7 **Abstract.** Continental collision is a crucial process in plate tectonics. However, in terms of the evolution and the controlling
8 parameters of its lateral heterogeneity, our understanding of the tectonic complexities at such a convergent plate boundary
9 remains largely unclear. In this study, we conducted a series of two-dimensional numerical experiments to investigate how
10 continental lithospheric thermal structure influences the development of lateral heterogeneity along the continental collision
11 zone. Two end members were achieved: 1) Continuous subduction mode, which prevails when the model has a cold
12 procontinental moho temperature (≤ 450 °C). In this case, a narrow collision orogen develops, and the subducting angle
13 steepens with the increasing retrocontinental moho temperature. 2) Continental subduction with a slab break-off, which
14 generates a relative wide collision orogen, and dominates when the model has a relatively hot procontinental moho
15 temperature (≥ 500 °C), especially when the moho temperature ≥ 550 °C. Radioactive heat production is the second-order
16 controlling parameter in varying the continental collision mode, while it prefers to enhance strain localization in the upper
17 part of the continental lithosphere and promote the growth of shear zones there. By comparing the model results with
18 geological observations, we suggest that the discrepant evolutionary paths from the continuous subduction underlying the
19 Hindu Kush to the continental subduction after slab break-off beneath eastern Tibet may originate from the inherited lateral
20 inhomogeneity of Indian lithospheric thermal structure. Besides, the high content of crustal radioactive elements may be one
21 of the most important factors that controls the formation of large thrust fault zones in the Himalayas.

22 **1 Introduction**

23 The collision between the Indian and Asian continents following the closure of the Neo-Tethys Ocean is regarded as
24 one of the key geodynamical processes of plate tectonics (Toussaint et al., 2004), which creates the world's largest orogen
25 (the Alpine-Himalaya orogen) and highest plateau (the Tibetan Plateau). It would be really hard to maintain a homogeneous
26 plate morphology and the crustal-mantle deformation features during such a large-scale collision stretching thousands of
27 kilometers. Many of the previous observations have already provided insights into the significant lateral heterogeneity of
28 Himalayan-Tibetan orogen (Zhou and Murphy, 2005; Li et al., 2008; Chen et al., 2015). Specifically, the horizontal
29 underthrusting distance of the Indian lithosphere decreases and the subducting angle increases laterally from west to east.

30 Despite various mechanisms have been invoked, including geometry of the subducting plate (Nettesheim et al., 2018;
31 Koptev et al., 2019), inhomogeneous inherit lithospheric structure, variations in rock composition, characters of terrane
32 assembly, and the complex tectonic settings (Beaumont et al., 2004; Chen et al., 2016, 2019; Vogt et al., 2018; Liu and Yang,
33 2022), the development of the collision zone's lateral heterogeneity remains ambiguous and requires further investigations.

