Dear Editor,

please you find included the revised version of our work “Lahar events in the last 2,000 years from Vesuvius eruptions. Part 1: Distribution and impact on densely-inhabited territory estimated from field data analysis”, which has been improved a lot thanks to the reviewers’ comments. The revised version consists of a reply to the three reviewers, and it follows the marked version of the manuscript with all changes highlighted. In particular, we have taken into account all reviewers’ comments, as it can be seen in the marked version of the work. Also, all the general comments have been replied one-by-one in the reply letter, and the specific ones are reported and accordingly modified in the text. The whole work is indeed better now particularly thanks to all these comments. We are available for any further information needed. Looking forward to hearing the submission results.

On behalf of all co-authors

Best regards

Dott. Mauro Antonio Di Vito
Reply to the Reviewers

In the present letter, we report detailed responses one-by-one to the main reviewers’ comments. All other comments that are annotated in the pdf documents attached by Reviewer 1 and Reviewer 2 are acknowledged and accepted in the revised version of the manuscript. In order to follow the full sequence for each of them (>250 annotated comments), we directly refer to the marked version of the manuscript, while here we reply to the main ones. With reference to these latter, they often coincide with the general comments.

Reviewer 1

This is an interesting article based on an astonishing effort of field work. Congratulations. It is beyond doubt that a thorough re-appraisal of volcanic deposits is required for enhanced risk analysis.

We acknowledge very much this comment and the encouraging words, which are precious for us to further improving our work at this stage. Yes, it is important to focus the whole work on volcanic deposits, in particular these ones (pyroclastic and lahar deposits) that are quite dispersed around the volcano and in the plain; they acted as field constraints in evaluating the impact of the eruption and associated phenomena, and as inputs for the numerical modelling (companion papers part 2 and part 3).

I have attached an annotated pdf with many comments and change suggestions.

We acknowledge the detailed Reviewer’s work as evident from the commented pdf attached. We have taken into account all corrections and suggestions, which can be better followed one-by-one directly on the marked version of the manuscript.

I have three main points:

1. Overall, I would like to see some restructuring of the manuscript as many figures in the Appendix would help the reader to better follow your reasoning. Please add several of them in the main body of the manuscript and not only the many maps with outcrop locations.

We acknowledge this comment, which we have taken into account considering the length of the whole manuscript. We have done our best to shorten some parts a little bit and favour some restructuring of the field description, including a table with the recognized lithofacies and one photo associated to
each of them; this is also a formal compromise to improve this part in the general context of the multidisciplinary work that we carried out.

2. Please add definitions to terms you are using that may be used in a subjective way (e.g. syn- and post-eruptive lahars) or numbers with units to statements that you are using in a poorly qualitative way (fine, finer...).

We acknowledge this comment very much, which has given us the chance to further check all definitions of lahars that we used in this work. This is aligned also with some comments by Reviewer 2. According to the concepts introduced by Sulpizio et al. (2006) and Iverson and Vallance (2015) and taking into account the field characteristics of the Pollena and 1631 lahar deposits around Somma-Vesuvius and in the Campanian Plain, we decided to reduce the number of lahar definitions from three to two, keeping in particular the syn-eruptive and post-eruptive ones. While the second definition applies to lahars occurred during long periods of volcanic quiescence (from several-to-tens of years to hundreds of years or more), the first one applies to those lahars occurred during or immediately after the eruptive activity. By immediate we mean even a few years because volcanic hazard (among the main goals of this work) can also occur due to lahars that are directly related to the volcanic activity. Of course, we could not exactly know when the studied lahars occurred in the past, which is why the two definitions are to be intended from the stratigraphic point of view (continuity, erosion, componentry, archeological evidence, etc…).

Besides, all details around the sedimentological part of the work have been double checked, in order to show results as quantitative and consistent as possible.

3. Being a non-native English speaker myself, I still feel that the manuscript could benefit from a language check.

We acknowledge this comment, which has given us the opportunity to double check all manuscript with the detail of single word. We think that now the manuscript is more fluent and more consistent among the various sections.

Reviewer 2
The paper represents an interesting contribution; new stratigraphic data are presented here for the Pollena and the 1631 plinian eruptions and associated lahars, based on which a new impact area is defined, with important implications on hazard assessment.

We acknowledge this comment, which is important for us as motivation to further improve the whole work thanks in particular to the Reviewer’s comments. The two studied eruptions are sub-Plinian and not Plinian, which we have double checked throughout the manuscript.

I think that authors should better describe their initial assumption and improve the description and interpretation, which are now quite poorly justified or vague. Below are some major points. It is an interesting paper, but it needs to be improved before its publication. Some figures need to be improved. The annotated PDF includes several suggestions.

We acknowledge this general comment and we acknowledge for all details included in the commented pdf, which we have taken into account comment-by-comment in the marked version of the manuscript. In particular, the description and interpretation, as well as the parts that get to the field-based volcanic hazard discussion are strengthened and better related to each other.

We have also worked on some figures and tables as shown in the marked version of the manuscript.

Terminology. I consider that authors should better define the terminology here used, especially for syn- post and inter-eruptive lahar. Post and inter-eruptive lahars do not necessarily point to similar events. Post-lahars can occur a few months or years after the eruption when the landscape is still responding to the hydrological and sedimentary-yield consequences of the eruption, and lahars are still remobilizing the primary pyroclastic deposits only. Inter-eruptive lahars occur without a direct volcanic influence. I have suggested some references to this point. I understand that authors refer to syn-eruptive lahar as those that originated from the primary pyroclastic deposits only, but the timing can be important for hazard assessment purposes.

We acknowledge this precious comment very much, which has helped us revising the full terminology, also in light of all the available literature. Lahars that are generated up to months to a few years after the eruption, especially when they are studied from the stratigraphic and archaeological points of view, can still be related to volcanic activity in a general sense, i.e. primary pyroclastic deposits can form then can be immediately remobilized triggering syn-eruptive lahars. We used this definition and meaning after Sulpizio et al. (2006) and Iverson and Vallance (2015), because we also wanted to stress the fact that even if the eruptive activity is over, the formation of
lahars due to a specific volcanic activity cannot be excluded in terms of volcanic hazard. Instead, what we defined as post-eruptive lahars enters more appropriately in the context of hydrogeological hazard, which can occur during long periods of volcanic quiescence; all of this is clearer now throughout the manuscript. Finally, we have removed the definition of inter-eruptive, as we did not use it in this work.

Lahar deposit textures are poorly described, please add a figure illustrating the main facies here described (line 377). En-masse deposition here described for lahars is poorly justified and contrasts with several recent studies. Water escape features are not evidence of en-masse deposition. A few descriptions and pictures are included in the appendix; I consider more useful for the reader to add some figures in the main text, is quite annoying to go to the appendix to understand the main text. I suggest including a simple table with a picture of each facies here described and a resume of their main characteristics.

We acknowledge this comment. We have added a table summarizing all recognized lithofacies, also taking into account some of the comments by Reviewer 1. In this way, we have taken the chance to reconsider the appendix on the field description (Appendix C), by strengthening the main body of the manuscript with more field details and figures.

With reference to the depositional mechanisms, we have clarified that the entire vertical sequences from lahars can form by rapid progressive aggradation, while each depositional layer forms en masse. These are impulsive and dense mass flows, which can be fed by multiple pulses. Each pulse gives rise to a variably-thick massive layer through a high depositional rate, while we agree that the vertical ‘‘sum’’ of the layers forms over time, i.e. by progressive aggradation. This is clearer now in the text. Indeed, the large-scale multiphase experiments by Roche (2012, 2015) confirm that the two end member depositional mechanisms are not in competition to each other, and that the mutual interplay between transport and deposition in lateral mass flows (vs. vertical fallout) makes the speed of local deposition higher or lower depending on relationships between single flow pulse, feeding time and local topography. Furthermore, the recognized water escape features for us are evidence of rapid aggradation of single units in a sequence crossed by these features during its contraction.

Authors should better describe the componentry of both Pollena and 1631 eruptions, their differences, and how they were used to discriminate syn-eruptive lahars from each one of these eruptions or if stratigraphic relationships were the main criteria. Right now is written as the reader perfectly knows the stratigraphy of the Somma-Vesuvius area.
We acknowledge this comment, which we have taken into account by specifying sedimentological details in the Materials and Methods section, and also throughout the manuscript wherever those features are presented. In particular, the stratigraphic methods and the archaeological pieces of evidence were used to discriminate the various lahar deposits, and besides a new paragraph on the eruptive history of Somma-Vesuvius has been added to help the reader following the sequence of the reconstructed volcanic events.

I suggest authors avoid mixing descriptions with interpretations.

We acknowledge this comment, which we have kept in mind during the revision process, by acting wherever that could have been confused or overlapped.

Figure 7 is not a distribution map; it is a map that shows the outcrops where lahars from Pollena eruption are outcropping. This map does not allow the reader to understand the source area of lahars nor how the volume of these lahar deposits was estimated. I suggest at least including as a layer the drainage system. And what does the 0 value mean in the thickness scale? In the map, there are several points (white dots) with this value. The same observations for the figure of the lahars associated with the 1631 eruption.

We acknowledge this comment. The mentioned figure refers to the geospatial dataset, in which all studied stratigraphic sections are reported; the figure shows those locations with the associated deposit thicknesses. In the section of presentation of the results, we have clarified, also after paleomagnetic considerations, about the provenance of the volcaniclastic material, etc…, by making clearer that the lahar volume calculations are referred to the numerical modelling companion papers (part 2 and part 3, the first of the two in particular). The drainage system is regulated by the slopes of the main valleys, also we have added arrows to show the material provenance following the sedimentological characteristics of the deposits and their lateral continuity. The main flow directions and provenance are now represented with comprehensive arrows as shown in the primary deposit distribution maps. The 0-m value refers to the locations in which no lahar deposits were observed, which as absence of presence gives some evidence of absence of the lahar deposits. The volume evaluation has been carried out with the GIS database, defining cells characterized by homogeneous thickness and morphology and using the average thickness within them.

It is not completely clear to me as syn-eruptive and “post(inter)” eruptive lahars from Pollena eruption are discriminated. One of the main parameters is that post-eruptive events crop on top of the humified surface or soil layers with evidence of anthropic use, while syn-eruptive lahar deposits lay directly
on top of the primary deposits (line 405). Can authors better explain this point as, for example, for the Avella area, were both syn-eruptive and post-eruptive lahars of the Pollena eruptions are described? Also, it is not clear how the outcrops in the SW area (white dots in figure 6) are interpreted as syn-eruptive if primary deposits from Pollena are not mapped here (based on Figure 5).

We acknowledge this comment and the suggestion to clarify the difference (from the stratigraphic viewpoint) between the two types of lahar deposits throughout the manuscript. Indeed, such difference is based on stratigraphic relationships between primary and secondary deposits, which we do think is clearer now (see previous reply).

Where the white dots with the 0-m value are present, it means that no secondary deposits are present, which is coherent with the absence of primary deposits occurring in some of the studied stratigraphic sections.

Line 422. Why post-eruptive (here consider as inter-eruptive) lahar are still associated with the Pollena eruption and defined as post only because they contain or are overlaid by fragments from Mercato and Avellino eruptions? Just as an example, at Colima volcano, all syn-eruptive, post or inter-eruptive lahars from recent activity contain pumice fragments from the 1913 plinian eruption. Syn-eruptive lahars can erode the substratum during their emplacement. Finally, why are post(inter)-eruptive lahars associated with a specific eruption? Still unclear how is the timing between a syn-eruptive and a post(inter)-eruptive lahar here considered if the post-eruptive events are still correlated to an eruption. Authors can solve this problem by changing the terminology here used and distinguishing between post and inter-eruptive.

Please see the response above about the syn-eruptive and post-eruptive features for the studied lahars and their deposits. In particular, the lahars defined as post-eruptive were defined on the basis of their stratigraphic position and to be related to one eruption but characterized by the presence of features typical of long time after the eruption (anthropogenic use of the territory, presence of paleosols, etc…).

Some lahars from the Valle de Avella and Somma-Vesuvius area show up to 50% of the mud fractions, it could be interesting to define the % of silt and clay, as inter-eruptive lahars could also be discriminated based on their granulometry.

We acknowledge this comment. Distributing the fine fraction (>5 phi) is something that was done by extrapolation modelling for inputs into the numerical modelling companion paper (part 2). This has
been clarified in the Material and Methods section. In particular, the high presence of ash and fine ash in the deposits of this area did not help us to discriminate between various type of lahars based on grain-size only.

Authors should better explain how the lahar volume is here estimated as the map distribution only shows their outcrops. And if the distribution of fall and PDC deposits from Pollena and 1631 eruptions are here redefined, it could be interesting if authors can estimate the new volume.

We acknowledge this comment, which we have taken into account by a GIS calculation of the volumes, as reported in the marked version of the manuscript. With reference to the lahar deposits, their volumes were calculated using GIS tassellation, by weighting each cell with its average deposit thickness, then multiplying the average value by the cell surface. With reference to the primary deposits, their dispersal has been assessed by calculating the areas of the 10-cm isopachs, then comparing the new values with the literature ones. However, we are still working on the volume estimation for both studied eruptions, but this is the subject of another paper in preparation.

Reviewer 3

The Manuscript contains a lot of information about occurrence of volcaniclastic flows/lahars in the Vesuvian area (Italy). The work is potentially of interest for an international audience, but, at present, it is too confused and in some part not consistent with current models and physics to be recommended for publication as it is.

