as important tracers of isoprene-
422 derived SOA (Hettiyadura et al. 2019; Cai et al. 2020). During isoprene oxidation by
423 •OH, these two OS species are produced under low (i.e., IEPOX pathway) and high
424 (i.e., HMML or methacrylic acid epoxide (MAE) pathways) NO_x conditions,
425 respectively (Surratt et al. 2010; Nguyen et al. 2015). The ratios of 2-MT-OS
426 concentration to 2-MGA-OS concentration in the daytime were 9.7 ± 3.1 and $12.1 \pm$
427 5.5 at urban and suburban sites, respectively (**Figure S5b**). A 2-MT-OS/2-MGA-OS
428 ratio of larger than 1 was also found in observations in summer 2020 (**Figure S5a**),
429 suggesting low NO_x channel dominated the formation of daytime OS_i in the two study
430 areas. This finding was similar to previous observations in Beijing (3.2) (Wang et al.
431 2020) and Guangzhou (7.6) (Bryant et al. 2021). Other abundant OS_i compounds
432 including C₅H₇O₇S⁻, C₄H₇O₆S⁻, and C₅H₉O₇S⁻ can be produced by the photooxidation
433 of isoprene, heterogeneous oxidative aging of 2-MT-OS, or sulfate radical-initiated
434 reaction with methacrolein and methyl vinyl ketone in the aqueous phase (Schindelka
435 et al. 2013; Wach et al. 2019; Hettiyadura et al. 2015). These OSs showed strong
436 correlations ($r = 0.74\text{--}0.90$, $P < 0.01$) with UV[O₃][SO₄²⁻], which further highlights the
437 significance of the photochemistry in OS_i formation.

438 In the nighttime, the formation •OH can be primarily attributed to the reactions of
439 olefins and O₃ (Paulson and Orlando 1996). As shown in **Figures 4d-f**, total OS_i and
440 major OS_i compounds were significantly correlated with the product of O₃ and SO₄²⁻
441 concentrations ($P < 0.01$, $r = 0.96\text{--}0.98$). Since the nighttime oxidant level (including
442 O₃ and •OH) was substantially lower than that in the daytime (**Table S5**), the production

443 of OS_i was weakened in the nighttime (**Table S2**). It is interesting to note the 2-MT-
444 OS/2-MGA-OS mean ratio in the nighttime was 13.1–15.0 (**Figure S5(b)**), significantly
445 higher than the mean ratio (9.7–12.1) in the daytime, indicating that the IEPOX
446 pathway may be a potential mechanism to generate OS_i in the nighttime. **Another**
447 **possible explanation for the decreased OS concentration in the nighttime is that these**
448 **OSs were mainly formed during the daytime, but had a lower abundance in the**
449 **nighttime due to deposition and weak nighttime formation. Namely, considering the**
450 **strong diffusion effect during the daytime and the weak diffusion effect at the nighttime**
451 **(Figure S4), the nighttime OSs may be partially derived from OSs formed via**
452 **photochemical processes during the daytime. This is because the enhanced diffusion**
453 **effect during the daytime can result in a decrease in the amount of OS produced during**
454 **the daytime to deposit into the nighttime.**

455 Furthermore, NO₃• chemistry in the nighttime was another possible pathway to
456 form OS_i, particularly NOSs. The nighttime NOS concentration was linearly correlated
457 with the product of NO₂ and O₃ ([NO₂][O₃], i.e., a proxy of NO₃•) (**Figure S6**).
458 Interestingly, most of NOS_i (e.g., C₅H₁₀NO₉S⁻, C₅H₈NO₁₀S⁻, C₄H₈NO₇S⁻, and
459 C₅H₈NO₇S⁻) have higher concentrations in the daytime, excepting for C₅H₉N₂O₁₁S⁻.
460 Thus, although nighttime NO₃• chemistry was important, the NOS_i formed via
461 photochemistry under the influence of NO_x in the daytime was still dominant
462 contributors to total NOS_i in our study areas. Regarding C₅H₉N₂O₁₁S⁻, its formation
463 pathway is mainly the NO₃• oxidation of C₅H₉NO₅ as illustrated in **Figure S7**
464 (Hamilton et al. 2021). Accordingly, the abundance of C₅H₉N₂O₁₁S⁻ peaked during the

