**WAVINESS OF THE SOUTHERN HEMISPHERE WINTERTIME POLAR
AND SUBTROPICAL JETS**

The recently developed average latitudinal displacement (ALD) methodology is applied to assess the waviness of the austral winter subtropical and polar jets using three different reanalysis data sets. As in the wintertime Northern Hemisphere, both jets in the Southern Hemisphere have become systematically wavier over the time series and the waviness of each jet evolves quite independently of the other during most cold seasons. Also, like its Northern Hemisphere equivalent, the Southern Hemisphere polar jet exhibits no trend in speed (though it is notably slower) while its poleward shift is statistically significant. In contrast to its Northern Hemisphere counterpart, the austral subtropical jet has undergone both a systematic increase in speed as well as a statistically significant poleward migration. Composite differences between the waviest and least wavy seasons for each species suggest that the Southern Hemisphere’s lower stratospheric polar vortex is negatively impacted by unusually wavy tropopause-level jets of either species. These results are considered in the context of trends in the Southern Annular Mode as well as the findings of other related studies.

KEYWORDS: Southern Hemisphere, winter, polar jet, subtropical jet, waviness

49 **1. Introduction**

50

51 Consideration of changes in the behavior of the tropopause-level jet streams in a warming
52 world has been catalyzed by the construction of long-period reanalysis data sets over the past
53 three decades (Kalnay et al, 1996; Kistler et al., 2001; Kobayashi et al. 2015; Copernicus
54 Climate Change Services [CS3], 2017). Recent analyses employing these data sets (e.g. Archer
55 and Caldiera, 2008; Barnes and Screen, 2015; Gallego et al. 2005; Manney and Hegglin, 2018;
56 Peña-Ortiz et al. 2013; Vavrus et al. 2017), in tandem with a number of studies based upon
57 climate model output (e.g. Barnes and Polvani, 2013; Lorenz and DeWeaver, 2007; Miller et al.
58 2006; Yin, 2005), have produced a consensus view that poleward displacement of both jets
59 accompanies warming. Along with an interest in latitudinal position, nearly all of the
60 aforementioned studies have also addressed either observed and/or forecasted changes in the
61 speed of the jet streams.

62 In a recent paper Martin (2021) offered a feature-based analysis of the *waviness* of the
63 tropopause-level polar and subtropical jets during Northern Hemisphere winter (DJF). The
64 analysis proceeded from the results of Christenson et al. (2017) that identified the isentropic
65 layers that house the two species of jets during NH winter. He found that 1) the polar jet (POLJ)
66 has undergone a statistically significant poleward migration over the time series, not matched by
67 the subtropical jet (STJ), and 2) neither jet species exhibited a trend in its speed. Additionally,
68 the analysis showed that both jets have become systematically wavier over the last 6 decades.

69 By virtue of its land/sea distribution, enhanced lower tropospheric warming at high
70 latitudes of the NH, known as Arctic amplification, has recently emerged as a prominent signal
71 of climate change (e.g., Serreze et al. 2009; Screen and Simmonds, 2013: and references therein).
72 Francis and Vavrus (2012) were among the first to propose that changes in the undulatory nature

73 of the jet stream might be linked to Arctic amplification. This suggestion initiated a decade-long
74 debate on this issue (e.g. Barnes, 2013; Blackport and Screen, 2020; DiCapua and Coumou,
75 2016; Francis, 2017; Francis and Vavrus, 2015; Francis et al. 2018; Martineau et al. 2017, Screen
76 and Simmonds, 2013; Vavrus, 2018). As noted by Martin (2021), at least some of the
77 controversy and attendant lack of consensus surrounding this question (Barnes and Polvani,
78 2015) was nourished by the absence of a robust method of assessing the waviness of the
79 tropopause-level jets. The average latitudinal displacement (ALD) methodology introduced in
80 Martin (2021) (briefly described later) offers one possible remedy to this deficiency.

81 The principle mode of variability in the SH extratropical circulation is the Southern
82 Annular Mode (SAM, Limpasuvan and Hartmann, 1999; Gong and Wang, 1999; Thompson and
83 Wallace, 2000), a nearly zonally symmetric structure with coincident geopotential height
84 anomalies of opposite signs in Antractica and the middle latitudes. In the decades prior to 2000,
85 the SH jets have shifted poleward and the SAM has tended toward positive polarity (e.g. Fogt
86 and Marshall, 2020). These coincident trends have been presumed to be a result of ozone
87 depletion. As the ozone recovers in the SH, simulations suggest a reversal of this trend may be
88 forthcoming (WMO, 2022). Spenberger et al. (2020) have questioned whether the associated jet
89 displacement also explains shifts in the storm tracks across the hemisphere. Instead they suggest
90 that SAM can be interpreted as a measure of the degree of coupling (or decoupling) between
91 Antractica and the southern mid-latitudes.

92 Recently, considerable attention has been devoted to interrogating the zonally
93 asymmetric component of SAM (e.g. Fan 2007; Silvestri and Vera, 2009; Fogt et al. 2012; Rosso
94 et al. 2018; Campetelli et al. 2022). This asymmetric component is characterized by a wave-3
95 pattern (Goyal et al., 2021; Goyal et al., 2022; Campetelli et al. 2022) with maximum amplitude

96 at 250 hPa in the Pacific and may be determinative of the overall positive trend in the SAM over
97 the reanalysis era. Such a wave-3, tropopause-level signal is immediately suggestive of the
98 influence of the jets. These observations motivate consideration of direct measurement of the
99 waviness of the SH wintertime jets.

100 Despite a number of recent studies that consider aspects of the interannual variability of
101 the austral winter subtropical jet (e.g. Gillett et al., 2021; Maher et al. 2019), to our knowledge, a
102 study by Gallego et al. (2005) is the only one to consider direct measurement of the waviness of
103 the austral winter jets. They employed an objective method focused on identifying the
104 geostrophic streamline of maximum average velocity at 200 hPa (i.e. the jet core at that level) to
105 separately consider the behaviors of the STJ and POLJ. This method allowed consideration of
106 the jets as continuous features around the hemisphere and thus enabled a number of novel
107 analyses of their behavior and trends. With particular relevance to the present study, they
108 considered a zonal index computed as the difference between the maximum and minimum
109 latitude of the jet core (i.e. the streamline at the core of the jet) on each day. A similar metric,
110 termed DayMaxMin, was employed by Barnes (2013) in her consideration of the behavior of the
111 NH 500 hPa flow. Though insightful, such a metric does not comprehensively account for the
112 waviness created by the full collection of troughs and ridges around the hemisphere that
113 routinely characterizes the jets.