We acknowledge this general comment. We have taken the chance in the revised version to improve our work taking into account these Reviewer’s general comments.

The paper is very long and in some part very hard to read due to the long description of data that may be better organised in Tables. I refer in particular to the stratigraphic description and sedimentological analysis, which are not well organised. In particular, I found not appropriate for a paper dealing with stratigraphic analysis not to present photos of the most significant outcrops in the main text. Also, the lithofacies analysis is poorly significant as it is. This is because the lithofacies codes are introduced without any explanation and they are not summarised in a table (shortening the description).

We acknowledge this comment. We agree that in particular the stratigraphic part was not so clear, which we have improved now, as it can be seen in the marked version of the manuscript. Such improvement has also been possible thanks to the comments from the annotated pdf documents of Reviewer 1 and Reviewer 2. We have added a table summarizing the recognized lithofacies, by also including one photo for each of them, in order to optimize the spaces in this multidisciplinary work.
The grain size data of figure 11 are poorly descriptive if the finest part is not analysed. Also, some of the statistical parameters of Table 1 are not significant, being the distributions very far from gaussian-like.

We acknowledge this comment. We have clarified in the marked version of the manuscript that the finest part (>5 phi) was defined in the numerical modelling companion paper (part 2); it has also been clarified in the Materials and Methods section. We agree that the table of the parameters should have been checked and reconsidered, which we have done in the revised version of the work.

A lot of inconsistencies are present throughout the manuscript (i.e. Somma-Vesuvius vs. Vesuvius, volcaniclastic flows vs lahars). They need to be accurately checked and corrected.

Checked and corrected. Thanks.

The calculation of the velocity and dynamic pressure is basically wrong, in absence of a detailed determination of the flow behaviour. The Authors assume the clasts are transported within the flow, but it may be not the case depending on flow conditions. Lahars can transport boulders as large as meters as passive load, solely due to the pore pressure within the underlying flow. On the other hand, it is not possible to derive the velocity of the flow from the deposit as it is presented, because simply it was zero at time of deposition. So, it is not possible to associate a dynamic parameter with a deposit location as in Figure 17.

We acknowledge this comment. We have clarified that this relatively simple method is not the key point to assess lahar volcanic hazard in the Campanian Plain. It is a simplified method that helps constraining the numerical modelling results just as orders of magnitude and results are used relying on their representativeness and uncertainty, as explained in the companion papers in Part. 2 and 3. However, the approximation here is that the calculated velocities and pressures are referred to the point locations upstream, meaning that those parameters should have been close to the calculated values in the areas nearby the boulder findings. The flow must have entrained and transported those clasts, and in order to do that the velocity and pressure must have been at least close to the values that we report (see Roche et al., 2013; Roche, 2015; Martì et al., 2019, and references therein for details on this approach).
Lahar events in the last 2,000 years from Vesuvius eruptions. Part 1: Distribution and impact on densely-inhabited territory estimated from field data analysis

Abstract

Lahars represent some of the most dangerous phenomena in volcanic areas for their destructive power, causing dramatic changes in the landscape with no premonitory signs and impacting on population and infrastructures. In this regard, the Campanian Plain turns out to be very prone to the development of these phenomena, since the slopes of the Somma-Vesuvius and Campi Flegrei volcanoes, along with the Apennine reliefs are mantled by pyroclastic deposits that can be easily remobilised, especially after intense and/or prolonged rainfall.

This study focuses on the analysis of the pyroclastic fall and flow deposits and of the syn- and post-eruptive lahar deposits related to two sub-Plinian eruptions of Vesuvius, 472 AD-CE (Pollena) and 1631. To begin with, historical and field data from the existing literature and from hundreds of outcrops were collected and organized into a database, which was integrated with several new pieces
of data. In particular, stratigraphic, sedimentological (facies analysis and laboratory) and
archaeological analyses were carried out, in addition to rock magnetic investigations and impact
parameter calculations. The new data are mainly also referred to the finding of ash beds in more distal
areas, which were included into new isopach maps for the two sub-Plinian eruptions.

The results show that for both the eruptions the distribution of the primary deposits is wider than the
one previously known. A consequence of these results is that a wider areal impact should be expected
in terms of civil protection, as the sub-Plinian scenario is the reference one for a future large eruption
of Vesuvius. Such distribution of the pyroclastic deposits directly affects the one of the lahar deposits,
also because a significant remobilization took place during and after the studied eruptions, which
involved the distal phreatomagmatic ash. From these integrated analyses, it was possible to constrain
the timing of the deposition and the kind of deposits remobilized (pyroclastic fall vs. flow), as well
as was possible to calculate the velocities and dynamic pressures of the lahars, and ultimately infer
the lahar transport and emplacement mechanisms.

The multidisciplinary approach adopted in this work shows how it is crucial to assess the impact of
lahars in densely populated areas even at distances of several to tens of km from active volcanoes.
This especially applies to large parts of the densely populated areas around Somma-Vesuvius up to
the nearby Apennine valleys.

Keywords: Somma-Vesuvius; Apennine valleys; pyroclastic deposits; lahars; areal distribution; local
impact.

1. Introduction

The emplacement–movement of volcaniclastic mass flows, and the consequent damage along the
flanks of active volcanoes and perivolcanic plains, represent a constant threat to inhabited areas and
populations (e.g., Waitt et al., 1983; Lowe et al., 1986; Pierson, 1985; Newhall and Punongbayan,
Such systems are variably-fluidized, gravity-driven flows that consist of a mixture of pyroclastic sediment and water. They can be triggered by various mechanisms, among which the most common are intense or prolonged atmospheric precipitations (Arguden and Rodolfo, 1990; Rodolfo and Arguden, 1991; Pareschi et al., 2000; Rodolfo, 2000; Scott et al., 2001; Vallance and Iverson, 2015). Such precipitations or water runoff, especially during and/or immediately after the eruptions, can cause the detachment of landslides that can evolve into lahars remobilization of pyroclastic deposits evolving into water-saturated multiphase systems called lahars (e.g., White et al., 1997; Sheridan et al., 1999; Scott et al., 2001; Baumann et al., 2020). The last century was affected by a significant number of highly-impacting lahar events associated to well-studied explosive volcanic eruptions worldwide, such as for example at Colima (Mexico) in 1913 (Rodriguez-Sedano et al., 2022), Nevado del Ruiz (Colombia) in 1985 (Voight, 1990), Ruapehu (New Zealand) in 2007 (Lube et al., 2012), and Merapi (Indonesia) in 2011 (Jenkins et al., 2015).

According to Rodolfo (2000), Sulpizio et al. (2006), and Vallance and Iverson (2015), volcaniclastic mass flows can be generated at variably--long time--intervals, spanning from eruptive to post-eruptive phases of tens to hundreds of years. In case these flows are directly related to volcanic eruptions (i.e., that is occurring during or shortly after the eruptive event), lahars are defined as syn-eruptive, and can represent an important multi-hazard factor in the short--to--middle term for perivolcanic areas (Rodolfo, 2000; Sulpizio et al., 2006). On the other hand, instead, in case they are unrelated to any eruption dynamics, so that is occurring during long periods of volcanic quiescence, they are defined as post--or inter--eruptive (Vallance and Iverson, 2015), and can represent a long-term hazard factor (e.g., Siebe et al., 1999; Pareschi et al., 2002; Zanchetta et al., 2004a, 2004b; Sulpizio et al., 2006). Usually, these latter post-eruptive lahars are not accounted for in the assessment of volcanic hazard, although their study is important for hydrogeological hazard assessment and long-term territorial planning.

In this sense, i.e.that is from the hazard assessment point of view, one of the priorities concerns the assessment of those areas potentially exposed to such a threat, taking into account the temporal
recurrences of the phenomena (during over days to months after an eruption, or years to decades after) and the physical features of the volcaniclastic mass flows (volume, thickness, velocity, dynamic pressure, concentration, and invasion areas). We stress the fact that the definition of syn-eruptive lahars (Sulpizio et al., 2006; Vallance and Iverson, 2015) adopted in the present work is important when accounting for the multihazard of explosive eruptions, which in areas like Vesuvius and surroundings should not be neglected for its assessment and mapping purposes (de’Michieli Vitturi et al., this issue; Sandri et al., this issue). The methodology used in this work is geological (see Section 3.2), and the syn-eruptive definition of lahars is necessary to avoid underestimations of the volcanic hazard from sub-Plinian eruptions at Vesuvius.

A lot of the existing literature analyzed the hazard related with volcaniclastic mass flows on the flanks of active volcanoes, through the reconstruction of historical and prehistoric events (e.g., Scott, 1989; Scott et al., 1995; Vallance and Scott, 1997; Zaragoza et al., 2020), by using empirical relationships or physical models (e.g., Macedonio and Pareschi, 1992; Costa, 1997; Iverson et al., 2000; Walsh et al., 2020). However, the areas affected by these phenomena can be extended well beyond the boundaries of the volcanic complex, also including the surrounding plains and the downwind-lying mountainous areas, which are subjected to tephra fallout sometimes even at great distances from the volcano (e.g., Siebe et al., 1999; Pareschi et al., 2000, 2002; Zanchetta et al., 2004a, 2004b; Di Crescenzo and Santo, 2005). In these areas, volcaniclastic mass flows may cause victims and damages, even where considered safe or scarcely affected by other volcanic hazards.

In this paper, we present the results of a multidisciplinary study, including geomorphological, stratigraphic, sedimentological and rock magnetic investigations, as well as impact parameter calculations by reverse engineering from the deposits. These investigations followed several surveying campaigns carried out in natural exposures, archaeological excavations, and trenches dug specifically for this purpose in the plain surrounding the Vesuvius edifice and along the Apennine valleys (Fig. 1). One of the goals of the study is to show the presence of lahar deposits even in areas very far from both the Apennine hills and the valleys of Somma-Vesuvius, demonstrating the high
mobility of these flows. Technically, the ones descending on the Apennine flanks should be termed as volcaniclastic debris flows; here we merge into an only one term, lahars, to indicate secondary mass flows strictly related to specific eruptions. The study of the past lahars deposits has been useful for the understanding of the feeding drainage basins for different types of volcaniclastic mass flows, their extent and facies variations with distance from the source area, and their associated environmental-impact on landscape. As already pointed out by Di Vito et al. (2013, 2019), in the past 4.5 ka repeated lahar and flooding episodes related to the main eruptions of Somma-Vesuvius and Campi Flegrei volcanoes strongly stroke the Campanian Plain and its human settlements, influencing their abandonment or evidencing attempts of resettlement. In particular, for the areas around Vesuvius, these phenomena included: i) large volume and high energy lahars, originated from the volcanic edifice, which affected the volcanic apron; ii) large flooding phenomena, i.e. overflowing of water affecting the Campanian plain; iii) lahars originated from the perivolcanic mountains that affected the Apennine valleys and invaded the areas of the plain at their mouths. All of these phenomena differed to each other in terms of amount and grain-size of the involved sediment. The data and pieces of information described here were the basis for validating a new model for lahar transport (de’ Michieli Vitturi et al., submittedthis issue), which was applied for assessing the related hazard at Vesuvius and Campanian Plain (Sandri et al., submittedthis issue).

The structure of the work consists of an integrated geological, geomorphological, stratigraphic and sedimentological integrated study, a paleomagnetic and sediment-mechanic impact assessment calculation, and a comprehensive discussion on the lahar problem in the Campanian Plain.

2. Geological setting

The study area is part of the Campanian Plain, which includes the lowlands surrounding Mount Vesuvius volcano and the nearby Apennine ridges and valleys (Fig. 1). The orography of the area is characterized by three WNW-ESE trending mountain ridges that border eastward the plain, with an
elevation ranging from 500 to 1600 m a.s.l., and slope angles from 30 to 60°. From north to south, the Avella-Partenio, Lauro-Visciano and Sarno-Quindici mountain ridges are separated by two depressions: the Avella-Baiano valley, in which the alluvial plain of the Clanio river occurs, and the Lauro valley. Both are narrow valleys that widen toward north-west, among the cities of Cicciano, Nola and Palma Campania (Fig. 1). The reliefs are characterized by a high drainage density, associated with a poorly developed and torrential hydrographic network, which over time has favored the incision and dismantling of the pyroclastic cover on the ridges, and the development of numerous detrital conoids that connect with the main valley floor (Di Vito et al., 1998).
Vesuvius, or more properly Mt. Somma-Vesuvius, is a composite central volcano less than 39,000 years old, composed of the remnant of the oldest Mt. Somma edifice, dismantled by repeated episodes of caldera collapse, and the more recent Mt. Vesuvius, grown inside it. Its volcanic history is characterized by an initial phase, dominated by low-energy effusive and explosive eruptions, which ended at around 22,000 years ago. Since then, the volcano generated four Plinian eruptions with VEI 5-6, each preceded by long periods of quiescence and all accompanied by a summit caldera collapse (Somma caldera; Cioni et al., 1999). The last Plinian eruption occurred in 79 CE and once again modified the Somma caldera, inside which the recent cone has subsequently grown due to an alternation of periods of open conduit, persistent Strombolian and effusive activity, and long periods of quiescence with obstructed conduit, interrupted by high-energy sub-Plinian eruptions. In historical times, the other more energetic events were the sub-Plinian ‘Pollena’ (472 CE) and 1631 eruptions (Santacroce et al., 2008). The last eruption occurred in 1944 and caused the return to obstructed conduit conditions, which characterize the current quiescent phase of the volcano. The rocks composition varies from slightly silica-undersaturated (K-basalt to K-trachyte) to highly silica-undersaturated (K-tephrite to K-phonolite). The Somma-Vesuvius complex is characterized by Mount Vesuvius is a composite central volcano with a well-developed radial drainage network, which feeds an extensive volcaniclastic apron that morphologically connects the edifice with the surrounding plain (Santacroce et al., 2003). It represents the active southern termination of the Plio-Quaternary volcanic chain that borders the eastern Tyrrenian margin (Peccerillo, 2003). Volcanism in this margin is related to the extensional tectonic phases that accompanied the anticlockwise rotation of the Italian peninsula, during the complex interaction between the Africa and Eurasian plates, which generated the Apennine thrust-and-fold belt (Ippolito et al., 1973; D’Argenio et al., 1973; Finetti and Morelli, 1974; Bartole, 1984; Piochi et al., 2004; Patacca and Scandone, 2007; Vitale and Ciarcia,
2018). The extension along the Tyrrhenian margin of the Apennine chain was accommodated by the activation of NW-SE normal faults and NE-SW normal to strike-slip transfer fault systems, which dismembered the chain in horst and graben structures, and allowed magmas to reach the surface and feed the volcanism (Mariani and Prato, 1988; Faccenna et al., 1994; Acocella and Funiciello, 2006).