465 nighttime (**Figure S8**). It should be pointed out that the $\bullet\text{OH}$ oxidation of $\text{C}_5\text{H}_9\text{NO}_5$ can
466 also contribute to the production of $\text{C}_5\text{H}_{10}\text{NO}_9\text{S}^-$ (**Figure S7**). Clearly, this mechanism
467 can be responsible for the higher $\text{C}_5\text{H}_{10}\text{NO}_9\text{S}^-$ concentrations in the daytime as
468 mentioned above. In general, increased OS_i level in the daytime demonstrated that the
469 formation of OS_i in urban and suburban areas was largely controlled by photooxidation
470 of isoprene in the presence of sulfate in the daytime, rather than nighttime $\text{NO}_3\bullet$
471 chemistry. Moreover, a decrease in average OS_i level from the urban area to the
472 suburban area can be explained by the weakened photooxidation of isoprene and the
473 decreased anthropogenic sulfate pollution (particularly in the relatively polluted period).

474

475 **3.3.2 Monoterpene-derived OSs**

476 The concentrations of the most abundant OS_m species ($\text{C}_{10}\text{H}_{15}\text{O}_7\text{S}^-$ and $\text{C}_8\text{H}_{13}\text{O}_7\text{S}^-$)
477 showed a strong correlation with the value of $\text{UV}[\text{O}_3][\text{SO}_4^{2-}]$ (and $\text{UV}[\text{O}_3][\text{SO}_2]$) in the
478 daytime at both urban and suburban sites ($r = 0.82\text{--}0.86$, $P < 0.01$), indicating that the
479 photooxidation of monoterpenes was a significant source for OS_m . Previous studies also
480 demonstrated that $\text{C}_{10}\text{H}_{15}\text{O}_7\text{S}^-$ can be produced through the photooxidation of
481 monoterpenes or sulfate radical reaction with α -pinene (Surratt et al. 2008; Nozière et
482 al. 2010).

483 In the nighttime, the concentrations of nitrogen-free OS_m species decreased
484 significantly with a decrease in the O_3 levels (Wang et al. 2020). However, NOS_m
485 species increased in concentration in the nighttime and showed a significant correlation
486 with the value of $[\text{O}_3][\text{NO}_2]$ (the proxy of $\text{NO}_3\bullet$, as mentioned above) ($r = 0.90\text{--}0.95$, P

487 < 0.01). Accordingly, nighttime $\text{NO}_3\bullet$ chemistry exerted a significant influence on the
488 abundance of NOS_m in these study areas. A study by Hamilton et al., (Hamilton et al.
489 2021) has reported that $\text{NO}_3\bullet$ chemistry plays an important role in the production of
490 NOS_m . However, the overall lower OS_m level in the nighttime (**Table S2**) suggests that
491 daytime OS_m production via monoterpenes photooxidation was still the dominant
492 contributor to total OS_m throughout the day. Although several filed studies have
493 reported the abundance of various NOS_m (e.g., $\text{C}_{10}\text{H}_{16}\text{NO}_7\text{S}^-$ and $\text{C}_9\text{H}_{14}\text{NO}_8\text{S}^-$) (Wang
494 et al. 2018; Bryant et al. 2021; Cai et al. 2020), their structures, formation mechanisms,
495 and relevant diurnal variations remain large uncertainties, which need to be deeply
496 explored in the future research.