34 Many of the laboratory experiments (Willingshofer and Sokoutis, 2009; Luth et al., 2010) and numerical modeling
35 (Beaumont et al., 1994; Pysklywec, 2001; Toussaint et al., 2004; Huangfu et al., 2017; Liao and Gerya, 2017; Vogt et al.,
36 2018; Liu et al., 2022b) have suggested that lithospheric thermal structure is one of the important controlling parameters
37 contributing to the regulation the evolution of continental collision (Pysklywec, 2001; Faccenda et al., 2008; Ueda et al.,
38 2012; Tang et al., 2020; Liu et al., 2022a). Pysklywec (2001) once used a series of thermomechanical models that focused on
39 the evolutionary modes of the continental lithospheric mantle during collision. The experiments suggested that an increase in
40 lithospheric geotherm resulted in a transition of the lithospheric mantle from an asymmetric, subduction-like mode to
41 ablative subduction. Similarly, on the basis of two-dimensional mechanical models, Toussaint et al. (2004) investigated the
42 potential scenarios for the evolution of continental collision. They concluded that models with a relatively low (< 550 °C)
43 moho temperature and a fast convergent rate (> 5 cm/yr) are more likely to maintain stable subduction. On the contrary,
44 among warmer and slower convergent models, lithospheric folding, pure-shear thickening, and Rayleigh-Taylor (RT)
45 instabilities prevailed. Ghazian and Buiter (2013) used 2D numerical models to discuss the sensitivity of various collision
46 modes to velocity, crust-mantle temperature structure, lithospheric rheology, and the density difference between the
47 lithospheric mantle and asthenosphere. They recognized that velocity, lithospheric rheology, and temperature have important
48 controls. More precisely, stable continental subduction evolves over a large range of values for convergent velocity and
49 lithospheric temperature. Fast and cold models tend to fold, while slow and warm ones can generate RT-type dripping.
50 Heron and Pysklywec (2016) subsequently presented dynamic thermomechanical experiments to explore the role of
51 lithospheric inherited weakness in the orogenic process. According to their model results, lithospheric temperature exerts a
52 strong control on lithospheric strength; it may influence the brittle-ductile transition depth to help determine which layer
53 (upper crust, lower crust, or lithospheric mantle) dominantly controls the lithospheric deformation style in a collision system.
54 Recently, Huangfu et al. (2019) employed systematic numerical simulations to study the dynamics of the lithospheric-scale
55 subduction and crustal-scale underthrusting of the continental collision zone. They found that models with low convergence
56 velocity and a cold upper plate are inclined to lithospheric-scale subduction, whereas models with high velocity and a hot
57 overriding plate contribute to crustal-scale underthrusting. Though numerous numerical simulations are employed to qualify
58 the effects of lithospheric thermal structure, it is noteworthy, however, that earlier studies consistently mainly focused on the
59 influences of the overriding lithospheric thermal structure. A fairly large number of them neglected oceanic subduction prior
60 to the continental collision for simplicity. Thus, our understanding of tectonic complexities that may emerge during
61 progressive crust-mantle deformation at the convergent plate boundary remains largely unclear.

62 Here we present a series of high-resolution numerical experiments to gain new insights on how continental
63 lithospheric thermal structure influences the evolutionary path of the continental collision system. Temperature

64 heterogeneities are incorporated by altering the continental moho temperature (T_{moho}) and crustal radioactive heat production
65 (H_r), respectively. In the end, the results of our models are used to draw comparisons with some first-order characters of the
66 Indian-Asian collision zone.

67 2 Materials and Methods

68 2.1 Governing equation

69 We use the parallel code **Advanced Solver for Problems in Earth's ConvecTion** (ASPECT) (Kronbichler et al., 2012),
70 an extensible code of the C++ program library deal.ii (**Differential Equations Analysis Library**, <https://www.dealii.org/>),
71 targeted at the computational solution of partial differential equations using adaptive finite elements (Arndt et al., 2021), to
72 solve three conservation equations. The methodology is similar to our recent work (Liu and Yang, 2022; Liu et al., 2022a).
73 The models are calculated by solving the following equations of conservation of mass, momentum, and internal energy for
74 an incompressible medium and adopting the extended Boussinesq approximation (van Zelst, 2022).

$$75 \quad -\nabla \cdot 2\eta \dot{\boldsymbol{\varepsilon}}(\mathbf{u}) + \nabla p = \rho \mathbf{g} \quad \text{in } \Omega, \quad (1)$$

$$76 \quad \nabla \cdot \mathbf{u} = 0 \quad \text{in } \Omega, \quad (2)$$

$$77 \quad \rho_0 C_p \left(\frac{\partial T}{\partial t} + \mathbf{u} \cdot \nabla T \right) - \nabla \cdot k \nabla T = \rho_0 H \quad (3)$$

$$78 \quad + 2\eta \dot{\boldsymbol{\varepsilon}}(\mathbf{u}) : \dot{\boldsymbol{\varepsilon}}(\mathbf{u})$$

$$79 \quad + \alpha T (\mathbf{u} \cdot \nabla P) \quad \text{in } \Omega$$

$$80 \quad \frac{\partial c_i}{\partial t} + \mathbf{u} \cdot \nabla c_i = 0 \quad (4)$$