The Campanian Plain is one of these grabens that hosts the Neapolitan volcanic area. It is a NW-SE elongated structural depression, filled by a thick sequence of marine and continental sedimentary deposits, and volcanic-volcaniclastic successions that compensated its subsidence, leading to a complete emersion at around 39 ka (Brocchini et al., 2001; De Vivo et al., 2001; Santangelo et al., 2017). This graben is bordered toward NW, NE and SE by the Meso-Cenozoic carbonate and terrigenous successions of the Apennine chain, and is subdivided in minor NE-SW oriented horst-and-graben structures (Carrara et al., 1973; Finetti and Morelli, 1974; Fedi and Rapolla, 1987; Brancaccio et al., 1991). Neapolitan volcanoes lie on these second-order structural highs (Marotta et al., 2022 and reference therein), and the products of their most powerful eruptions blanketed the Apennine reliefs and filled their valleys with several meter-thick covers of loose-pyroclastic fall deposits, composed of pumice lapilli and ash layers separated by paleosoils (Pareschi et al., 2002; Bisson et al., 2007; Cinque and Robustelli, 2009; Gurioli et al., 2010).

In terms of water drainage of the water, the pyroclastic cover has peculiar geotechnical characteristics, such as a positive correlation between grain-size and permeability, which enabled the development of lahars in the area. In particular, coarser pumice layers are characterized by interconnected void spaces that control water accumulation, instead ash layers, soils and paleosoils by a high water retention capacity (Andosol-like soils), so that the differential behavior can regulate equilibrium among deposits stability vs. remobilization (Fiorillo and Wilson, 2004).

Regarding the volcanic activity of Vesuvius in the last 2,000 years, the largest eruptions after the 79 CE Plinian one were two sub-Plinian eruptions, the 472 CE Pollena and 1631 ones, but several other effusive and explosive events frequently occurred in historical times. In the Campanian Plain, lahar deposits related to these two eruptions are quite abundant due to past heavy rains (Fiorillo and Wilson,
2004; Zanchetta et al., 2004b; Stanzione et al., 2023), also the sub-Plinian scenario is of interest for civil protection purposes, which is why in the present work we focus on these reference explosive CE Pollena and 1631 eruptions. Throughout the work, a particular attention is put on to the distribution of the primary pyroclastic deposits and the related syn-eruptive lahars, which are mass flow events strictly related to specific eruptions, even if the condition is not necessarily that of an event contemporaneous to the eruption. Those deposits are mainly composed by of >90% fragments from the parental eruption, while the remaining fragments pertain to other eruptions mixed by volcaniclastic colluvium (Sulpizio et al., 2006). The syn-eruptive feature is thus related to the involvement—remobilization of pyroclastic deposits more than to the exact timing of lahar emplacement, the latter being of the order of max a few years (before significant humification processes or significant human activities can occur). Such a feature distinction is important because directly related to volcanic hazard.

3. Materials and methods

3.1. Evidence from historical sources

We collected data from historical sources, maps, documents, and newspapers to supplement the geological data, gathered directly or indirectly, for the definition of the areal distribution of the syn-eruptive and post-eruptive lahar deposits at Vesuvius and in the surrounding region. Such collection concerned the phenomena that took place starting from the sixteenth century CE to 2005. This time span has been chosen depending on data availability, and to show the high recurrence of events over time in the area. The data were collected and grouped not only by years but also by the municipal areas existing at those times. It should be noted that the distribution of the data can be affected by the different urbanization over time, and by the presence of damage to people, things, infrastructures and goods, economic activities and settlements. In the absence of local instrumental meteorological weather data series, corresponding to over the analyzed period, we assumed that the
phenomena of remobilization of the pyroclastic deposits, and the consequent generation of large alluvial-flooding events and volcaniclastic mass flows, coincided with extreme weather events often described and reported in the analyzed sources. The reports reach a quite significant number, approximately 500, and concern 97 municipalities. We identified about 500 individual reports, covering events between the sixteenth century CE and 2005 that took place in 97 different municipalities. The data were organized in a geospatial database, so that it was possible to define different areas affected by frequent syn-eruptive floods and lahars, concomitant/related with the sub-Plinian eruption of 1631, to be used as benchmark for the main geological analyses. With reference to We could not add the Pollena eruption to this historical data set, as there are no historical-available sources for similar occurrences other than documents deriving from archaeological excavations activities (see next sections).

The municipalities with the highest number of reports are: Sarno (43), Salerno (32), Siano (26), Vietri sul Mare (22), Bracigliano (21), Nocera Inferiore (20), Maiori (19), Quindici (17) (Fig. 1). The events of greatest intensity, which affected more than five municipal territories at the same time, are 19-they likely were multiple soil-slip debris flows. Some of these occurrences result closely connected with the volcanic events of Vesuvius, such as those that occurred in 1631, 1823, 1910, 1949 and 1954, simultaneously or within months to a few years after the Vesuvius eruptions of 1631, 1822, 1906 and 1944.

Tab. 1. Historical archive of lahars and alluvial events related to the four most significant Vesuvius eruption in the last four centuries, and municipalities affected by such events.

The absence of information in the Lauro and Avella-Baiano valleys is likely due to the absence of detailed descriptions of alluvial events, or most likely to the position of the inhabited areas generally located on the hills thus far from the lower part of the valleys.

3.2. Field and archaeological investigations

We used a set of geological, stratigraphical, sedimentological, archaeological, and pedological information for the reconstruction of the type of events, their emplacement mechanisms, timing, and impact on pre-existing structures/environment. Such an approach enabled us to cross-check geological and archaeological evidence allowing us to accurately fix the age of events. Conversely, the presence of well-dated primary pyroclastic deposits can define the age of human traces otherwise not easily datable. Furthermore, the identification of the “primary” (fallout and pyroclastic current, along with the archeological findings) can give the absolute age (ante or post quem) of a given deposit.

The definition of isochronic paleosurfaces can also contribute to the reconstruction of the paleo-environments affected by the deposition, and of the variations that occurred during depositional processes. For this purpose, particular attention was paid to the basal contacts between the deposits.
In some areas like Nola, the lahar deposits directly overlie the primary pyroclastic deposits (of both the 472 CE Pollena or-and 1631 eruption), while in other areas some pyroclastic units or the whole primary deposits are missing (eroded) or lacking. Only the correlation with the nearby areas permitted to define whether the emplacement of the secondary deposits eroded partly or entirely significantly the underlain primary deposits, vice versa the complete absence in the emplacement areas was could also be simply due to their distribution of these latter. The analysis of the internal structure marked by sharp changes in grain sizes, color, presence of erosive-erosional unconformities, or interposition of lenses of coarser material also permitted the identification of one or more flow units within the same individual deposit package. The macroscopic characteristics of the sequences permitted some inferences on the transport and depositional mechanisms, while the grain-size and componentry analysis analyses provided information on the source deposits that were remobilized. This brings to another important definition, that is syn-eruptive vs. post-eruptive lahars, according to the definition of Sulpizio et al. (2006) and Iverson and Vallance (2015), which applies during or respectively soon after the eruption vs. several years to centuries after the eruption ended, respectively. The macroscopic analysis allowed us to distinguish between the syn-eruptive and post-eruptive deposits, which. The first ones are defined by the occurrence of pyroclastic components with homogeneous a lithology, similar to the one of the primary deposits, and the post-(or inter-) eruptive deposits. The second ones are characterized by some evidence of depositional stasis, such as like humified paleosurfaces, evidence below the lahar deposits or of anthropogenic anthropogenic activitiy, or also through deposits that contain the presence of humified material and/or fragments of older eruptions in the deposits following the progressive erosion within the feeding slopes and valleys. All these characteristics allowed the correlation between the various volcanioclastic units for the whole set of the studied sequences, marking the differences needed to hypothesize on the source and invasion areas.

We reviewed all the volcanological and archaeological data collected during the last 20 years from drill cores, outcrops, archaeological excavations, and from the existing literature, in collaboration
with colleagues of the Archaeological Superintendence of Campania region. The preliminary
collection and analysis of the existing data permitted to plan a hundred of new stratigraphic trenches
(Fig. 2), with the aim of collecting stratigraphic, stratimetric, sedimentological, lithological and
chronological data on the sequences both of primary pyroclastic and secondary (lahar) deposits.
Particular attention was also paid to the primary pyroclastic deposits and to syn- and post-eruptive
lahars, and to their geometric relations of these deposits with the paleotopography and the preexisting
anthropic-anthropogenic structures.

![Figure 2](image_url)

Fig. 2. Shaded relief of the studied area and location of all the sites where stratigraphic analyses were carried out.

The collected data were organized into a geospatial database (QGIS Platform), in which each point
represents an investigated site linked to a series of information, such as the precise location, the
kindtype of volcanic sequence, and the stratimetric stratigraphic features (primary and secondary
units, thickness, type of deposit, etc.). The data were visualized using a Digital Elevation Model
(DEM) of the Campanian Plain as reference topography and the UTM WGS 84 – Zone 33N reference projection.

3.3. Geomorphological analysis

This analysis is aimed at identifying the macro-basins that fed the lahars in the study area after the two sub-Plinian eruptions (Pollena and 1631). The analysis was carried out on the basis of the slopes distribution and the watersheds extracted from a Digital Elevation Model (DEM). The DEM was derived from a LiDAR flight of 2012 and stored with (cell size of 10 m). In particular, six macro-basins characterized by slopes > 20° were identified in the Somma-Vesuvius area, whereas fifteen macro-basins with slopes > 25° were identified in the Apennines to the East of the volcano (Fig. 3). The different slopes thresholds are defined starting from previous studies (Pareschi et al., 2000, 2002; see also Bisson et al., 2013, 2014), and on the basis of a better analysis of the physical characteristics of the remobilized material, in turns related to the various types of deposits. In fact, along the slopes of the steep slopes and in the valleys of Somma-Vesuvius, the deposits are mainly ash-rich pyroclastic current deposits and subordinately lapilli fallout deposits, while for on the Apennines they are ash and lapilli fallout deposits emplaced along the variably deep slopes. Each basin was considered as a single feeding unit for the lahars generation, and this is an input for the modeling of possible future lahars in the companion papers (de’ Michieli Vitturi et al., submitted this issue; Sandri et al., submitted this issue).
Fig. 3. The macro-basins defined on the basis of their geomorphological features to study the areas of possible accumulation and mobilization of deposits, which are used in modeling lahar generation of future events.

3.4. Laboratory and analytical work

3.4.1. Grain-size

In several the selected studied sites among all the studied ones reported in (Fig. 4), macroscopic analysis analyses of the stratigraphic sequences was were first carried out in the field to first identify...
any homogeneities or similarities between the juvenile fraction of the primary and secondary deposits, and then recognize the various volcaniclastic units. This was followed by sampling the deposits and carrying out the laboratory analyses.

In particular, the sampling was mostly made on the syn-eruptive lahar deposits, but also on the post-eruptive and, in a few cases, on the primary pyroclastic deposits. All lab analyses were performed in the laboratories of sedimentology and optical microscopy at the Istituto Nazionale di Geofisica e Vulcanologia, Sezione di Napoli Osservatorio Vesuviano (INGV – OV). The material samples were pre-heated at a temperature of 60-70 °C to eliminate any fraction of humidity, then were quartered and sieved. To avoid any breaking of fragile clasts like pumices, the dry sieving of the grain-size classes between -4 (a coarse limit variable depending on the sample) and 0 phi was made manually, while for the classes between 0.5 and 5 phi a mechanical sieving apparatus was used.