497

498 3.3.3 C_2 - C_3 and anthropogenic OSs

499 The OS species with two or three carbon atoms (C_2 - C_3 OSs) are generally
500 considered to originate from both biogenic and anthropogenic emissions (Wang et al.
501 2020). The abundant C_2 - C_3 OS species, including $\text{C}_2\text{H}_3\text{O}_6\text{S}^-$ (glycolic acid sulfate;
502 GAS), $\text{C}_3\text{H}_5\text{O}_5\text{S}^-$ (hydroxyacetone sulfate; HAS), and $\text{C}_3\text{H}_5\text{O}_6\text{S}^-$ (lactic acid sulfate;
503 LAS), were significantly correlated with the values of $\text{UV}[\text{O}_3][\text{SO}_4^{2-}]$ in the daytime at
504 both urban and suburban sites ($r = 0.79\text{--}0.91$, $P < 0.01$), indicating that the
505 photochemical processes largely contributed to the formation of C_2 - C_3 OSs. Recently,
506 the heterogeneous $\bullet\text{OH}$ oxidation of particulate 2-MT-OS has been shown to generate
507 a series of C_2 - C_3 OSs (e.g., $\text{C}_2\text{H}_3\text{O}_6\text{S}^-$, $\text{C}_3\text{H}_5\text{O}_6\text{S}^-$, and $\text{C}_2\text{H}_3\text{O}_5\text{S}^-$) (Chen et al. 2020).
508 Moreover, $\text{C}_3\text{H}_5\text{O}_4\text{S}^-$ and $\text{C}_3\text{H}_7\text{O}_5\text{S}^-$ have previously been reported to be produced by

509 the photooxidation of diesel vehicle exhausts (Blair et al. 2017).

510 Most of the quantified OS_a compounds, including C₁₃H₂₅O₅S⁻, C₉H₁₅O₇S⁻,
511 C₈H₁₇O₄S⁻, benzyl sulfate (C₇H₇O₄S⁻), phenyl sulfate (C₆H₅O₄S⁻), as well as
512 C₆H₉O₆S⁻, C₅H₇O₆S⁻, and C₄H₇O₄S⁻, exhibited a strong correlation ($P < 0.01$) with the
513 values of UV[O₃][SO₄²⁻] in the daytime. C₁₃H₂₅O₅S⁻ has been detected in diesel exhaust
514 (Cui et al. 2019), which is the homologous compound of C₁₂H₂₃O₅S⁻ produced from
515 dodecane photooxidation (Riva et al. 2016b). A chamber study has detected C₉H₁₅O₇S⁻
516 in decalin SOA and speculated that it was produced via •OH oxidation of a C₉-carbonyl
517 hydroperoxide (C₉H₁₆O₃) and subsequent reaction on acidic sulfate aerosols (Riva et al.
518 2016b). In addition, photooxidation of diesel fuel vapor in the presence of SO₂ has been
519 suggested to be an important source of C₆H₉O₆S⁻, C₅H₇O₆S⁻, and C₄H₇O₄S⁻ species
520 (Blair et al. 2017). The formation of C₇H₇O₄S⁻ and C₆H₅O₄S⁻ can also be attributed to
521 the photooxidation of naphthalene and 2-methylnaphthalene (Riva et al. 2015).

522 We note that the concentrations of most of C₂-C₃ OS and OS_a species decreased
523 significantly from the daytime to the nighttime (**Table S2** and **Table S3**). **As discussed**
524 **above, the OSs observed in the nighttime may partially come from the OSs generated**
525 **during the daytime. Thus,** the deposition effect from the daytime to the nighttime was
526 an important factor controlling nighttime levels of C₂-C₃ OSs and OS_a. In addition, the
527 nighttime gas-phase oxidation process was also likely associated with C₂-C₃ and
528 anthropogenic OS formation at both urban and suburban sites, as suggested by the
529 significant correlations of C₂-C₃ OSs and OS_a with O₃ and [O₃][NO₂] in the nighttime
530 ($r = 0.89-0.91$, $P < 0.01$). Overall, these results further highlight the importance of

531 photochemistry in controlling the all-day abundance of OSs, as discussed earlier.