114 In this paper we apply the methodology of Martin (2021) to assess recent trends in the
115 waviness of the SH wintertime polar and subtropical jets. The method of identifying the austral
116 winter polar and subtropical jet locations in isentropic space is described in Section 2 along with
117 a description of the data sets used. Also included there is a short description of the method of
118 assessing waviness introduced in Martin (2021). In Section 3, elements of the long-term trend

119 and interannual variability of the waviness of the austral winter polar and subtropical jets are
120 presented along with differences between composites of the waviest and least wavy seasons for
121 each species. A summary and conclusions are offered in Section 4.

122

123 **2. Data and Methodology**

124

125 In the foregoing analysis, the zonal (u) and meridional (v) winds as well as temperature (T),
126 at 6 h intervals from three different reanalysis data sets are employed. 72 austral winters (JJA)
127 (1948-2019) of the National Centers for Environmental Prediction/National Center for
128 Atmospheric Research (NCEP/NCAR) reanalysis, at 17 isobaric levels to 10 hPa on a 2.5°
129 latitude-longitude grid (Kalnay et al., 1996; Kistlet et al., 2001) are used. We employ 62 winters
130 (1958-2019) of the Japanese 55-year (JRA-55) reanalysis with data on 60 vertical levels up to 0.1
131 hPa on a horizontal grid mesh of ~ 55 km (Kobayashi et al., 2015). Finally, the ERA5 reanalysis
132 data set on 137 vertical levels from the surface to 80 km with a grid spacing of 31 km covering
133 the period from 1979 to 2019 (Copernicus Climate Change Service [CS3], 2017) are used as
134 well. The waviness of the jets is assessed in the context of understanding their relationships to
135 the horizontal gradient of potential vorticity (PV) in prescribed isentropic layers. A similar
136 approach was taken with respect to the STJ in recent work by Maher et al. (2019). The first step
137 in the present analysis involves identification of the isentropic layers that house the austral winter
138 jets. This was accomplished empirically by identifying the isentropic level at which the
139 maximum wind speed was observed in each grid column (between 10 and 80°S) at each analysis
140 time in JJA over the 62-year time series of the JRA-55 data set. The use of isentropic space here
141 differs from the insightful approach taken by Manney et al. (2017) and Manney and Hegglin

142 (2018) which employed separate latitude and elevation criteria to differentiate between the STJ
143 and the POLJ. Of the three data sets employed in the present work, the JRA-55 was chosen for
144 this preliminary analysis step because both its length of time series as well as its horizontal and
145 vertical resolutions are between those characterizing the other two data sets employed here.
146 Following Koch et al. (2006) we only considered columns in which the integral average wind
147 speed exceeded 30 ms^{-1} in the 100-400 hPa layer. The resulting distribution is clearly tri-modal
148 with frequency maxima, and therefore separate jet features, approximately located in the 305-
149 320, 340-355, and 395-410K isentropic layers (Fig. 1a). The latter isentropic layer appears in the
150 lower stratosphere and is associated with the austral polar night jet (PNJ), which, being located
151 *above* the tropopause, is not a focus of the present analysis. Further separation of the STJ and
152 POLJ is achieved through reference to Fig. 2 of Gallego et al. (2005) which strongly implies that
153 the STJ sharply peaks near 30°S while the POLJ more broadly peaks around 50°S . Accordingly,
154 we further constrained the analysis to latitude bins $0\text{-}40^{\circ}\text{S}$ for the STJ and 40 to 65°S for the
155 POLJ. With this additional refinement, the analysis identifies the STJ in the 340-355K isentropic
156 layer and the POLJ in the 310-325K isentropic layer (Fig. 1b). Similar analyses of the other two
157 data sets (not shown) revealed the robustness of this result. It is important to note that 53.8% of
158 all qualifying columns (to 380K) in the $0\text{-}40^{\circ}\text{S}$ bin (STJ) were in the 340-355K layer while
159 46.8% of all qualifying columns in the $40\text{-}65^{\circ}\text{S}$ bin (POLJ) were in the 310-325K layer
160 supporting the isentropic assignments for the two species mentioned previously. It is
161 immediately apparent, consistent with prior analyses (e.g. Bals-Elsholz et al. 2001, Nakamura
162 and Shimpo 2004, Gallego et al. 2005), that the STJ is the dominant jet feature in the southern
163 winter.

164 The analysis method to be used here involves assessment of the circulation which
165 requires calculation of contour length. As a result, fair comparison among the different data sets
166 requires adoption of a uniform grid spacing. Consequently, all three data sets were bilinearly
167 interpolated onto isentropic surfaces at 5K intervals (from 280 to 380K) and 2.5° latitude-
168 longitude grid spacing using programs within the General Meteorological Analysis Package
169 (GEMPAK) (desJardins et al., 1991). The average PV and average zonal and meridional wind
170 speeds in both the polar jet (310:325K) and subtropical jet (340:355K) layers were then
171 calculated from the four times daily data for each day in each of the three time series.
172 As reviewed in Martin (2021), consideration of the quasi-geostrophic potential vorticity
173 (QGPV), following Cunningham and Keyser (2004), demonstrates that local maxima in the
174 cross-flow gradient of QGPV are collocated with maxima in the geostrophic wind speed. In the
175 Southern Hemisphere, the jets lie on the high PV edge of this PV gradient. By searching through
176 daily average isertels from -0.5 to -5.0 at 0.1 PVU intervals ($1 \text{ PVU} = 10^{-6} \text{ m}^2 \text{ K kg}^{-1} \text{ s}^{-1}$), the
177 analysis identifies a “core isertel” along which the circulation per unit length (i.e. average speed)
178 is maximized in the separate POLJ (310:325K) and STJ (340:355K) isentropic layers for every
179 day in each of the time series. This core isertel is, by design, an analytical proxy for the jet core.
180 A glimpse into the fidelity of this method in identifying the meandering cores of the POLJ and
181 STJ jets is illustrated in Fig. 2. In each case the objectively identified core isertel, in black, lies
182 very near, or at, the center of the analyzed isotach maxima around the hemisphere with
183 physically defensible exceptions. For instance, the red dashed lines in Fig. 2b indicate portions
184 of the bold black line in Fig. 2d (i.e. the overlying STJ core) suggesting that those portions of the
185 isotach maxima in Fig. 2b that are somewhat removed from the POLJ core isertel are the lower
186 portions of the overlying STJ core. Similarly, an extensive isotach maxima region in Fig. 2d has

187 a blue dashed line, a portion of the bold black line in Fig. 2b, slicing through it. This region,
188 well poleward of the STJ core isertel, is clearly the upper portion of the underlying POLJ core.