In particular, the fine ash-rich deposit samples with a high degree of cohesion (with a significant amount >0 phi) were first combined with diluted in distilled water and thus, then boiled to remove all the ash aggregates, before being analyzed for granulometry grain-sizes following a wet procedure, and finally dried and weighted by classes. The cumulative class >5 phi was further separated by interpolation modelling (de’Michieli Vitturi et al., this issue). In the post-processing of the data, the GRADISTAT excel package by Blott and Pye (2001) was used to determine the main statistical parameters. On selected samples, a microscopic componentry analysis was performed, consisting of recognizing and separating the various lithotypes that compose the volcaniclastic deposits, that is juvenile, lithic and crystal clasts. The clasts recognition was made manually for the coarser fractions, while for the finest fractions it was necessary the use of a reflected-light binocular microscope.
Fig. 4. Location of sites in which the sampling was carried out for sedimentological and paleomagnetic analyses. The pink triangles represent the sites for which a paleomagnetic study was carried out (AC1_74, AC1_77, AC2_83, and Nola_Via_Saviano). In several sites, multiple samples were taken at different stratigraphic heights; samples labeled with US were taken at CM_Pozzonuovo site (see results).

3.4.2. Input for impact parameters

A significant number of large clasts and boulders was also found embedded in the ash matrix of the lahar deposits at different locations. These clasts have dimensions from several centimeters to several tens of centimeters in diameter, and their nature is variable, that is limestone, ceramic, brick, tephra, lava, sandstone, iron (in order of abundance). Most of the clasts are fragments of artifacts from buildings, structures, and other archaeological finds of the Roman period, and their shape can be approximated in the field to ellipsoid. All these features suggest that they were entrained from substrate into the lahars to ultimately be deposited together with the ash main finer solid load of the
lahars. In the dynamics of volcaniclastic mass flows like lahars and pyroclastic currents, the occurrence of boulder entrainment by flow dynamic pressure is recognized as a quite common feature (e.g., Zanchetta et al., 2004a; Pittari et al., 2007; Duller et al., 2008; Toyos et al., 2008; Cas et al., 2011; Carling, 2013; Doronzo, 2013; Jenkins et al., 2015; Roche, 2015; Martí et al., 2019; Guzman et al., 2020). The capability of a flow to entrain a clast is a function of flow properties (velocity, density) and clast properties (dimension, density, shape), and dynamic pressure well syntheses and quantifies such capability also in terms of flow hazard (Toyos et al., 2008; Zuccaro and De Gregorio, 2013; Jenkins et al., 2015). In Appendix A, a theoretical scheme is presented to invert these field features for calculation of the impact parameters at local scale.

3.4.3. Rock magnetism

The lahar deposits related to the Pollena eruption were analyzed by rock magnetism at two localities, in the municipalities of Acerra and Nola at four localities (Fig. 4), where the lahars interacted with anthropogenic structures. At each locality, we collected oriented samples, then measured about 200 specimens. We sampled both the deposit matrix and some potsherds embedded along three trenches (74, 77 and 83) and in the “Nola-Via Saviano” excavation (Fig. 4). The purpose of the magnetic measurements was threefold: i) evaluating the magnetic fabric of the deposits to infer the local to regional flow directions of the lahars and possibly their origin, whether from the Apennines or from Vesuvius. The magnetic fabric in this type of deposits records the main flow direction (local/regional) followed during the emplacement processes; ii) estimating the deposition temperature ($T_{dep}$) of the deposits, to understand whether the lahar was triggered soon after the eruption or at later times. The hypothesis is that the temperature is higher in case of syn-eruptive lahars deriving from hot (pyroclastic current) deposits, and lower in all other cases of post-eruptive ones; iii) testing the relative sequence (contemporaneity) of the lahars emplacement with respect to the Pollena eruption. All hand-samples were oriented in-situ with magnetic and solar compasses and
reduced to standard sizes at the CIMaN-ALP laboratory (Peveragno, Italy), where all the magnetic
measurements were made. In Appendix 2B, the adopted paleomagnetic techniques and nomenclature
are described.

4. Results

4.1. Field stratigraphy and sedimentological features

In this study, data of about 500 sites were collected, covering an area of >1000 km² from the plain
around the volcanic edifice to the Apennine valleys to the north and east (Fig. 2).

4.1.1. Pyroclastic deposits: eruptions of Pollena and 1631 eruptions

The integration of the collected data with the existing ones (Rosi and Santacroce, 1983; Rosi et al.,
1993; Rolandi et al., 2004; Sulpizio et al., 2005; Perrotta et al., 2006; Bisson et al., 2007; Santacroce
et al., 2008; Gurioli et al., 2010; De Simone et al., 2011) allowed the reconstruction of the distribution
maps for both the fallout and pyroclastic current deposits. In particular, the spatial distribution
highlights that for both the Pollena and 1631 primary deposits, thick fine ash deposits are widely
distributed and cover the coarse fallout sequence or directly the ground, modifying the isopachs
reconstructed by previous authors (Sulpizio et al., 2006 and references therein; Figs. 5 and 6). This
enlargement of the area affected can have important implications on the hazard evaluation in terms
of possible damages on a densely inhabited territory.

The area covered by the comprehensive isopach maps (including both the lapilli fallout and ash
fallout) turns out to be wider than the one previously known, above all because we also took into
account for the ash deposited by fallout occurred during the final phreatomagmatic stages of the
eruptions, mostly dominated by phreatomagmatic explosions (Rosi and Santacroce, 1983; Sulpizio et
al. 2005). The great distribution and availability and distribution of these ash deposits could explain
the wide generation and distribution of the syn-eruptive lahars in the area. This has important
implications in the evaluation of the source area and of the material available for the lahars accompanying and following this eruption. In particular, Interestingly, there is an increase of the areas covered by pyroclastic deposits and the calculated volume of the emitted products. For example, the area covered by the pyroclastic current deposits thus results in is of about 200 km$^2$ for the Pollena eruption, and 120 km$^2$ for the 1631 eruption, while. More significantly, the QGIS recalculated 10-cm isopach area for covered by the fallout deposits is of 433,837.35 km$^2$ (Pollena eruption) and 427,528.51 km$^2$ (1631 eruption), respectively which compared to the lower values of 569 km$^2$ (Pollena eruption) and 158 km$^2$ (1631 eruption) after Sulpizio et al. (2006) give an extra surface of about 47% and 230%, respectively. Geotechnically, another implication is that the wide presence of fine and cohesive ash, not only on top of the coarse fallout sequences and, in general but also on the ground, reduces the permeability of the substrate, preventing the infiltration of the water and favoring the stream formation, surficial runoff and creating sliding surfaces (Baumann et al., 2020). They can also enhance the mobility of the flows by creating sliding surfaces.
Fig. 5. Pollena eruption: the black lines represent the isopachs (in cm) of the fallout deposits modified after Sulpizio et al. (2006) (in the inset) on the basis of the new collected data (green dots), while in pink is colored the area affected by the pyroclastic current deposits (isopachs in cm, purple lines), modified after Gurioli et al. (2010) (purple lines). The dotted parts of the isopachs represent some uncertainty related to the absence of new further data are extrapolated.

The light blue arrows represent the general remobilization of the pyroclastic fallout deposits and lahar propagation from the Apennine slopes, while the pink one represents the combined remobilization of the pyroclastic current and fallout deposits and lahar propagation from Somma-Vesuvius.
Fig. 6. 1631 eruption: the black lines represent the isopachs (in cm) of the fallout deposits, modified after Santacroce et al. (2008) (in the inset) on the basis of the new collected data (orange dots), while in yellow is colored the area affected by PDC–pyroclastic current deposits (isopachs in cm, light blue lines). The light blue lines represent the inferred distribution on the basis of an integration between field data and font-chronicles, modified after Gurioli et al. (2010). The dotted parts of the isopachs represent some uncertainty related to the absence of new further data are extrapolated. The
light blue arrows represent the general remobilization of the pyroclastic fallout deposits and lahar propagation from the Apennine slopes and Somma-Vesuvius.

The significant widening of the area affected by accumulation of the 1631 eruption tephra—fallout deposits is wider than previously known, particularly towards the north for the 1631 eruption, which follows the inclusion of the final ash deposits into the new isopachs. Interestingly, such widening of the area agrees with the widespread occurrence of lahars in the plain north of Vesuvius, as documented in the chronicles and historical sources (Rolandi et al., 1993; Rosi et al., 1993, and references therein), and as follows.

4.1.2. Lahar deposits

The lithological and sedimentological analyses carried out in the field allowed the macroscopic definition of the primary pyroclastic deposits involved in the remobilization, and of the lahar deposits. In many cases, the archaeological findings permitted to define the local paleoenvironment and the related land use, and also to then permitted to constrain the age and timing of the deposition.

We grouped all deposit descriptions into representative lithofacies to more directly characterize both the primary pyroclastic and lahar deposits (Tab. 2 and Fig. 7). Given the amount of data and description of the studied areas, we used these lithofacies to characterize a number of macro-areas between the Somma-Vesuvius sector and the nearby Apennine valleys (Appendix C). The lithofacies mostly recognized are P to indicate paleosoil and humified surface, mL and mA (massive lapilli and massive ash, respectively) to indicate the primary deposits, while the lahar deposits usually belong to the facies Gms and mM, which indicate massive, matrix-supported gravel deposits and massive lahar deposits, respectively. Other recognized lithofacies are Sh, Ss and fM. Sh indicates hyper-concentrated flow deposits, and consists of an alternation of coarse and fine beds. Ss includes scour
and fill structures, and consists of an erosive, concave-upwards basal surface and a planar/convex top. fM is fine mud, and indicates the decantation deposit formed when the flow loses its energy.

Tab. 2. Symbol and description of the recognized lithofacies, and photos representative of each of them.
a)
Fig. 7. In these three photos of archaeological excavations (a-b, Nola; c, Acerra), the main lithofacies recognized in the field are shown, including paleosols, pyroclastic deposits, and lahar deposits; the corresponding lithofacies descriptions are reported in Tab. 2.
Usually, the syn-eruptive lahar deposits directly overlie the primary pyroclastic deposits, sometimes eroding them. They have a matrix-supported texture and are composed of fine to very fine cohesive cohesive ash, and contain scattered and more or less abundant mm–cm-sized pumices and lithic fragments. In general, the deposits are generally composed of multiple depositional flow units, each one resulting from single-pulse “en masse” transport-emplacement, the piling of which resulting from rapid progressive aggradation through multiple flow pulses, in analogy with dense pyroclastic currents (Sulpizio et al., 2006; Doronzo, 2012; Roche, 2012, 2015; Breard and Lube, 2017; Smith et al., 2018; Guzman et al., 2020; see Sulpizio et al., 2014, p. 56) and similarly to lahar events occurred for example at Ischia (Italy) in 2022 (De Falco et al., 2023). For this reason, the studied lahars were modelled using a shallow layer approach (de’Michieli Vitturi et al., this issue). The different depositional flow units in the same deposit are distinguishable (still in continuity) from each other based on vertical granulometric changes, sparse pumice alignments, internal lamination deposit layering and/or unconformities. Compared to channeled pyroclastic currents, dense water flows and floods, such depositional units (layers) could have been repeatedly emplaced, from bottom to top, under accumulation rates of several of a few tens to a few hundreds kg/m²s (Lowe, 1988; Russell and Knudsen, 1999; Whipple et al., 2000; Girolami et al., 2010; Roche, 2015; Marti et al., 2019; Guzman et al., 2020). In various areas, the “en masse” transport such rapid sequential emplacement is suggested by the presence of water escape structures through the whole deposit and by crossing the sequence of several units. These are vertical structures consisting of small vertical “pipes” filled by fine mud, transported by the escaping water, and formed soon after the emplacement of the lahar units. The lithological textural characteristics are variable even within the same site, but in general the deposits are generally massive, and contain vesicles, from circular to flattened, and coated by fine ash that adhered into the voids after water evaporation loss. For the syn-eruptive lahar deposits, the pumice fragments are those of the primary deposits, while, on the other hand, in the upper parts of the sequences it is not uncommon to find units that contain pumice fragments related to previous
eruptions, in particular the (9.0 ka B.P. "Mercato" and the-3.9 ka B.P. "Avellino" Plinian eruptions), recognizable based on pumice texture and crystal content (Santacroce et al., 2008). In this second case, these lahar deposits are considered as post-eruptive, meaning that the pyroclastic deposits older than the two studied sub-Plinian eruptions were progressively involved in an advanced erosion of the slopes and valleys exposed to weathering for some time, and then were deeply remobilized. Also, the presence in the sequences of slightly humified surfaces below the lahar deposits or the evidence of human artifacts, such as for example excavations, plowing, etc., are considered as constraints for a long period of non-deposition, and; also in this case, the lahars generation is considered as post-eruptive. In other words, the similar componentry of the secondary lahar deposits vs. and primary pyroclastic deposits for related to the two sub-Plinian eruptions, as well as the evidence of short-term exposure between these two vertical continuity between the fallout and lahar deposits directly lying on the fallout deposits, are strong indicators of the syn-eruptive occurrence of the lahar events. Instead, the absence of such features is more indicative of a post-eruptive origin, with lahars events more spaced in time from the corresponding eruption.

In Appendix 3C, a description is reported for some of the most representative sequences, which were sampled in different areas throughout the plain (Figs. 2 and 4).