81 On the right hand-side of Eq. (3), the three terms represent the internal heat production that includes radioactive decay,
82 frictional heating, and adiabatic compression of material. η is the viscosity, $\dot{\boldsymbol{\varepsilon}}(\mathbf{u}) = \frac{1}{2}(\nabla \mathbf{u} + \nabla \mathbf{u}^T)$ is the deviator of the
83 strain rate tensor, \mathbf{u} is the velocity, p is the pressure, \mathbf{g} is the gravitational acceleration, Ω is the interesting domain, C_p is the
84 heat capacity, k is the heat conductivity, H is the intrinsic specific heat production, α is the thermal expansion coefficient, ρ_0
85 is the adiabatic reference density. c_i named compositional fields here (e.g., upper crust, lower crust, Kronbichler et al., 2012).
86 As the medium was considered incompressible, we assumed that the density (ρ) in Eq. (1) satisfied the equation:

$$87 \quad \rho = \rho_0 (1 - \alpha (T - T_0)) \quad (5)$$

88 where ρ_0 is the reference density at reference temperature T_0 (293 K).

89 2.2 Rheology

90 Our models are based on the common assumption that solid earth materials are treated as highly viscous fluids. Thus,
91 we apply a viscoplastic rheology (Glerum et al., 2018). The viscous regime uses a composite of diffusion and dislocation
92 creep that can be conveniently formulated as follows: (Karato and Wu, 1993; Karato, 2008).

$$93 \quad \eta_{\text{diff/disl}} = \frac{1}{2} A_{\text{diff/disl}} \frac{1}{n} \frac{m}{d^n} \dot{\epsilon}_e^{\frac{1-m}{n}} \exp\left(\frac{Q_{\text{diff/disl}} + PV_{\text{diss/disl}}}{nRT}\right) \quad (6)$$

$$94 \quad \eta_{\text{comp}} = \left(\frac{1}{\eta_{\text{diff}}} + \frac{1}{\eta_{\text{disl}}}\right)^{-1} \quad (7)$$

95 where $\dot{\epsilon}_e$ is the square root of second invariant of the deviatoric strain rate. In the case of diffusion creep, $n = 1$, $m > 0$, while
96 for dislocation creep $n > 1$, $m = 0$. Definitions and values of other symbols are shown in Table S1 in Supporting Information.
97 Surface erosion and sedimentation are neglected.

98 The plastic yielding is defined by the Drucker–Prager criterion as Eq. (8) (Davis and Selvadurai, 2002):

$$99 \quad \eta_{\text{yield}} = \frac{C \cos(\phi) + P \sin(\phi)}{2\dot{\epsilon}_e} \quad (8)$$

100 Where C is the cohesion and ϕ is the initial friction angle. We also include strain weakening in the plastic regime, through
101 which C and ϕ are linearly weakened by a factor of 2 or 4 between plastic strains of 0.5 and 1.5.

102 The effective viscosity is eventually given by:

$$103 \quad \eta_{\text{eff}} = \min(\max(\eta_i, \eta_{\text{min}}), \eta_{\text{max}}) \quad (9)$$

104 where i is one of the subscripts among diff, disl, comp, and yield. η_{max} and η_{min} are user-defined viscosity cutoffs (Table S1).

105 2.3 Initial model configuration and boundary conditions

106 The numerical model domain is 2000 km \times 660 km in the horizontal and vertical directions. It contains a
107 retrocontinental lithosphere and a procontinental lithosphere, with an oceanic lithosphere in between (Fig. 1). A weak zone
108 with a width of 10 km (gabbro, Wilks and Carter, 1990) abuts the oceanic plate to facilitate subduction. The continental
109 lithosphere is 120 km thick, consisting of a 25-km-thick upper crust (wet quartzite, Gleason and Tullis, 1995), a 10-km lower
110 crust (wet anorthite, Rybacki et al., 2006), and an 85-km lithospheric mantle. The oceanic lithosphere (\sim 90 Ma) contains a
111 4-km-thick sediment layer (gabbro, Wilks and Carter, 1990), an 8-km-thick oceanic crust layer (gabbro, Wilks and Carter,
112 1990), and an 88-km-thick lithospheric mantle. Dry olivine (Hirth and Kohlstedt, 2003) is used for the mantle. All material
113 properties are listed in Table S1. The numerical resolution incrementally increases along the depth direction from 2 km \times 2
114 km to 8 km \times 8 km.