189 Figure 3a shows the average latitude for the core isertels of each jet species from each of the
190 three reanalyses data sets used in the study. The analyses return essentially identical results for
191 the core isertel of the STJ and very nearly identical results for the POLJ. Superimposing the
192 NCEP-NCAR reanalysis' JJA average 200 hPa isotachs on top of the STJ core isertels (Fig. 3b)
193 illustrates the fact that the average core isertel accurately represents the axis of the average STJ.
194 The relationship is also strong between the POLJ core isertels and the 700 hPa average isotachs
195 (Fig. 3c).

196 The waviness of each jet is assessed by calculating a hemispheric average of the meridional
197 displacements of the core isertel from its equivalent latitude – the northern extent of a polar cap
198 whose area is equal to the area enclosed by the core isertel. This metric is referred to as the
199 average latitudinal displacement (ALD). The method does not require that the core isertel be the
200 same in both jet layers on a given day, nor that it be the same from day-to-day in a given jet
201 layer. Consequently, it is important to examine its distribution in each jet layer over the entire
202 time series. Figure 4 portrays the frequency of occurrence of the core isertels in both the STJ
203 and POLJ layers for each of the three time series. The STJ core isertels peak between -1.95 and -
204 2.1 PVU across the three data sets. Considering all three data sets, 81.5% of all JJA days exhibit
205 a core isertel between -1 and -3 PVU in the STJ layer. The POLJ distribution is shifted toward
206 higher PV values. Overall, 74.8% of JJA days had a core isertel between -1 and -3 PVU in the
207 POLJ layer. The frequency of occurrence in the several isertelic bins for each species of SH jet
208 match quite well with what Martin (2021) found for the NH wintertime jets, even when
209 accommodating for the different isentropic layer for the austral POLJ.

210

211 3. Analysis

212

213 The JJA seasonal average latitudinal displacement (ALD) of each jet is calculated as a
214 92-day average of the daily ALD in each cold season. The results are shown in Fig. 5. It is
215 instantly clear that, as in the NH, the POLJ is wavier than the STJ and that both jets have become
216 systematically wavier over the 62-year JRA-55 time series with $p < 0.004$ for both time series (a
217 one-sided Student's t -test was employed). Interestingly, the austral winter STJ is less wavy than
218 its NH counterpart but the waviness of both has increased identically at 0.005 deg/yr (0.0125
219 deg/yr for NCEP since 1958 and -0.001 deg/yr for ERA-5). The winter POLJ in the SH is, on
220 the other hand, wavier than in the NH and is trending faster (0.017 versus 0.009 deg/yr; 0.023
221 deg/yr for NCEP since 1958 and 0.009 deg/yr for ERA-5) than its NH complement. Daily time
222 series of the ALD of each jet can also be examined to determine the extent to which the waviness
223 of the two jets covaries. Figure 6 illustrates the POLJ and STJ daily ALDs for 1999 from each of
224 the three data sets. The low correlation between the waviness of the two species in this example
225 year represents the rule rather than the exception. All told, more than 93% of the STJ and POLJ
226 ALD seasonal time series constructed for this study are correlated with magnitudes less than 0.3.
227 This result strongly suggests that the waviness of the two species evolves independently.

228 By definition, the average wind speed along the chosen core isertel on any given day
229 represents the average jet speed for that species on that day. Time series of seasonal average jet
230 core wind speeds for the wintertime STJ and POLJ in both hemispheres are shown in Fig. 7. As
231 in the NH winter (Martin, 2021), the austral POLJ shows almost no trend in jet core speed and
232 the slight change is not statistically significant. Notably, however, the SH POLJ is $\sim 6 \text{ m s}^{-1}$

233 slower on average than its NH equivalent. Aside from the fact that the NCEP reanalysis is quite
234 different from the JRA-55 until about 1970, the austral winter STJ exhibits a robust, and
235 statistically significant (p -value < 0.001), increase in speed over the JRA-55 time series – in clear
236 contrast to its NH counterpart. It is also apparent that the SH STJ is slightly weaker but less
237 interannually variable than the NH STJ.

238 Another characteristic of interest that emerges directly from the ALD analysis method is
239 the daily value of the jet core's equivalent latitude which closely approximates its zonally
240 averaged position. Consequently, it is straightforward to construct a time series of the seasonal
241 average equivalent latitudes of the two species of jets, shown in Fig. 8. Again, as in the NH, the
242 poleward shift of the SH POLJ is occurring three times faster than that exhibited by the STJ. In
243 contrast to the situation in the NH, however, the slight poleward displacement of the SH STJ *is*,
244 like that of the POLJ, statistically significant (p -values for the POLJ and STJ are < 0.001 and
245 0.002 , respectively). It is interesting to note that while the SH STJ is located at a roughly similar
246 latitude as the NH STJ throughout the time series, the SH POLJ is $\sim 4^\circ$ further poleward during
247 winter than the NH POLJ. Overall, a much more systematic and dramatic poleward migration of
248 the two jets has occurred over the last 6 decades in SH winter as compared to NH winter.

249 Next we consider aspects of the analysis in the context of the SAM. Figure 9 shows a
250 histogram of the JJA average SAM index (calculated after Gong and Wang (1999))
251 superimposed upon the average JJA ALD from the JRA-55 reanalysis. The tendency toward
252 positive SAM over the time series appears to be reflected in the increase in ALD. However, the
253 correlation between the two time series is 0.053 suggesting almost no relationship exists between
254 the two.