4.1.3. Distribution maps of the lahar deposits

Here we present the distribution maps for the lahar deposits of the eruption of Pollena and 1631 eruptions (Figs. 8-10). The maps show the distribution of all thicknesses detected in the studied sites. In particular, the syn-eruptive Pollena lahar deposits are distributed in the NW quadrants of the volcano and in the Avella, Lauro and Sarno valleys (see Fig. 1), with a thickness exceeding 1 m in the Vesuvius apron and in the plain between Nola and Cimitile (see Figs. 1 and 8). A volume estimation of the remobilized deposits is of the order of $7.3 \times 10^6$ m$^3$ for the northern Vesuvius area.
and \(42 \times 10^6\) m\(^3\) for the Lauro Valley. Such volumes are referred to the depositional areas, and not to the detachment ones; for the latter see de’Michieli Vitturi et al. (this issue) and Sandri et al. (this issue). The provenance of the material in each site was inferred by sedimentological recognition and magnetic reconstruction. Then, the covered areas were subdivided into polygons in the geospatial database, in order to weight the local deposit thicknesses and estimate the volumes with a lower approximation.

![Distribution of the syn-eruptive lahar deposits related to the Pollena eruption](image)

The post-eruptive lahar deposits of the Pollena eruption are more concentrated in the Avella and Lauro valleys, and in the plain north of the volcano close to the apron area (low-angle edifice outer slopes) (Figs. 1 and 98). Their deposits contain both fragments from the Pollena eruption and from preceding eruptions, suggesting that pyroclastic deposits of the older sequences were...
progressively eroded and involved in remobilization processes over time. As an example, in Figs. A3a-d C1-4 it is possible to recognize whitish pumice fragments from the Pomici di Avellino and Mercato eruptions were identified on top of the Pollena lahar deposits.

Fig. 9b. Distribution of the post-eruptive lahar deposits related to the Pollena eruption.

The distribution of the syn- and post-eruptive Pollena lahar deposits is related to the primary pyroclasts deposition: the dense distribution of the lahar deposits north of Somma-Vesuvius depends on the presence of thick pyroclastic current deposits that were remobilized from the northern slopes of the volcano, while the distribution in the Apennine valleys is related to the fallout deposits that are thicker along the major Pollena dispersal axis (Fig. 5).

Above the Pollena primary and secondary pyroclastic and lahar deposits (meaning after the emplacement of the Pollena lahars) (both syn- and post-eruptive), the studied sequences in almost all the sites show the presence of a well-developed soil bed with many traces of cultivation, as well as
of the presence of inhabited areas and buildings (Figs. A3a-d, C1-4). These traces and the presence of a well-developed soil bed are evidence of a progressive geomorphological stabilization of the territory. The occurrence of the 1631 sub-Plinian event determined a new phase of marked geomorphological instability for a large territory surrounding the volcano. In Fig. 109, it is shown the distribution of the syn-eruptive lahar deposits for the 1631 eruption in all the studied areas with having a variable thickness, generally <50 cm. Such distribution affected mostly the areas of Acerra-Nola, Sarno, the Vesuvius apron and the Apennine valleys (Figs. 1 and 109). Rosi et al. (1993) and Sulpizio et al. (2006) reported that floods and lahars heavily impacted (also with injuries and victims) the N and NE quadrants of Somma-Vesuvius soon after the eruption with a timescale of days (Rosi et al., 1993; see also the historical chronicles of Braccini, 1632), corroborating the syn-eruptive behavior of such lahars. Furthermore, some lahar deposits are also intercalated within the primary pyroclastic deposits, while but in generally they directly stand in continuity on top of the primary pyroclastic deposits (Rosi et al., 1993); both cases unequivocally constrain the syn-eruptive behavior of the 1631 eruption lahars.
The 0 m points represent the studied sites where the lahar deposits were absent, and in some cases even the primary pyroclastic deposits below were absent; they are reported anyway, as their absence might have not necessarily occurred by no deposition (local erosion).

In Fig. 10, minor post-eruptive lahar deposits of the 1631 eruption are reported, with a preferential distribution to the E quadrants of the volcano from N to S, both in the plain and the valleys. These deposits are still significant, with a thickness of around half a meter to a meter or more in a few points.
The distribution of the syn- and post-eruptive 1631 lahar deposits mainly reflects the major dispersal axis affecting the fallout deposits distribution, while the pyroclastic current deposits were minorly remobilized as exposed on the gentler slopes of southwestern Vesuvius (Fig. 6).

4.1.4. Sedimentological characteristics of the Pollena lahar deposits

The field analysis was carried out on about 500 studied different sites for the construction of the database and maps, and while the laboratory analysis carried out was carried out on 30 selected representative samples representative of the different areas contribute; both analyses contributed to the distinction between syn- and post-eruptive lahars in the area. The results of the grain-size analyses in the form of histograms, cumulative curves and statistical parameters are presented in Fig. 12 and Tab. 1.
Petrological analysis on the syn-eruptive lahar deposits have not been performed because the lithology (colour, texture, mineral content) of the components is the same as the juvenile material of the primary deposits (more details can be found in Sulpizio et al., 2005). The loose crystals consist of sanidine, leucite, biotite and pyroxene fragments. Based on the results of the grain-size analyses, the coarser classes are defined from -4 to -1 phi, the medium ones are from -0.5 to 2.5 phi, and the finest one are from 3 phi. The juvenile pumice clasts are an ubiquitous component of the lahar deposits (both syn- and post-eruptive), but they decrease with distance toward finer grain-size classes, while the crystal content increases in with the same progression. The lithic clasts are abundant in for the coarser classes, they decrease with distance in for the middle-medium grain-size classes, and increase again in for the finer classes.

Tab. 34. Statistical parameters (mean and sorting) extracted from the grain-size analyses, and reference lithofacies (see Tab. 2 for descriptions). Mode 1, 2 and 3 indicate the coarsest, medium and fine modes, respectively. Mode 1, 2 and 3 represent the most frequently occurring grain-size classes.

Field observations and statistical granulometric grain-size parameters analyses (modes, skewness, sorting), highlight significant differences between the sectors of Lauro Valley, Avella-Baiano Valley, and Somma-Vesuvius. A common feature between the three sectors is that the lahar deposit samples are mostly massive, poorly-sorted and polymodal; only a few samples are moderately-sorted and unimodal (more than one grain-size are present but one prevails sorting <1.5 phi). On the
other hand, the grain-size modes extracted show some interesting differences (in Fig. 12 the cumulative curves are shown). The coarse modes for Lauro Valley and Avella-Baiano Valley span from fine/medium lapilli to coarse ash, while for Somma-Vesuvius span from coarse to fine ash. The medium modes for Lauro Valley and Avella-Baiano Valley span from coarse to medium ash, while for Somma-Vesuvius span from medium to fine ash. The fine modes for Lauro Valley and Avella-Baiano Valley, and for Somma-Vesuvius span from medium to fine ash. Also, the skewness values for Lauro Valley and Avella-Baiano Valley show a fine to coarse mode while for Somma-Vesuvius show a coarse mode. All these differences basically depend on the origin of the primary pyroclastic deposits, fallout vs. pyroclastic currents, which were remobilized from different sectors, Apennines and Somma-Vesuvius. The grain-size analysis of the above described granulometry is used to inform as an input information for the model of lahar transport model (de’ Michieli Vitturi et al., submitted this issue) aimed at assessing the related hazard (Sandri et al., submitted this issue).

4.2. Magnetic results

Both Acerra and Nola localities show a well-defined magnetic fabric for the Pollena syn-eruptive lahar deposits, irrespective of being syn- or post-eruptive. Principal susceptibility axes ($K_1 > K_2 > K_3$) are clustered. Magnetic lineation ($K_1$) and magnetic foliation ($K_3$, pole of the plane) are mostly sub-horizontal or gently embricated and. The magnetic anisotropy degree $P_j (K_1/K_3)$ is mostly lower than 1.060, but can reach high values ($P = $ like 1.200). At Acerra, the magnetic foliation is always dominant, and the fabric is oblate. The $P_j$ is linearly correlated to the mean susceptibility ($k_m$). In Appendix B, the full nomenclature is defined for completeness. The magnetic fabric has a horizontal magnetic foliation and a clustered magnetic lineation, whose mean direction is NE-SW. Considering the chaotic nature of the lahar deposits, the high $P_j$ and the clustered susceptibility axes can highlight a channelized flow (Fig. 132). At Nola, instead, the fabric is both prolate/oblate, and $P_j$ is lower than 1.040. The susceptibility axes are more dispersed than Acerra, but mean magnetic lineation clearly
shows a NW-SE direction. If one considers the oblate specimens only, the magnetic foliation is sub-horizontal, on the contrary, the magnetic foliation of the prolate specimens is steeply dipping (65°) toward SE. At Nola, the flow direction inferred by AMS is consistent and parallel to the invasion basin.

Fig. 1. Equal area projection and Rose diagram of the $K_1$ directions at Acerra and Nola.

The deposition temperature is low at both deposits. At Acerra the $T_{\text{dep}}$ interval is 120-140 °C, while for Nola $T_{\text{dep}}$ is lower than 120 °C (Fig. 1). In the Nola case, a low temperature magnetization component lower than 120 °C cannot be directly considered as a TRM. In fact, the low $T_b$ Earth’s field component of magnetization can also be produced by a viscous remanent magnetization (VRM), acquired during exposure to weak fields (Bardot and McClelland, 2000). The acquisition of the VRM depends on the duration of the exposure. For age around that of the Pollena eruption, the minimum $T_{\text{dep}}$ which can be distinguished is ca. 120 °C. For this reason, we considered the Nola lahar to be emplaced at low temperature.
Fig. 14. Deposition temperature at Acerra and Nola. The site $T_{\text{dep}}$ is estimated from the overlapping reheating temperature ranges for all lithic clasts sampled.

The mean paleomagnetic direction for each locality, calculated using Fisher’s statistics, is well-defined, and its directional value and confidence limits do not overlap (Fig. 14). Thus, the two directions and are statistically distinguishable at the 95% confidence limit. Since a paleomagnetic direction is a record of the Earth’s magnetic field acting during the emplacement, it follows that Therefore, the lahar deposits of at these two localities are not synchronous.

Overall, all magnetic measurements just discussed show distinctly different characters between Acerra and Nola, clearly indicating two distinct events of emplacement.
4.3. Lahar dynamics

By inverting the field evidence and data, it is possible to reconstruct the macroscopic flow dynamics that occurred in the lahar invasion, which are particularly interesting to understand the impact that those lahars had on the Vesuvius territory. As already described, the lahar deposits show thicknesses that are variable from several centimeters to a few meters, and this can depend on multiple local factors: i) topography; ii) distance from source; iii) erosion; iv) source area and type of remobilized sediment (variably sized fallout vs. flow deposits). In particular, thicker deposits are found near the mouth of the valleys and in the flat alluvial plain, as shown in the deposit distribution maps. On the other hand, the deposits show on the whole a general tabular-like shape (Fig. 7), and an average thickness is of the order of 0.5-1 m recurrent for several studied sites, which is the first evidence of the lahars impact and mass flow emplacement in the area. In terms of runout distance, the lahars travelled for 10 to 15 km from sources (Somma-Vesuvius and Apennine detachment areas), measured directly on the deposit distribution maps based on the geospatial database that includes all studied sites. It was possible to infer the source areas based on the common sedimentological features
of the lahar deposits between nearby sites. On the other hand, distant sites with sedimentologically
different deposits were fed from different source areas. These important quantitative constraints are
used to validate and inform lahar numerical models (de’ Michieli Vitturi et al., submitted this issue)
and simulations (Sandri et al., submitted this issue) using a shallow layer approach for hazard
assessment. We cannot rule out that lahar pulses from different source areas (Somma-Vesuvius vs.
Apennines) might have overlapped and further aggraded in the open plain.

At several locations, we found erosive erosional unconformities between (Fig. 16a) between the
lower and upper flow units (Fig. 16b), as well as between primary the pyroclastic deposits and lahar
units deposits. Erosion is an important factor for the entrainment of pre-existing material and objects,
which including large-size clasts external to the remobilized pyroclastic material. Size and density
of the largest clasts embedded in the deposits can give an idea of the carrying capacity of the lahar.

Fig. 16a
Fig. 15. a) Sites with evident erosion traces at the base of the lahar units; b) Sites in which multiple depositional flow units are vertically identified. Both evidences corroborate the interpretation of the depositional mechanisms, as well as constrain the choice of the shallow layer approach for the lahar models and simulations (de’Michieli Vitturi et al., this issue; Sandri et al., this issue).

Evidence Occurrences of oversize large clasts and boulders are observed-reported in all the studied areas invaded by the lahars, with a distribution that is similar to follows the one of the lahar deposits themselves (but with less proportions), and in particularly both are found at the mouth of the valleys, and in the alluvial plain (Fig. 15a). The presence of the erosional features (Fig. 16a), and the fact that the deposits are ubiquitously mostly composed of massive and relatively thick units (Fig. 16b), suggest that high sediment transport and deposition were not exclusive processes both occurred, i.e. they both occurred even at local scale in the same area (Doronzo and Dellino, 2013; Roche, 2015).

Such occurrences of erosion and accumulation of multiple units were useful to inform the lahar modelling of de’Michieli Vitturi et al. (this issue).
We calculated local velocities of the syn- and post-eruptive lahars based on the biggest clasts that are found in the deposits at various stratigraphic heights, with boulder dimensions from several centimeters to a meter, and for flow density ≥ water density (Appendix 4A). The faster the lahar the higher the capability of its flow to entrain bigger external clasts. This occurred at locations where such clasts were freely available on the substrate, or where the lahars impacted and damaged anthropogenic structures.