532

533 **3.3.4 The effects of ALW and pH on OS formation**

534 We have demonstrated that the atmospheric oxidation capacity (e.g., UV[O₃] and
535 [O₃ + NO₂]), sulfate pollution, and nighttime NO₃• chemistry exerted considerable
536 influences on the formation of OSs in both urban and suburban areas. In addition,
537 laboratory and field studies have suggested that aerosol properties including acidity and
538 ALW also play important roles in OS formation (Iinuma et al. 2007; Surratt et al. 2007b;
539 Wang et al. 2020; Wang et al. 2018; 2022). The aerosol pH in Shanghai in summer
540 averaged 2.7 ± 0.9 and 2.2 ± 0.7 in urban and suburban areas, respectively. The mean
541 pH value was similar to that in northern China (summer) (Ding et al. 2019; Wang et al.
542 2018), but higher than that in the Pearl River Delta (PRD) region (Fu et al. 2015). In
543 this study, only the 2-MT-OS concentration showed an evident negative correlation with
544 the pH value ($r = 0.58$, $P < 0.05$), suggesting the aerosol acidity is not a limiting factor
545 for the formation of most OS species.

546 A positive correlation was observed between the concentrations of OSs and ALW
547 only in the urban area during both daytime and nighttime (**Figure 5**), consistent with
548 our previous observations in urban Shanghai (Wang et al. 2021). It is interesting to note
549 that although higher ALW concentrations and lower pH values were observed at the
550 suburban site, the OS concentrations were significantly higher at the urban site (**Table**
551 **S5**). This result further confirms that atmospheric oxidation capacity and sulfate
552 pollution level governed the formation of OSs in urban and suburban Shanghai

553 (particularly in the relatively polluted period), though ALW and aerosol acidity also
554 played a role. Therefore, a synergistic regulation of atmospheric oxidation capacity and
555 anthropogenic SO₂ emissions would be important for the mitigation of OS and SOA
556 pollution in the megacity Shanghai.

557

558 **4. Conclusions**

559 We investigated the spatial and diurnal variations of aerosol OS formation in
560 Shanghai in summer. Isoprene- and monoterpene-derived OSs were found to be the
561 dominant OS groups during the entire sampling campaign, likely suggesting that the
562 formation of OSs was largely controlled by biogenic VOCs. Most OSs decreased from
563 the daytime to the nighttime, while NOS_m peaked during nighttime. These findings
564 suggested that OSs were mainly produced via daytime formation processes in both
565 urban and suburban areas, excepting NOS_m. Moreover, the average abundance of
566 various types of OSs showed a decrease trend from the urban area to the suburban area,
567 which can be explained by weakened atmospheric oxidation capacity and sulfate
568 pollution in the suburban area (primarily in the relatively polluted period). Further,
569 daytime OS formation was concretized according to the interactions among OSs, UV,
570 O₃, and SO₄²⁻, suggesting that the concentrations of most OSs were significantly
571 correlated with the values of UV[O₃][SO₄²⁻] during daytime in both urban and suburban
572 Shanghai. We concluded that an enhancement in the photochemical process and sulfate
573 level can exacerbate OS pollution in the urban area. These findings were summarized
574 in a diagram (**Figure 6**). Generally, our study not only deepens the understanding about

575 the importance of photochemical process and anthropogenic sulfate pollution in
576 controlling OS formation but also provides potential management strategies to decrease
577 the abundance of particulate OSs.

905 **Table 1.** Organosulfate quantification using UPLC-ESI(-)-QToFMS(/MS).