255 In order to investigate the relationship of ALD to extremes in the polarity of the SAM
256 index, the three winter months with the most positive and most negative SAM extremes since
257 1979 were considered. The core isertels of the POLJ (from the JRA-55 reanalysis) for each of
258 these three months is portrayed in Fig. 10. Positive extremes of SAM (Figs. 10a, c, and e) show
259 a clear poleward encroachment of the SH polar jet while negative extremes (Figs. 10b, d, and f)
260 suggest the opposite. There appears to be no systematic connection, however, between extremes
261 in SAM and the waviness of the POLJ as quantified by ALD.

262 Thus far the analysis has presented elements of the seasonal average behavior of the
263 austral winter jet species. The methodology, of course, allows for evaluation of daily time series
264 of ALD as well and, in fact, such an analysis underlies the presentation in Fig. 6. Using such
265 daily time series, identification of the waviest and least wavy seasons for each jet species since
266 1979 is accomplished by summing the daily departures from calendar-day average ALD over the
267 92 days of each cold season. The list of such seasonally integrated departures from average
268 waviness for each species of jet for each reanalysis data set is shown in Table 1. From this list,
269 the 5 waviest and 5 least wavy seasons for each jet species were selected to construct composites
270 of geopotential height at several isobaric levels employing the JRA-55 data. In the foregoing
271 analysis, height differences are obtained by subtracting values associated with the composite
272 least wavy seasons from those associated with the composite waviest seasons.

273 Figure 11a shows the 500 hPa geopotential height differences between the waviest and
274 least wavy POLJ seasons. Wavy POLJ years are characterized by positive height anomalies over
275 the continent and adjacent to its east and west coasts with belts of negative anomalies in a
276 crescent stretching from southwest of Chile and then extending from the east coast of South
277 America to southern Africa toward Australia, suggestive of a negative SAM. The strongest

278 negative height anomalies in such seasons occur west of South Africa implying a slight
279 weakening of the zonal winds just south of the Cape of Good Hope. Meanwhile wavy STJ years
280 exhibit negative composite height differences in roughly the same locations as the positive
281 composite differences just described for wavy POLJ years (Fig. 11b), suggestive of a positive
282 SAM. These composite difference patterns strengthen slightly at 250 hPa (Fig. 12) suggesting an
283 equivalent barotropic structure to the tropospheric portion of the difference fields.

284 The difference fields at 50 hPa imply that the waviness of both jets exerts an
285 influence on the strength of the austral polar vortex in the lower stratosphere. The anomalous
286 height field associated with wavy POLJ years (Fig. 13a) suggests a broad, though modest,
287 anticyclonic circulation anomaly just off the pole in the Western Hemisphere. Such a
288 perturbation flow would appear to interfere with the establishment and/or persistence of strong
289 vortex flow in the same location. Wavy STJ seasons also impose a dipole of positive heights the
290 axis of which stretches from Cape Horn to East Antarctica (Fig 13b). Such a configuration
291 implies that the polar vortex is both weaker and displaced off the pole in winters with wavy
292 STJs. Thus, the analysis suggests that in winters characterized by unusually wavy jets of either
293 species, the SH polar vortex is likely weaker than normal. Further investigation of this intriguing
294 implication is the subject of ongoing work.

295

296 **4. Summary**

297

298 The analysis presented here extends the application of a method developed by Martin
299 (2021) to assess the waviness of the tropopause-level jets to analysis of the austral winter polar
300 and subtropical jets. The analysis demonstrates that both jets have become systematically wavier

301 over the past 60+ years. In addition, as in the NH, the waviness of the two species of austral
302 winter jets is largely uncorrelated suggesting little systematic influence of one on the other
303 throughout the season. Along with these similarities, there appear to be some fundamental
304 asymmetries in the behavior of the wintertime tropopause-level jets between the hemispheres.
305 The austral POLJ, like its NH counterpart, has exhibited no trend in its average speed over the
306 time series, though it is notably slower than its NH wintertime equivalent. The STJ, on the other
307 hand, has roughly the same speed as that in the NH winter but, unlike its NH counterpart, has
308 undergone a systematic, statistically significant increase in its core speed since ~1960.
309 Additionally, as opposed to the situation in the NH where only the POLJ migration toward to
310 pole is statistically significant, *both* SH jets exhibit a significant poleward creep with the POLJ
311 encroachment occurring at ~3x the rate of that characterizing the STJ.

312 The observed poleward migration of the STJ reported here is consistent with the analysis
313 of CMIP5 simulations of historical and projected changes to the SH wintertime STJ by Chenoli
314 et al. (2017). Though the present work employs a similarly dynamical definition of the STJ as
315 that used in the study by Maher et al. (2019), they found no evidence of a poleward shift of the
316 SH wintertime STJ. We suggest that the emphasis on empirically identifying a core isertel,
317 rather than the maximum gradient of θ on a predetermined isertelic surface (i.e. 2 PVU as the
318 dynamic tropopause) may account for this difference.

319 Finally, circulation differences between the waviest and least wavy POLJ and STJ
320 seasons are manifest in both the troposphere and lower stratosphere. In the troposphere the
321 signals are not as coherent in the SH as they were revealed to be in the NH (Martin 2021).
322 Interestingly, the analysis implies that when either the POLJ or STJ is wavier than normal in a

323 given winter, the lower stratospheric polar vortex is negatively impacted. Again, this is different
324 from the behavior of the NH polar vortex in the face of extremes in waviness.

325 The results presented here, combined with those in Martin (2021), demonstrate that in
326 both hemispheres a wavier than normal STJ during winter serves to weaken the lower
327 stratospheric polar vortex. Though, as suggested by the analysis supporting Fig. 6, the STJ and
328 POLJ do not appear to influence one another systematically, there are still instances in which the
329 waviness of the two jets can be phased so as to promote intense interactions. Daily perusal of
330 hemispheric synoptic maps suggests that such instances of jet interaction often lead to intense
331 lower tropospheric cyclogenesis events. Current research is examining whether such jet
332 interaction-induced cyclogenesis events from specific seasons systematically correspond to
333 episodes of polar vortex weakening.

334

335 **COMPETING INTERESTS:** The contact author has declared that none of the authors has any
336 competing interests.