![Fig. 1](image)

Fig. 1. Average lahar velocities (in m/s) estimated with a point-by-point reverse engineering approach.

Then, we used the flow velocities (Fig. 1) to calculate local dynamic pressures of the lahars (Fig. 1) as a function of the clast properties (size, density and shape). The obtained estimations are used by Sandri et al. (submitted this issue) to validate the PProbabilistic Hazard AAssessment of lahars from Vesuvius eruptions.
The data presented in Figs. 176 and 187 represent respectively minimum local values of the flow velocity and dynamic pressure, respectively, useful to assess some minimum impact of the lahars in the alluvial plain. An approximation of this point-by-point approach is that the values were calculated for the finding locations of the clasts in the deposits, meaning that the values are overestimated for those exact locations, while they should more properly be referred to the immediate surroundings upstream. In particular, we did a parametric test to quantify the sensitivity for different physical states of the multiphase flow, depending on initial fluidization and flow density, and considering two end members, from a non-fluidized case to an initially fluidized and non-expanded case (see Appendix 4A; Roche et al., 2013). From the performed analysis (see Appendix 1), we found that the most typical values are referred to the initially fluidized and slightly expanded case (that is a few % more expanded than the non-expanded case), with most of the points falling in the range of velocity...
of 2–4 m/s, and dynamic pressure of 4–8 kPa.

Lastly, in eight points we found the lahar deposits emplaced against meter-sized obstacles, from which we estimated, by comparison, local flow heights of the order of 1–1.5 m, and particle volumetric concentrations of ~30% or more, i.e. the deposit thickness is ~1/3 of the lahar thickness (cf. Capra et al., 2018). On the other hand, it is reasonable to argue that these are local values, and that flow height, particle concentration, and deposit thickness significantly varied over space due to the multiphase nature of the lahars (see de’ Michieli Vitturi et al., submitted; Sandri et al., submitted).

5. Discussion

The historical sources used as benchmark for the problem of the lahars around Somma-Vesuvius and in the Apennine valleys remark the frequent and broad impact that explosive eruptions of Vesuvius had in historical times. Some of the eruptions occurred in the last four centuries (e.g., 1631, 1822, 1906 and 1944) reached contemporaneously and repeatedly over time impacted on a number of municipalities due to the explosive character of the events, particularly during the sub-Plinian eruption of 1631. Heavy rain events caused remobilization of the primary pyroclastic deposits, triggering multiple lahars during or immediately after the eruption up to a few years (syn-eruptive lahars; Sulpizio et al., 2006); post-eruptive lahars were triggered on the longer term.

On the other hand, the Pollena eruption had an even wider impact, both in terms of primary pyroclastic deposition and secondary (lahar) impact. For this event, the historical sources are scarce or-to-absent.

The analysis of – and realization of a database with – more than 500 stratigraphic sections were done, which also includes the sedimentological features both of primary (fall, flows) and secondary (the lahars, alluvial events) deposits relative to the two sub-Plinian Vesuvius eruption case–studies from Vesuvius, Pollena and 1631. The detailed reconstruction and mapping of these primary deposits allow an updating of the pyroclasts distribution on the territory allowed to update the area affected by
pyroclastic deposit dispersal, as and it was found that both eruptions had an impact larger than previously known. In particular, the stratigraphic and sedimentological reconstruction of the deposits was done not only in open spaces the countryside but also close to urban areas, and this is important in terms of local impact of the lahars vs. broad impact in the environment. Specifically, such impact investigation was done in urban areas including archaeological findings (e.g., villages, urban structures, walls, etc.).

These findings include not only new data from the Somma-Vesuvius plain, but also more distal data from Lauro Valley and Avella-Baiano Valley (Apennines), which were subjected to heavy remobilization also of the finer primary deposits as for the presence of including the widely-dispersed fine ash deposits present in both proximal and distal areas formed in the late stage of the eruptions. Indeed, the accumulation areas that were reconstructed reveal an enlargement and extra 2047% (Pollena eruption) and 230% (1631 eruption) coverage that was not previously known and, considering the physical characteristics of the ash, it and this should be considered in any the hazard and impact evaluation in the Campanian plain and on the nearby Apennine reliefs. The full database thus allows a more precise reconstruction of the new isopachs, both for the Pollena and 1631 eruptions, which is possible given the high number of data points in the study area.

With particular reference to the lahar deposits, the syn-eruptive ones that were emplaced occurred by relatively short-term (during or immediately after the eruption) events, stand and were directly emplaced on the primary pyroclastic deposits, both for the Pollena and 1631 eruptions case studies.

Also, there are not any significant erosion surfaces nor humification traces in the sequences due to prolonged exposure of the primary deposits, testifying that the secondary emplacement was quite immediate (max a few years; Sulpizio et al., 2006) after or even during the eruption. The syn-eruptive features of these deposits are also testified by the absence of anthropic anthropogenic traces or humified surfaces at the base of or within interbedded in the deposits lahar deposits, as further evidence of a very short-term time span between the eruptions and the lahar events. Another interesting features are the presence of multiple depositional flow units in the lahar deposits, as
evidenced by granulometric changes, some clast alignments and concave erosion surfaces inside the lahar deposits. Such flow depositional units were emplaced by en-masse deposition (with reference to each single flow pulse), while the whole lahar deposits were formed by rapid progressive aggradation of the various flow units (Vallance and Scott, 1997; Doronzo, 2012; Roche, 2012; Smith et al., 2018; Martí et al., 2019; Guzman et al., 2020; see also Sulpizio et al., 2014, p. 56), which does not contradict the principle of superposition and this can be argued by the generally massive facies of each flow unit in the deposits, and by the presence of water escape structures that cross vertically the entire lahar deposits sequences. This latter evidence testifies a rapid and contemporaneous water loss through vertical escaping “pipes” during or soon after the emplacement-aggradation of the sequences. In other words, the various flow units (layers) must decouple from the transport system, and such decoupling occurs unit-by-unit and not particle-by-particle (Sulpizio et al., 2006, 2014; Roche, 2012; Doronzo and Dellino, 2013; Breard and Lube, 2017; Smith et al., 2018), through a massive accumulation rate (Duller et al., 2008; Doronzo et al., 2012; Martí et al., 2019).

The analysis of the Pollena lahar lithofacies allowed the identification of mainly two main deposit categories. The first one occurs over an area that extends for more than 10 km north of Mount Somma, and the second one occurs on an area which extends west of the Apennines. For the latter, we can recognize two significant sub-categories of deposits, corresponding to the main valleys in northwest-southeast direction, Avella-Baiano Valley and Lauro Valley. This difference between the first and the second deposit categories seems to reflect the type of primary deposits that were remobilized and (just fine ash vs. ash and lapilli). In the first area, Avella-Baiano Valley, the area north of Mount Somma, which also comprises the municipalities of Acerra and Afragola, the primary lapilli fallout deposits are absent, while On the other hand, in this part of the plain, there is almost always a very thin level-layer of phreatomagmatic ash is widely present in the p-plain, while and thick, fine-grained pyroclastic current deposits are present in the Mt. Somma.
valleys feeding the lahars that fed some of the lahars. The other basin comprises many valleys feeding the lahars. In Avella-Baiano Valley and Lauro Valley, which also comprises the municipalities in the area around Nola (Fig. 1 and Appendix 3C), where the lahar deposits are generally coarser, and consist of multiple depositional units with different lithofacies (Tab. 3). In this case, both granulometry-grain-size and componentry indicate the that lahar deposits resulted from the remobilization of the fallout deposits. Such considerations also derive from the full compilation of the geospatial database. A volume estimation of the remobilized syn-eruptive deposits, based on a QGIS calculation, is of $7.3 \times 10^6$ m$^3$ for the northern Vesuvius area and $4.2 \times 10^6$ m$^3$ for the Lauro Valley.

Referring to the 1631 eruption, previous maps have shown the distribution of the 1631 lahar deposits toward east, basically following the distribution of the primary pyroclastic fall deposits (Sulpizio et al., 2006), while in Figs. 10 and 11 we show a significantly larger distribution area particularly toward the north (Somma-Vesuvius ramps and plain) and east (mountain Apennines valleys), and less toward the southeast. In particular, this distribution is well explained by the wide distribution of the ash fallout deposit toward both north and northeast (Fig. 6), remobilized during the lahar generation along both from the Mount Somma and Apennine slopes. On the other hand, looking at the average deposit thicknesses, they reach on average half a meter to in the N-north and NE-northeast, while reaching a couple of meters in some points-locations to-in the NE-northeast (aligned with the dispersion axis of the primary fallout deposits and out of the Apennine valleys).

The sedimentological analyses carried out on a number of samples from the different studied sectors (Somma-Vesuvius, Lauro Valley, Avella-Baiano Valley) are useful for discriminating the various factors that contributed to the initiation of the lahars and emplacement of their lahar deposits. The samples from Lauro Valley and Avella-Baiano Valley are coarser (but have a significant finer tail) than the ones for Somma-Vesuvius, and this can depend on three factors: i) depositional mechanisms-genetic types of the primary pyroclastic deposits (fall vs. flow); ii) interaction between lahars and morphology (valley vs. plain); iii) major involvement-remobilization for-in Lauro Valley
and Avella-Baiano Valley of the distal fine-phreatomagmatic fine ash deposits formed in the final late eruptions stages. In other words, the primary grain sizes involved in the remobilization (finer and higher-water retention for Somma-Vesuvius), as well as the general topography (gentler but longer ramp for Somma-Vesuvius) likely acted as the main factors directly impacting the distribution of the lahar deposits, and the decay of the flow velocities and dynamic pressures in the area. Interestingly, an emplacement temperature (~120 °C) of the lahar deposits was calculated for those generated along the Somma-Vesuvius slopes, indicating a relatively hot provenance after remobilization of the pyroclastic current deposits. Instead, the remobilization from the Apennines sectors involved only cold fallout deposits. The sampled clasts might have been incorporated multiple times by the flows, and the heating/cooling processes that we interpret as indicating $T_{dep}$ in the diagrams are the last to have occurred and affected the samples. Besides, a third heating component is clearly observed for some of them. The paleomagnetic data directions of flow direction are statistically distinguishable also indicate, supporting that the lahar emplacement at Nola and Acerra was not synchronous, as a further evidence of the different timing and hence likely different detachment areas involved during the pyroclasts remobilization. However, the comparison with the paleosecular variation curves of the Earth’s magnetic field does not allow to better constrain the entity of the time span between the two lahar events. The parental lahars acted as mass flows capable of entraining outsized clasts (where available) from substrate under the action of shallow-layer flow velocity and dynamic pressure (de’Michieli Vitturi et al., this issue), then emplaced massive flow units with uplifted external clasts set into the much finer matrix (see Roche, 2015). In various some lahar units, multiple various clasts have been found, showing some alignment that depends on the mechanisms of entrainment and uplift (with respect to substrate) within the flow.

In terms of local impact in the Pollena case study (the largest one), while most of the calculated points (44) fall in the range of lahar velocity of 2-4 m/s and dynamic pressure of 4-8 kPa, a few peak values of velocity of 13-15 m/s and dynamic pressure of 90-115 kPa are also calculated, which are directly related to meter-sized clasts entrained into the lahars on the steep slopes, then deposited downstream.
of alluvial fans. Such values of the velocity and dynamic pressure are well comparable with those calculated for lahars that occurred recently at Ruapehu in 2007 (Lube et al., 2012) and Merapi in 2011 (Jenkins et al., 2015), and in historical times at El Misti (Thouret et al., 2022). In particular, the estimated velocities and pressure agree with those of Lube et al. (2012) and Jenkins et al. (2015). Moreover, multiplying velocity and density gives a power per unit surface, so those most representative values correspond to a flow power per unit surface of $8 \times 10^3 - 3.2 \times 10^4$ W/m$^2$, with peak values of $1.17 \times 10^6 - 1.72 \times 10^6$ W/m$^2$, in agreement with typical values reported for floods and megafloods (Russell and Knudsen, 1999; Whipple et al., 2000; Carling, 2013).

6. Conclusions

A number of points can be highlighted after the integration of the historical, stratigraphic, sedimentological, laboratory, and impact parameter analyses carried out in the Vesuvius area allow us updating on the lahar invasion related to the Pollena and 1631 eruptions. In general, the physical characteristics of the analyzed deposits indicate that syn-eruptive lahars are related to the rapid remobilization of large volumes of pyroclastic material, which is mainly fine-grained and almost exclusively derived from the accumulation of products related to a single eruption. The analysis also shows that tardive (post-eruptive) mass flows are common, and involve multiple and variably altered deposits, and that their energy and frequency are progressively lower over time, after the last eruption has occurred. In particular, a higher impact both from primary and secondary phenomena is something that should be accounted in the Vesuvius area and that:

i) The new isopach maps of the Pollena and 1631 eruptions allow us to infer a larger impact than previously known for these two sub-Plinian events of the Vesuvius. Thus, it is worth reconsidering the territorial impact that sub-Plinian eruptions can have in the Vesuvius (but not only) area. In particular, the ash deposits can have a high impact in relation to their high density and low permeability.
ii) The primary impact from fallout and pyroclastic current processes in the Vesuvius area was - and may be in the future – followed by the secondary impact from lahars generated during or immediately after the eruption events. Both impacts can have a wide distribution, because they are directly controlled by the primary deposits distributions, both around Somma-Vesuvius and in the Apennines valleys.

iii) The runouts of such lahars were significant both for the Pollena and 1631 eruptions, by reaching distances of 10 to 15 km from the sources, and their deposits geometry is tabular-like with average thicknesses of 0.5 to 1 m.

iv) The paleotemperature data highlight a relatively hot dynamics (~120 °C) for those lahar flow pulses that traveled along-down the Somma-Vesuvius slopes because of pyroclastic current deposit remobilization. This did not occur from the Apennines sectors, where pyroclastic currents did not get to, and only cold fallout deposits were remobilized.

v) A reverse engineering approach allowed to calculate the local lahar velocities (2-4 m/s, with peaks of 13-15 m/s), dynamic pressures (4-8 kPa, with peaks of 90-115 kPa), and solid volumetric concentration (~30%, implying a 1:3 ratio between deposit and flow thickness), on the basis of the external clast properties entrained into the flows then emplaced into the ash matrix, and on the presence of the lahar deposits in proximity of obstacles and archaeological findings.