Formula ^a	MW (Da)	Standard	Structure	Reference
Isoprene-derived OSs (n = 12)				
C ₄ H ₇ O ₇ S ⁻	198.9912	Lactic acid sulfate (LAS)		(Hettiyadura et al. 2015)
C ₅ H ₁₁ O ₆ S ⁻	199.0276	LAS		(Riva et al. 2016a)
C ₅ H ₉ O ₇ S ⁻	213.0069	LAS		(Riva et al. 2016a)
C ₄ H ₇ O ₅ S ⁻	167.0014	LAS		(Schindelka et al. 2013)
C ₄ H ₇ O ₆ S ⁻	182.9963	LAS		(Shalamzari 2013)
C ₅ H ₇ O ₇ S ⁻	210.9912	LAS		(Hettiyadura et al. 2015)
C ₅ H ₉ O ₆ S ⁻	197.0120	LAS		(Riva et al. 2016a)
C ₅ H ₁₀ NO ₉ S ⁻	260.0076	LAS		(Surratt et al. 2007a)
C ₇ H ₉ O ₇ S ⁻	237.0069	LAS		(Nozière et al. 2010)
C ₅ H ₈ NO ₁₀ S ⁻	273.9869	LAS		(Nestorowicz et al. 2018)
C ₅ H ₁₀ NO ₉ S ⁻	260.0076	LAS		(Surratt et al. 2007a)
C ₅ H ₁₁ O ₇ S ⁻	215.0225	LAS		(Surratt et al. 2010)

Other quantified isoprene-derived OSs were shown in **SI Monoterpene-derived OSs (n = 10)**

$C_{10}H_{17}O_7S^-$	281.0695	α -Pinene sulfate		(Nozière et al. 2010)
$C_{10}H_{17}O_5S^-$	249.0797	α -Pinene sulfate		(Wang et al. 2017)
$C_8H_{13}O_7S^-$	253.0382	Glycolic acid sulfate (GAS)		(Schindelka et al. 2013)
$C_7H_{11}O_6S^-$	223.0276	GAS		(Yassine et al. 2012)
$C_{10}H_{16}NO_7S^-$	294.0647	α -Pinene sulfate		(Surratt et al. 2008)
$C_9H_{15}O_6S^-$	251.0589	Limonaketone sulfate		(Wang et al. 2017)
$C_{10}H_{16}NO_{10}S^-$	342.0495	Limonaketone sulfate		(Yassine et al. 2012)
$C_9H_{14}NO_8S^-$	296.0440	Limonaketone sulfate		(Surratt et al. 2008)
$C_{10}H_{15}O_7S^-$	279.0538	GAS		(Surratt et al. 2007a)
$C_7H_{11}O_7S^-$	239.0225	GAS		(Nozière et al. 2010)
Other quantified monoterpene-derived OSs were shown in SI				
C₂-C₃ OSs (n = 6)				
$C_3H_5O_4S^-$	136.9909	GAS	unknown	(Yassine et al.
$C_2H_3O_6S^-$	154.9650	GAS		(Olson et al. 2011)

$C_3H_5O_6S^-$	168.9807	LAS		(Olson et al. 2011)
$C_3H_7O_5S^-$	155.0014	GAS		(Hettiyadura et al. 2019)
$C_2H_3O_5S^-$	138.9701	GAS		(Yassine et al. 2012)
$C_3H_5O_5S^-$	152.9858	GAS		(Hettiyadura et al. 2015)
OSa (aliphatic-OSs) (n = 1)				
$C_8H_{17}O_4S^-$	210.0926	Sodium octyl Sulfate (SOS)		(Wang et al. 2021)
Other quantified aliphatic-derived OSs were shown in SI				
OSa (aromatic-OSs) (n = 2)				
$C_6H_5O_4S^-$	172.9909	Phenyl sulfate		(Wang et al. 2021)
$C_7H_7SO_4S^-$	218.9786	Phenyl sulfate		(Wang et al. 2021)
Other quantified aromatic-derived OSs were shown in SI				
OSa-other (n = 3)				
$C_4H_7O_4S^-$	151.0065	Methyl sulfate	unknown	(Wang et al. 2021)
$C_5H_7O_6S^-$	194.9963	GAS	unknown	(Wang et al. 2021)
$C_6H_9O_6S^-$	209.0120	GAS	unknown	(Berndt et al. 2016)

906 ^a MS/MS data supports tentative structural identification based on the listed references.