337

338 **AUTHOR CONTRIBUTIONS:** J. Martin completed the ALD analysis and did all the writing,
339 figure drafting and preparation of the manuscript for submission. T. Norton performed the
340 analysis that determined the POLJ and STJ isentropic housings during SH winter.

341

342 **ACKNOWLEDGEMENTS:** This work was supported by the National Science Foundation under
343 grants ATM-1640055 and NSF-2055667. JRA-55 data available from the Research Data
344 Archive at the National Center for Atmospheric Research. The authors would like to thank Prof.
345 Andrea A. Lopez-Lang for helpful comments and suggestions.

TABLE 1 Integrated seasonal departures from average ALD (degrees) for polar and subtropical jets from the three reanalysis data sets employed in this work. Gray (light blue) shading represents one of the top 5 waviest (least wavy) seasons.

FIGURE CAPTIONS

516
517
518 Fig. 1 (a) Distribution of grid-column maximum wind speeds found in 5K isentropic layers from
519 10 - 80°S for every 6h analysis time in JJA from 1958-2019 from the JRA-55 reanalysis. (b) As
520 for Fig. 1a except limited to (i) grid-columns in which the integral average wind speed from 400
521 to 100 hPa exceeded 30 m s^{-1} and (ii) to latitudes 0 - 40°S for the STJ and (iii) latitudes 40 to
522 65°S for the POLJ.

523
524 Fig. 2 (a) Isotachs of the daily averaged wind speed (contoured every 10 m s^{-1} and shaded above
525 30 m s^{-1}) and the core isertel (bold black line) in the 310:325K isentropic layer on 13 July 1995
526 from the JRA-55 reanalysis data. The core isertel value is -1.3 PVU. (b) As in (a) but for 24
527 August 2001. Core isertel value is -2.0 PVU. Dashed red line indicates portion of the core
528 isertel from the overlying STJ layer (depicted in Fig. 2d). (c) As in (a) but for wind speeds and
529 core isertel in the 340:355K isentropic layer on 13 July 1995. Core isertel value is -3.6 PVU. (d)
530 As in (c) but for 24 August 2001. Core isertel value is -1.4 PVU. Dashed blue line indicates a
531 portion of the core isertel from the underlying POLJ layer (depicted in Fig. 2b). See text for
532 further explanation.

533
534 Fig. 3 (a) Solid (dashed) lines are the positions of the average core isertels of the STJ (POLJ)
535 from each of the three reanalyses employed in this study. The different reanalyses are color
536 coded. (b) Thick solid lines are the positions of the average core isertels for the STJ from each
537 of the reanalyses superimposed with JJA average 200 hPa isotachs from the NCEP-NCAR

538 reanalysis. (c) Thick dashed lines are the positions of the average core isertels for the POLJ
539 superimposed with JJA average 700 hPa isotachs from the NCEP-NCAR reanalysis.

540

541 Fig. 4 Frequency of occurrence of the core isertel value for each reanalysis time series in (a) the
542 STJ layer and (b) the POLJ layer. Solid blue, red and green lines in (a) and (b) are the SH
543 distributions from the NCEP, JRA55 and ERA5, respectively. The dashed blue, red and green
544 lines are the NH distributions from the NCEP, JRA55 and ERA5 reanalyses, respectively. In (b),
545 the NH distributions are from the 315:330K layer which houses the POLJ in the boreal winter.
546 Thin blue, red and green lines in (a) and (b) indicate the peak values of the core isertel in each
547 layer from each data set. Isertel values are given in potential vorticity units (PVU,
548 $1 \text{ PVU} = 10^6 \text{ K m}^2 \text{ kg}^{-1} \text{ s}^{-1}$), and are multiplied by -1 for the NH values.

549

550 Fig. 5 Seasonal average ALD (in degrees) of the SH wintertime subtropical and polar jets for
551 each cold season in the three reanalysis time series. The polar jet values are in the three shades
552 of blue while the subtropical jet values are in the three three shades of red. The dashed black line
553 through each time series represents the trend line for each (derived from the JRA-55 time series)
554 and is significant at the 96% level. Gray lines are the boreal winter ALD analysis from Fig. 6 of
555 Martin (2021). The “YEAR” on the abscissa indicates the year in which December of that cold
556 season occurred.

557

558 Fig. 6 Time series of the daily ALD of the polar (blue lines) and subtropical (red lines) jets from
559 the (a) NCEP-Reanalysis, (b) JRA-55, and (c) ERA5 data sets for austral winter 1999. The
560 correlation between the two times series from each data set is indicated.

561

562 Fig. 7 Seasonal average U along the core isertel for the subtropical (red lines) and polar (blue
563 lines) jets from each of the three SH reanalysis data sets. The thin black lines are trend lines for
564 each time series from the JRA-55 data. Gray lines are the equivalent boreal winter U analysis
565 from Fig. 9 of Martin (2021).

566

567 Fig. 8 Time series of the seasonal average equivalent latitude of the polar (blue lines) and
568 subtropical (red lines) jets from the three different SH reanalysis data sets. The thin black lines
569 are the trend lines (from the JRA-55 data) and are significant above the 99% leve for both jet
570 species. Gray lines are the boreal winter equivalent latitude analysis from Fig. 10 of Martin
571 (2021).

572

573 Fig. 9 JJA average SAM index (histogram) from NCEP's Climate Prediction Center. The index
574 is calculated by projecting the daily 700 hPa geopotential height anomalies poleward of 20S onto
575 the leading pattern of the Antarctic Oscillation (AAO) ofGong and Wang (1999). Black solid
576 line is theJJA average ALD of the POLJ from the JRA-55 reanalysis.

577

578 Fig. 10 Spaghetti plots of core isertels from SH summer months with maximum positive (red)
579 and negative (blue) SAM indices since 1979. (a) Daily JRA-55 core isertels from June 2009, the
580 June with the most positive SAM in the record. (b) As for Fig. 10a but for June 1992, the June
581 with the most negative SAM in the record. (c) As for Fig. 10a but for July 1998. (d) As for Fig.
582 10b but for July 1995. (e) As for Fig. 10a but for August 1994. (f) As for Fig. 10b but for
583 August 1981. Average ALD for the given months are listed in the bottom left of each panel.