115 Temperature is fixed at the model surface (0°C) and the base of the lithosphere (1300°C), while various continental
116 T_{moho} is defined ranging from 450 – 600 °C. The initial continental lithospheric temperature profile follows Chapman (1986),
117 taking into account the thickness of each lithologic layer (Eqs. (11) - (13)). According to these equations, T_{moho} and H_r are

118 not independent parameters, we thus fixed T_{moho} when investigating the influence of H . Specially, we first choose a surface
 119 (T_{T}), moho temperature (T_{B}), and radioactive heat production (H), then calculate the surface heat flow (q_{T}) based on Eq. (12).
 120 After that, we substitute the above T_{T} , q_{T} , and H into Eq. (11) to get the continental crustal temperature structure. The
 121 oceanic lithospheric temperature distribution follows the half-space cooling model (Turcotte and Schubert, 2002), and in all
 122 models we use the same initial oceanic lithospheric thermal structure. Besides, a temperature gradient of $0.5\text{ }^{\circ}\text{C}/\text{km}$ is
 123 assumed for the sublithospheric mantle (Huangfu et al., 2019).

$$124 \quad T_Z = T_{\text{T}} - \frac{q_{\text{T}}}{k} Z - \frac{H Z^2}{2k} \quad (11)$$

$$125 \quad T_{\text{B}} = T_{\text{T}} + \frac{q_{\text{T}}}{k} \Delta Z - \frac{H \Delta Z^2}{2k} \quad (12)$$

$$126 \quad q_{\text{B}} = q_{\text{T}} - H \Delta Z \quad (13)$$

127 T_Z is the temperature at depth Z ; T is the temperature, q is the heat flux, the subscript T and B denote the top and
 128 bottom boundaries of each lithologic layer, respectively; ΔZ is the layer thickness; H is the volumetric heat production; k is
 129 the thermal conductivity.

130 We apply a free surface and free slip lower boundary, and impose a $5\text{ cm}/\text{yr}$ convergence rate to the trailing end of the
 131 procontinental lithosphere. Equivalent material flows out through both side walls of the mantle domain to keep mass balance
 132 within the whole computational domain (Fig. 1).