As a general conclusion, we have demonstrated that the areal impact of both primary deposits and lahars, in case of sub-Plinian events at Somma-Vesuvius, involves a territory wider than previously known and for several years, with possible decreasing damages over time.

Appendix A. Calculation of lahar velocities and dynamic pressures

A theoretical scheme is presented to quantify local velocities and dynamic pressures of the lahars, by inverting the field features at selected locations. The final goal is to map the values of velocity and
dynamic pressure to assessing the hazard from lahars in the study area. Flow dynamic pressure, $P_{dyn}$, results from a combination of flow density, $\rho_f$, and flow velocity, $v$, and is defined as follows

$$P_{dyn} = 0.5\rho_f v^2$$  \hspace{1cm} (A1)

In the study area, the original flow was a multiphase flow of water + pyroclastic sediment, which during remobilization evolved into a flow of water + pyroclastic sediment + external clasts. Generically, flow density results from a combination of particle density, $\rho_p$, and water density, $\rho_w$, through particle volume concentration, $C$, and is defined as follows

$$\rho_f = \rho_p C + \rho_w (1-C)$$  \hspace{1cm} (A2)

In order to define flow velocity, we take into account stratigraphic and sedimentological characteristics of the lahar deposits: i) they are ubiquitously massive, and result from remobilization of the primary pyroclastic deposits then emplacement from mass flows; ii) they contain big external clasts entrained (by dynamic pressure) and uplifted (also by pore pressure) from substrate into the flows. With these field characteristics, flow velocity can be expressed as a combination of entrained clast properties and flow density, and is defined as follows (modified after Roche, 2015)

$$v = \sqrt{\frac{X\Psi (\rho_c - \rho_w)g}{\gamma \rho_f}}$$  \hspace{1cm} (A3)

where $X$ is clast small axis, $\Psi$ is clast shape factor, $\rho_c$ is clast density, $g$ is gravity acceleration and $\gamma$ is an empirical constant. Eq. 3 allows quantifying the incipient motion of the big clasts, and gives minimum values of flow velocity required to entrain and uplift the clasts from substrate, possibly more than once, before being emplaced into the lahar deposits by flow velocity drop. Such equation has been originally derived in laboratory experiments for a multiphase flow of air + sediment, and is highly performing at $\rho_f \sim 1000$ kg/m$^3$ (hindered settling) for dense pyroclastic currents controlled by topography then opened to alluvial plain (Martí et al., 2019), which is a case similar to the lahars in the study area. Substituting Eq. 3 into Eq. 1 and simplifying gives
For given clast properties, flow dynamic pressure has a unique value, while flow velocity is a function of flow density. Indeed, the present scheme is a spot model that basically depends on, and is limited to, the finding of big clasts and boulders within the lahar deposits. An approximation is that velocity and dynamic pressure are calculated for the locations where the clasts are found in the deposits, meaning that the calculated values are overestimated for those exact locations, while they are more properly referred to the immediate surroundings upstream.

At the selected locations in the study area, we collected the dimensions of the biggest clasts found in the lahar deposits, and we characterized petrographically–lithologically the clasts in the field, to calculate flow dynamic pressures using Eq. 4. We used the following values for the various parameters in the calculations: $\Psi$ (ellipsoid) = 0.66; $\rho_c$ (limestone) = 2500 kg/m$^3$; $\rho_c$ (ceramic) = 2000 kg/m$^3$; $\rho_c$ (brick) = 2000 kg/m$^3$; $\rho_c$ (tephra) = 1500 kg/m$^3$; $\rho_c$ (lava) = 2500 kg/m$^3$; $\rho_c$ (iron) = 8000 kg/m$^3$; $\rho_w$ = 1000 kg/m$^3$; $g$ = 9.81 m/s$^2$; $\gamma$ = 0.031 – 0.071. Also, we calculated flow velocities using Eq. 3, in the following range of flow density: $\rho_w \leq \rho_f \leq \rho_p$, where $\rho_w$ = 1000 kg/m$^3$ and $\rho_p$ = 2000 kg/m$^3$. In this way, flow density spans from two extreme cases: i) $\rho_f = \rho_w$, negligible pyroclastic sediment and external clasts, so water flow only; ii) $\rho_f = \rho_p$, negligible water and dominant pyroclastic sediment, so ash flow only. For the empirical constant in Eq. 3, we used three different values to test the sensitivity with respect to different physical states of the multiphase flow: $\gamma$ (non-fluidized) = 0.031; $\gamma$ (initially fluidized and slightly expanded) = 0.057; $\gamma$ (initially fluidized and non-expanded) = 0.071 (see Roche et al., 2013; Fig. A1).

Regarding flow velocity, after calculation we can rewrite Eq. 3 in a simpler form (to more directly relate velocity to density) as follows

$$v = \frac{a}{\sqrt{\rho_f}}$$

where $a > 0$ depends on clast properties, and its square has dimension of pressure. On the other hand,
it is not straightforward to constrain local flow velocities with unique values of flow densities, mostly because small variations of velocity correspond to large variations of density, and this is particularly valid for volcaniclastic mass flows (Carling, 2013; Jenkins et al., 2015; Roche, 2015; Martí et al., 2019; Guzman et al., 2020; Thouret et al., 2022).
At some locations in the study area, we found lahar deposits against meter-scale manufacturing obstacles (Di Vito et al., 2009). The peculiarity is that the deposits in proximity of the obstacles are thicker than the correlated ones in the free field, but never reach the top of the obstacles themselves. This means that the lahars were not much expanded, so unable to overcome the obstacles as stratified flows would have done (cf. Spence et al., 2004; Gurioli et al., 2005; Doronzo, 2013; Breard et al., 2015). With this field evidence, we can assume that local flow height, $H$, was similar to deposit thickness against the obstacle, $h_o$, as follows

$$H \approx h_o \quad \text{(A6)}$$

In order to estimate flow density using Eq. 2, we focus on particle volumetric concentration. For well-sorted deposits, such concentration can be defined with an average value over flow height as follows
where \( h_f \) is deposit thickness in the free field. Substituting Eq. 6 into Eq. 7 gives

\[
C = \frac{h_f}{H}
\]  

(A7)

In particular, \( h_f \) refers to those lahar deposits relatively close to the obstacles, but which were not affected by them during emplacement, i.e. close but not so much. We assessed that correlation taking into account the stratigraphic and sedimentological characteristics of the lahar deposits, and the fact that Eq. 7 performs better with layers emplaced after remobilization of primary pyroclastic fallout or dominantly ash flow deposits.

Lastly, we macroscopically assessed erosion in the field, by characterizing the unconformities present both on the primary pyroclastic and lahar deposits. In particular, the syn-eruptive lahar deposits consist of more than one flow unit, so it is important to understand how the different flow pulses interacted with each other during emplacement. The main unconformities that are found in the field are referred to the partial absence of a flow unit, and the loss of lateral continuity despite some flat geometry of the deposits. On the other hand, at some locations we were not able to assess if erosion occurred or not due to multiple open issues: i) eventual-possible absence of the primary pyroclastic deposits; ii) eventual-possible exclusive presence of the post-eruptive lahar deposits; iii) impossibility to get to some outcropping deposit base and eventual-possible unconformities.

**Appendix B. Paleo-temperature and paleo-direction determinations**

The magnetic fabric of a deposit was investigated by measurements of the magnetic susceptibility and its anisotropy (AMS). AMS was measured with a Kappabridge KLY-3 (AGICO), and data were
elaborated by the software Anisoft5 (AGICO). AMS depends on the type, concentration, and distribution of all the minerals within the specimen. It is geometrically described by a triaxial ellipsoid, whose axes coincide with the maximum (k1), intermediate (k2) and minimum (k3) susceptibility directions. The magnetic fabric of a specimen is then described by the direction of the k1 axis, the magnetic lineation (L) and that of the k3 axis, which is parallel to the pole of the magnetic foliation plane (F). Besides, the modulus of the susceptibility axes provides some magnetic parameters useful to express the intensity of the anisotropy (Pj) and the oblate/prolate fabric occurrence (T) (Jelinek, 1981). Generally, sedimentary vs. pyroclastic deposits fabric, here considered as the proxy of the lahar fabric, is oblate with a horizontal to gently imbricated (less than 20°) magnetic foliation. The magnetic lineation is normally clustered along the foliation plunge. In this case, both the F imbrication and the L direction can provide the local flow direction. Other times, L is orthogonal to the F plunge or F is statistically horizontal, and it is not possible to infer the flow direction.

For Tdep estimation, pottery sherds were subjected to progressive thermal demagnetization (PTD), with heating steps of 40 °C, up to the Curie Temperature (Tc), using the Schonstedt furnace and the spinner magnetometer JR6 (AGICO). The rationale of the method has been described in detail in several papers (McClelland and Druitt, 1989; Bardot, 2000, Porreca, 2007; Paterson et al., 2010; Lesti et al., 2011), many of them dedicated to PDCs of the Vesuvian area (Cioni et al., 2004; Di Vito et al., 2009; Giordano et al., 2018; Zanella et al., 2007; 2018; 2015). Typically, measurements are made on accidental lava lithics that were entrained during pyroclastic or lahar flows. In this case, we had the opportunity to estimate the Tdep by measuring ancient pottery artifacts. Briefly, pottery is characterized by a thermal remanent magnetization (TRM) acquired during its manufacture and its subsequent history of daily use. Whenever it is heated, part of its TRM, the one associated with blocking temperatures (Tb) below the heating one (Th), is overwritten. Without alteration phenomena, the heating/cooling is a reversible process, except for the magnetic directions. The original TRM shows a random paleomagnetic direction, due to the transport during emplacement. Subsequent
TRMs show directions parallel to the Earth’s magnetic field during their cooling. This is clearly illustrated in the Zijderveld diagrams. The composition of the different magnetization components reveals thermal intervals characteristic of the heating history of the potsherd. Of course, this explanation is simplified, but the method is well-established and has been shown to work well with heated artifacts, such in the case of tiles and pottery embedded in the PDC deposits at Pompeii (Gurioli et al., 2005; Zanella et al., 2007), Afragola (Di Vito et al., 2009) and Santorini (Tema et al., 2015). In case of lahar, we expect low T_{dep} or cold deposits. This can be a major concern because of the difficulties to distinguish between the TRM secondary components, and the chemical (CRM) and viscous (VRM) remanent magnetization. The CRM may develop due to mineralogical changes during reheating (McClelland, 1996). Instead, VRM is typical of ferromagnetic grains with low T_{b} and often occurs in most rocks. Following Bardot and McClelland (2000) relationship for time intervals in the 10^2–10^6 year range, T_{b} = 75+15 log (acquisition time in years), and using the Pollena eruption date (472 AD CE), we obtain a lower limit of the T_{b} around 123 °C. This means that this temperature helps us in discriminating between “hot” (T_{b} > 120 °C) or “cold” lahar (T_{b} < 120 °C).

Finally, routine magnetic measurements on the lahar matrix were done on the lahar matrix to determine the Characteristic Remanent Magnetization (ChRM) by Thermal and Alternating Field demagnetizations. The direction of the Earth’s Magnetic Field during the Pollena eruption is well-known (Zanella et al., 2008). If the sampled lahars were emplaced shortly after the eruption, both the secondary TRMs and the matrix of the lahars should show a remanent magnetization direction similar to the Pollena ones. ChRMs can also test if the two lahars (Acerra and Nola) are coeval.

Appendix C. Description of the studied areas

Area 1 – Nola

In the area surrounding Nola, it is possible to recognize the complete fallout sequence of the Pollena eruption (a in Fig. C1 and C2), which usually covers ploughed soils (p in Fig C1) and late Roman
archaeological remains. The sequence is composed by an alternation of coarse pumice and thin ash fallout layers. Its top is always made of a cohesive fine ash bed related to the phreatomagmatic phase of the eruption (b in Fig. C1 and C2), with a thickness ranging from 1 to 14 cm due to erosion. They are almost always overlain by lahar deposits composed of several flow units (c in Fig. C1 and C2) with a large thickness variability due to channeling and presence of barriers and edifices buildings. They sometimes include blocks, tiles, and other archaeological remains.