584

585 Fig. 11 500 hPa height differences between the composite waviest and least wavy (a) polar jet
586 and (b) subtropical jet seasons constructed from the JRA-55 reanalysis. See Table 1 for
587 identification of the specific years comprising each composite. Positive (negative) height
588 differences are in solid red (blue) lines labeled in m and contoured every 10 m (-10 m) beginning
589 at 10 m (-10 m).

590

591 Fig. 12 250 hPa height differences between the composite waviest and least wavy (a) polar jet
592 and (b) subtropical jet seasons constructed from the JRA-55 reanalysis. See Table 1 for
593 identification of the specific years comprising each composite. Positive (negative) height
594 differences are in solid red (blue) lines labeled in m and contoured every 10 m (-10 m) beginning
595 at 10 m (-10 m).

596

597 Fig. 13 50 hPa height differences between the composite waviest and least wavy (a) polar jet
598 and (b) subtropical jet seasons constructed from the JRA-55 reanalysis. See Table 1 for
599 identification of the specific years comprising each composite. Positive (negative) height
600 differences are in solid red (blue) lines labeled in m and contoured every 10 m (-10 m) beginning
601 at 10 m (-10 m).

602

603

604

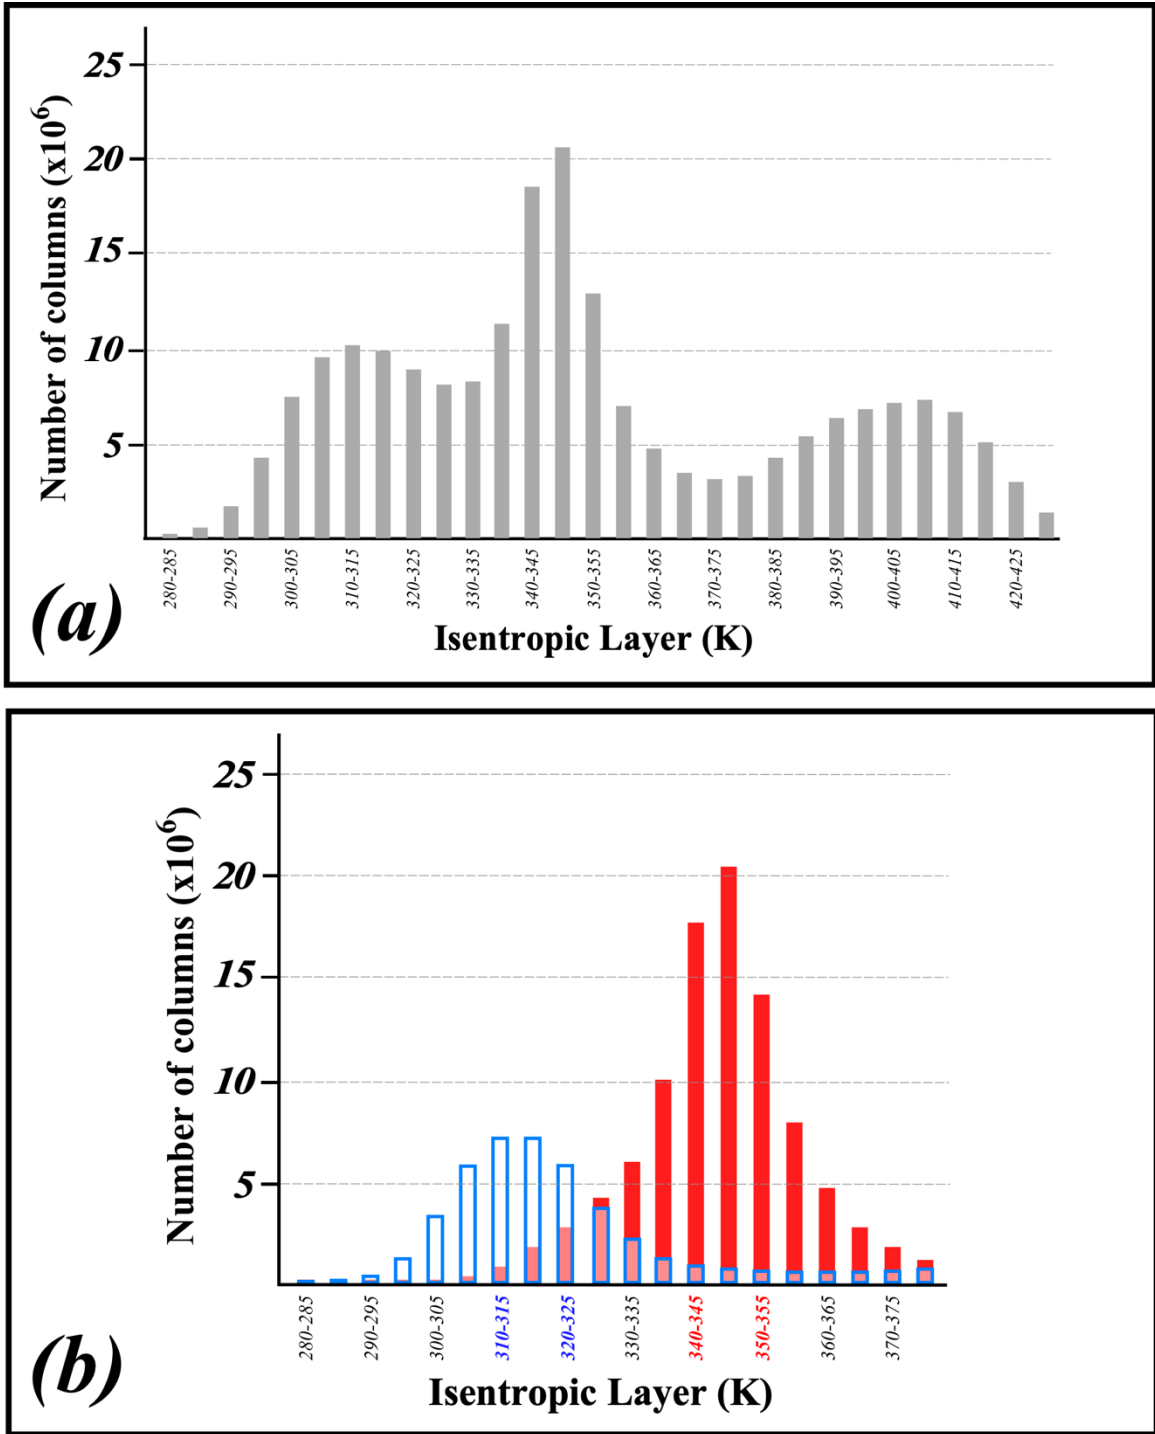

Fig. 1 (a) Distribution of grid-column maximum wind speeds found in 5K isentropic layers from 10 - 80°S for every 6h analysis time in JJA from 1958-2019 from the JRA-55 reanalysis. (b) As for Fig. 1a except limited to (i) grid-columns in which the integral average wind speed from 400 to 100 hPa exceeded 30 m s^{-1} and (ii) to latitudes 0 - 40°S for the STJ and (iii) latitudes 40 to 65°S for the POLJ.

605

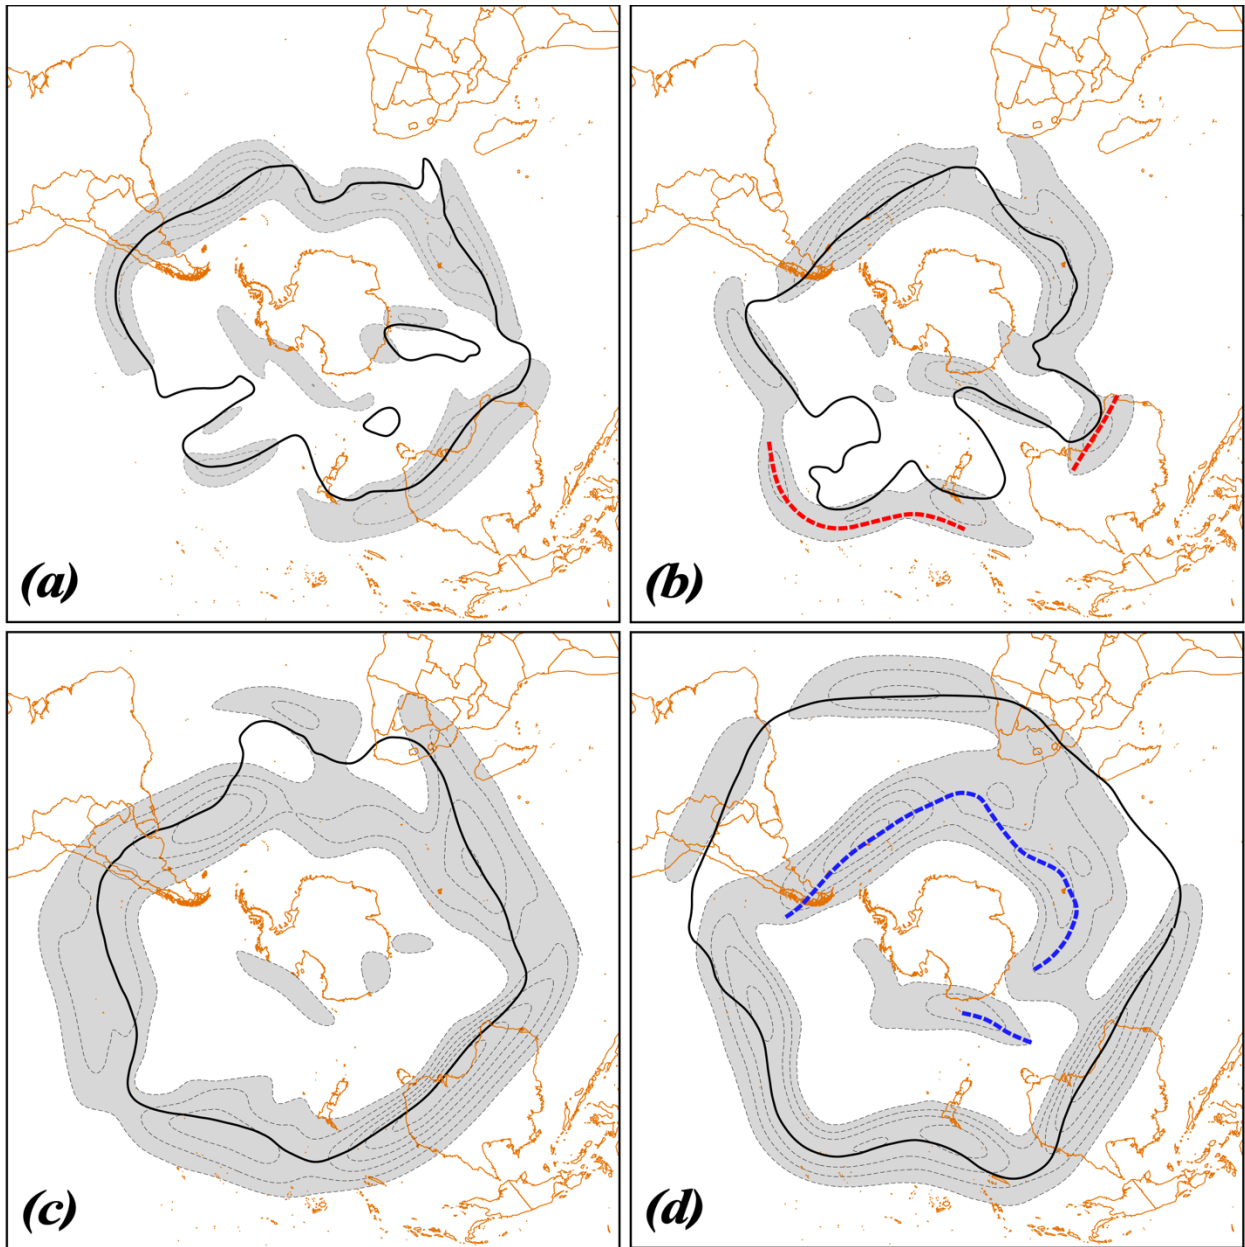

Fig. 2 (a) Isotachs of the daily averaged wind speed (contoured every 10 m s^{-1} and shaded above 30 m s^{-1}) and the core isertel (bold black line) in the 310:325K isentropic layer on 13 July 1995 from the JRA-55 reanalysis data. The core isertel value is -1.3 PVU. (b) As in (a) but for 24 August 2001. Core isertel value is -2.0 PVU. Dashed red line indicates portion of the core isertel from the overlying STJ layer (depicted in Fig. 2d). (c) As in (a) but for wind speeds and core isertel in the 340:355K isentropic layer on 13 July 1995. Core isertel value is -3.6 PVU. (d) As in (c) but for 24 August 2001. Core isertel value is -1.4 PVU. Dashed blue line indicates a portion of the core isertel from the underlying POLJ layer (depicted in Fig. 2b). See text for further explanation.