In Fig. C1, above the primary deposit, there is an example of a well-exposed sequence composed by at least five units (c in Fig. C1). The first one is a massive and matrix-supported deposit composed by fine and not vesiculated ash (lithofacies Gms), with fragments of greenish to blackish scoriae and minor fragments of pumices, lavas and limestones. The fragments are cm-sized and are both angular and rounded. The second flow unit is similar to the one below, but is darker and contains less coarse fragments. Its matrix is composed by an alternation of fine to medium ash layers. It follows a plane-parallel sequence of well-sorted fine sand and silt layers characterized by the lithofacies fM.

A massive deposit follows upward, it is progressively humified and contains abundant reworked and rounded pumice clasts from the Avellino eruption. The top humified surface is almost always eroded by anthropogenic activity and is generally ploughed (p1 in Fig. C2), whose surface is overlain by the primary deposits of the 1631 eruption of 1631 (d in Fig. C2). It is few cm thick and is composed by a basal layer of dark coarse ash (small pumice fragments), overlain by a very cohesive and massive ash bed, containing abundant accretionary lapilli. The following deposit thickens in the plowing furrows and depressions, and is composed by massive fine-ash beds, vesiculated and cohesive, and is interpreted as a lahar deposit (lithofacies mM) (e in Fig. C2). This deposit (e in Fig. C3) overlies the foundations of Palazzo Orsini (blocks in Fig. C3), now seat of the Court of Nola and built in the second half of the XV century (Fig. C3). The top is always eroded by the modern anthropogenic activity, and locally by deposits of recent eruptions of Vesuvius (e.g., 1822, 1906).
Fig. C1. Nola, Pollena fallout deposits overlain by at least five lahar units. In particular: p = paleosol; a = alternation of coarse and fine fallout sequence of the Pollena eruption; b = final ash fallout of the eruption; c = sequence of syn-eruptive lahars; c1 = post-eruptive lahar containing white pumice fragments of the Pomici di Avellino eruption. For the description of lithofacies see Tab. 2.
Fig. C2. Pollena lahar deposits overlain by a cultivated paleosol, and by the 1631 ash fallout and lahars. In particular: a = alternation of coarse and fine fallout sequence of the Pollena eruption; b = final ash fallout of the eruption, partially eroded; c = sequence of three lahar units; p1 = ploughed paleosol; d = 1631 ash fallout deposit mantling the undulated paleosol; e = lahar deposit composed of a massive ash layer. For the description of lithofacies see Tab. 2.
In Nola and in the nearby Cimitile, the effects on the territory of the lahar emplacement related to the Pollena eruption are testified by numerous archaeological remains. The Nola and Cimitile areas are covered by thick sequences of fallout and lahar deposits. In fact, the previous ground level was at least 2-3 m below the present one. This effect is well visible in the Amphitheater Laterizio, which...
was completely filled by the primary and secondary deposits, and the same in Cimitile, where in the archaeological site of the Early Christian basilicas the present ground level is about two meters higher than the one before the eruption. It is worth noting that in Cimitile the flows were able to carry limestone blocks of 50 cm in diameter, likely along the main flow direction of the lahars (Fig. C4).
Fig. C4. Cimitile. Sequence of three m-thick syn-eruptive lahar units with the evidence of transport of calcareous block (up to 50 cm). The largest are in the lower unit. The base of the lahar sequence and the underlying fallout deposit of the Pollena eruption are not visible in the photo. For the description of lithofacies see Tab. 2.

Area 2 – Acerra-Afragola

The Acerra and Afragola territories are located north and north-west of Vesuvius, and are almost flat areas crossed by the Clanis river. Both the coarse fallout deposits of the Pollena and 1631 eruptions are absent in this area. Here, only a thin, centimetric ash bed overlies the Late Roman paleosol. This fine ash bed, which we correlate with the final phreatomagmatic phases of the Pollena eruption, is homogeneous, cohesive and mantles the ground without any significant lateral variation. The overlying deposit is characterized by high thickness variations, it is generally massive and contains vesicles from circular to flattened and coated by fine ash. It has a matrix-supported texture and is composed of fine to very fine, very cohesive ash, and contains scattered and more or less abundant pumice and lithic fragments (lithofacies mM) and remains of vegetation (Barone et al., 2023). From
one to three depositional units have been recognized, marked by unconformities, and differences in
grain-size or color. The uppermost unit always contains white pumice fragments of the Avellino
eruption. Very common are drying out structures and water escape structures, which are vertical
structures (Fig. C5), looking like fractures a few cm large, filled by finer material transported by the
escaping water, formed soon after the emplacement of the sequence of the syn-eruptive lahars (Fig.
C5). The maximum thickness recorded in this area is about 90 cm.

Fig. C5. Lahar deposit (unit 2) in Acerra overlaying a cultivated paleosol (unit 3). The index finger indicates a water
escape structure crossing the sequence of lahars. For the description of lithofacies see Tab. 2.

The top is almost always horizontal due to the erosion related to the modern anthropogenic activity,
and only in a few exposures it is capped by a paleosol, with traces of human presence of the Medieval
times and of the deposits of the 1631 eruption as well. The base of this latter deposit is a cm-thick
fine-ash bed with an internal plane-parallel layering emplaced by fallout. It underlies a massive deposit with high thickness variations (max 20 cm) at the outcrop scale. It is composed of fine ash, cohesive and vesiculated and contains scattered small pumice fragments (lithofacies mM). The pumice fragments are vesicular, dark gray to blackish, highly porphyritic with leucite, pyroxene and feldspar crystals. The stratigraphic position and lithology confirm their attribution to the 1631 primary and secondary (lahars) deposits.

**Area 3 – Pomigliano-Marigliano**

This area is located along the northern outer part of the Vesuvius apron (Santacroce et al., 2003). The studied sequences start from the paleosoil developed on top of the ash deposits of the AD 79 eruption. The paleosoil is mature and contains pottery fragments till the II century AD. Its top is undulated with traces of ploughing spaced about 50 cm (a in Fig. C6). Representative sequences of the area include a basal ash layer with a thickness ranging from 1 to 4 cm (b in Fig. C7), thickening in the depressions, cohesive and locally vesiculated. It is here interpreted as co-ignimbritic ash emplaced by fallout during the phreatomagmatic final phases of the Pollena eruption. Upwardly, the sequence includes several lahar units from massive to slightly stratified, composed of fine and very cohesive ash, and containing scattered greenish pumice fragments (lithofacies mM) (b1 in Fig. C7). Locally this deposit, also in the case of multiple units, is cut by vertical drying cracks. The sequence is overlain by a 25-30 cm thick mature paleosoil, containing cultivation traces and majolica fragments (c in Figs. C6 and C7).

The top of this paleosoil is undulated and covered by the primary deposit of the 1631 eruption (d in Fig. C7). This latter is represented by a discontinuous medium-to-fine ash layer, slightly laminated for contrasting grain-size, up to 5 cm thick, with a gray to violet color, and containing dark pumice fragments and loose crystals of leucite, pyroxene and biotite (Fig. C7). Its thickness variation is due both to slight internal variations (thickening in correspondence of depressions) and erosion by the following lahars. These latter are composed of one to three flow units (d1 in Fig. C7), with a
cumulative total thickness varying from 10 to 45 cm. They are composed of massive fine and very cohesive ash, and contain rare scattered dark pumice fragments similar to those of the 1631 eruption (lithofacies mM). These sequences are overlain by recent, cultivated soil. Locally, thin ash beds of the recent Vesuvius activity (like 1822, 1906) overlie the 1631 deposits.
Fig. C6. Pomigliano locality. Sequence of deposits including bottom to top: Bronze Age paleosol, Pomici di Avellino (unit EU 5 of Di Vito et al., 2009), paleosol developed on top of Pomici di Avellino and buried by the Pollena eruption deposits. In the central part, fine ash deposits of the 79 CE eruption are visible. The top of the paleosol is undulated and ploughed. In particular: 

- \(a\) = paleosol of Roman Age; 
- \(b\) = primary and secondary deposits of the Pollena eruption; 
- \(c\) = paleosol between Pollena and 1631 deposits; 
- \(d\) = 1631 primary and secondary deposits. Further details in Fig. C7.
Fig. C7. Particular of the Fig. C6: a = paleosol containing potteries of the II Cent. AD; b = ash deposit of the Pollena eruption; b1 = syn-eruptive lahars of the Pollena eruption; c = paleosol between Pollena and 1631; d = primary deposits of the 1631 eruption, overlain by syn-eruptive lahars (d1). For the description of lithofacies see Tab. 2.

Area 4 – Avella-Baiano Valley

We have analyzed several sequences along the Avella-Baiano Valley, both exposed and excavated for the present work. Here the sequences of primary deposits are often affected by deep erosion, in fact, in some places the Pollena primary deposits are completely lacking and only the syn-eruptive lahar deposits are present on top of the late Roman paleosol. Where preserved, the paleosol has often an undulated surface due to cultivation (ploughing and hoeing). The Pollena eruption sequence consists of an alternation of coarse pumice and fine ash layers emplaced by fallout (a in Fig. C8). It is up to 50 cm thick and ends with a cohesive yellowish ash layer (b in Fig. C8), overlain by the lahar deposits, generally composed by of 2-3 flow units (c in Fig. C8). The total thickness of the lahars is largely variable with maxima at the base of the slopes where it can reach 2-3 m. In some excavations we did not reach the base of the deposit, deeper than 3.5 m. In Fig. C8, it is possible to observe a complete sequence of the Pollena deposits of Pollena overlying a late Roman paleosol. The sequence includes the fallout layers and thick lahar deposits. These latter are always massive, matrix-supported, and contain abundant scattered pumice and lithic fragments (lithofacies Gms). In some cases, the lower part contains several limestone fragments up to 10 cm in diameter. The described deposit has been also found in the Roman Amphitheatre of Avella, where it has a variable thickness (order of decimetric). Here, it has been almost all excavated and only remnants are presently exposed.

Generally, the upper part of the sequences is composed by of an alternation of plane-parallel to cross-layered sands and gravels, with abundant rounded limestone fragments, emplaced by several alluvial episodes (post-eruptive) (lithofacies Sh-Ss). In these post-eruptive deposits, it is not uncommon to find terracotta fragments from the Imperial Roman age.
The Pollena primary and secondary sequences are overlain by a mature paleosoil with frequent evidence of cultivation (ploughing, p in Fig. C9) and locally by the 1631 eruption deposits. The primary deposit related to the 1631 eruption is not always present. It is up to 2 cm (a in Fig. C9) thick ash layer, gray-violet in color deposited by fallout deposit and overlaying a ploughed paleosoil (p in Fig. C9). It is overlain by lahar deposits (b in Fig. C9) composed by of several units and characterized by contrasting grain-sizes. The deposits are composed of medium ash, are massive and matrix-supported, and contain abundant scattered mm- to cm-sized pumice fragments (all with the same lithology of the primary deposits) and sometimes vegetal remain traces (lithofacies Gms).
Fig. C9. Avella-Baiano Valley (Avella valley): particular of the 1631 primary (a) and secondary deposits (b, syn-eruptive lahars) in a trench at Cicciano locality. For the description of lithofacies see Tab. 2.

Area 5 – Lauro Valley (Vallo di Lauro)

Lauro Valley (Vallo di Lauro) has characteristics similar to the Avella-Baiano Valley (Avella valley), but the primary deposits of Pollena and 1631 eruptions are thicker (Figs. 5 and 6) and coarser. In this valley, also the sequences are locally deeply eroded. In fact, the deposits of the Pollena eruption (normally 50-70 cm thick) (Fig. C10) are sometimes missing. They overlie a mature paleosol with abundant traces of cultivation. Overall, the characteristics of the deposits are very similar to the ones
of the Nola area. The overlying lahar deposits are always massive, matrix-supported, and composed of fine and very cohesive ash with abundant scattered pumices and lithic fragments (similar in lithology to those of the primary deposits) (lithofacies Gms). These deposits have a high variable thickness, with a measured maximum up to 2 m, but sometimes reduced by erosion. In some trenches the base of the sequences was deeper than the investigated depth (>3.5 m).
In particular: a = Sequence of the Pollena fallout deposits (a) overlain by syn-eruptive lahars (b). p = At the base the late Roman paleosoil at the base (p). For the description of lithofacies see Tab. 2.

It is possible to evaluate the effects of the lahars on building in the Roman Villa di Lauro, at Taurano, where a 70 cm thick fallout is overlain, without paleosoil, by syn-eruptive lahars which engulfed and transported pieces of walls, bricks and potteries. The lahar deposits are matrix supported and composed by of fine to coarse ash and contain abundant pumice lapilli (all similar to the Pollena fallout deposits). They are massive, cohesive and have a thickness up to about 1 m, thickening in depressions and near barriers (Fig. C11).

The sequence related to the eruption of 1631 is not always present, but it is possible to find its primary deposit, composed by of a basal layer of stratified fine and medium thin ash beds, and minor dark
pumice and lithic fragments overlain by a thin, very fine and cohesive accretionary lapilli-rich ash bed. The maximum measured thickness is 30 cm. The overlying lahar deposits are massive and matrix-supported, composed of fine to coarse ash and contain abundant pumice fragments of the primary deposit.

Fig. C11. Taurano (Villa Lauro), baulk showing a thick sequence of the Pollena syn-eruptive lahar units filling the Roman Villa. Some units engulf and transport pieces of walls and large blocks. The fallout sequence is not exposed in the Villa, likely due to the presence of a roof. The deposit below the damaged walls is composed of multiple lahar units represented by the Gms lithofacies (see Tab. 2).