606

607

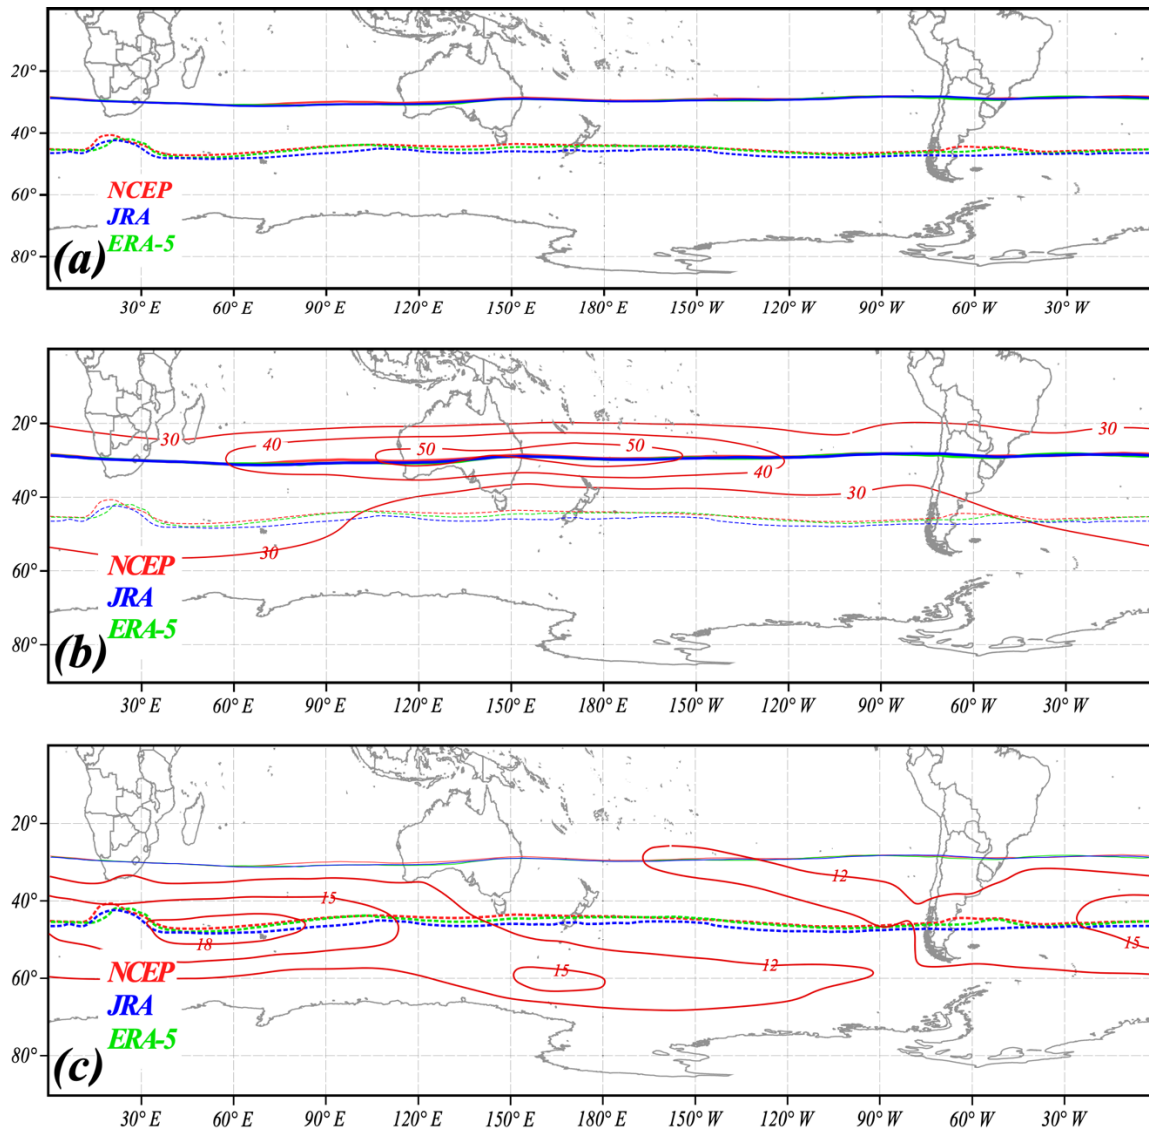

Fig. 3 (a) Solid (dashed) lines are the positions of the average core isertels of the STJ (POLJ) from each of the three reanalyses employed in this study. The different reanalyses are color coded. (b) Thick solid lines are the positions of the average core isertels for the STJ from each of the reanalyses superimposed with JJA average 200 hPa isotachs from the NCEP-NCAR reanalysis. (c) Thick dashed lines are the positions of the average core isertels for the POLJ superimposed with JJA average 700 hPa isotachs from the NCEP-NCAR reanalysis.

Fig. 4 Frequency of occurrence of the core isertel value for each reanalysis time series in (a) the STJ layer and (b) the POLJ layer. Solid blue, red and green lines in (a) and (b) are the SH distributions from the NCEP, JRA55 and ERA5, respectively. The dashed blue, red and green lines are the NH distributions from the NCEP, JRA55 and ERA5 reanalyses, respectively. In (b), the NH distributions are from the 315:330K layer which houses the POLJ in the boreal winter. Thin blue, red and green lines in (a) and (b) indicate the peak values of the core isertel in each layer from each data set. Isertel values are given in potential vorticity units (PVU, $1 \text{ PVU} = 10^6 \text{ K m}^2 \text{ kg}^{-1} \text{ s}^{-1}$) and are multiplied by -1 for the NH values.