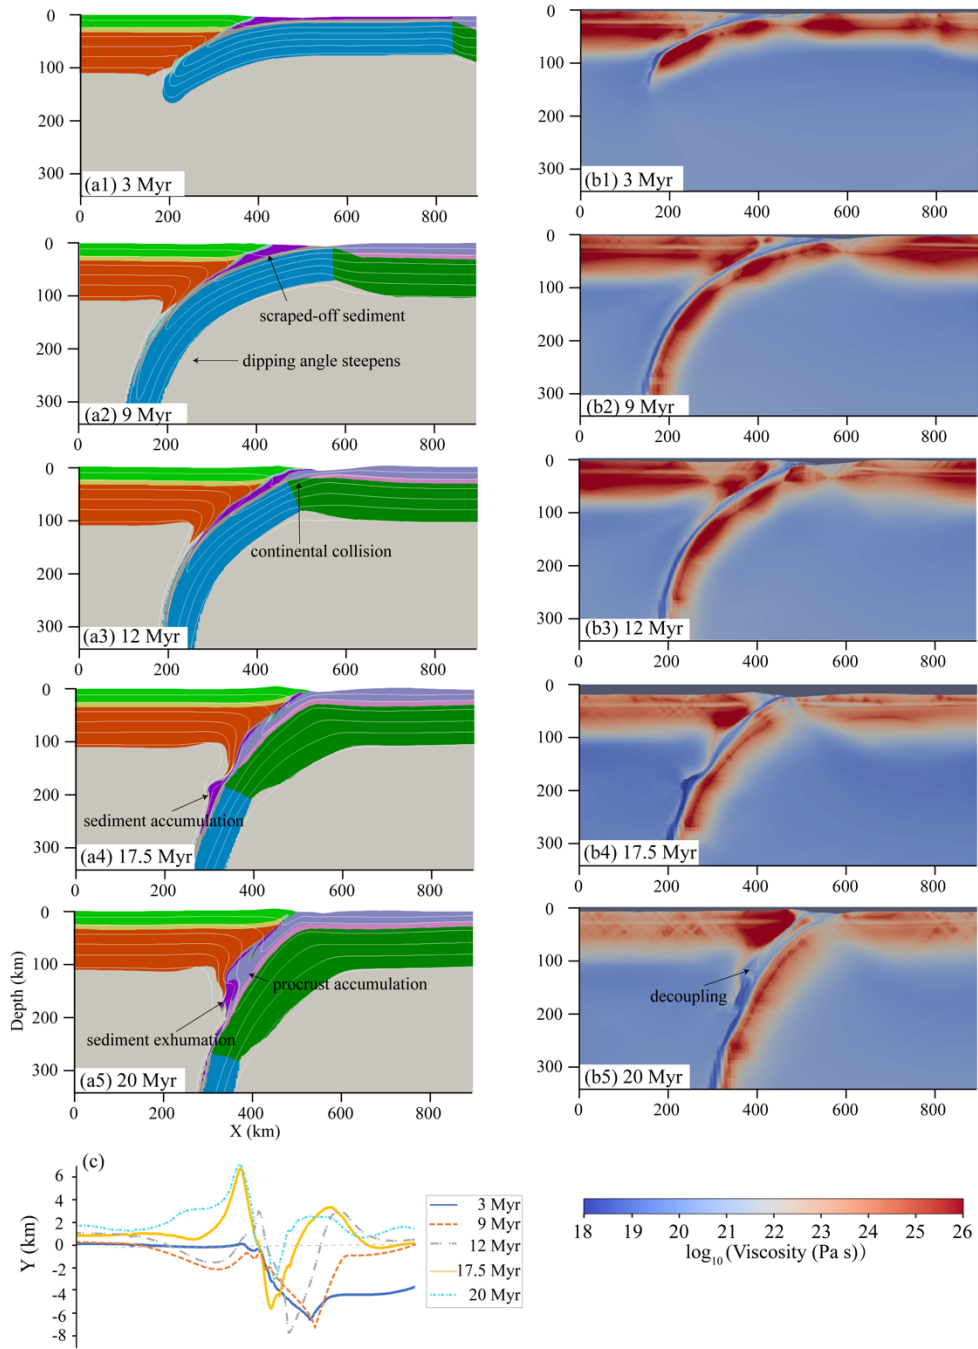

133
 134 **Figure 1.** (a) Reference model configuration and boundary conditions. Different colors reflect different lithologies: 1, 8,
 135 continental upper crust; 2, 9, continental lower crust; 3, 10, continental lithospheric mantle; 4, weak zone; 5, sediment; 6,
 136 oceanic crust; 7, oceanic lithospheric mantle; 11, sub-lithospheric mantle (Table S1). The white lines are isotherms of $200\text{ }^{\circ}\text{C}$
 137 increments in the range of $200\text{ }^{\circ}\text{C}$ to $1200\text{ }^{\circ}\text{C}$. T_{surf} is the surface temperature, T_{lab} is the bottom temperature of continental
 138 lithosphere. V_{in} and V_{out} denote where material flows in and out. (b) Initial distributions of procontinental ($T_{\text{cp_pro}}$),
 139 retrocontinental ($T_{\text{cp_retro}}$) and oceanic (T_{top}) lithospheric temperatures.

140 **3 Results**

141 We conducted 48 numerical experiments by varying the moho temperature, upper crustal H_{r_uc} and lower crustal
142 H_{r_lc} of the retrocontinent and procontinent, respectively, to capture different continental thermal structures. Two distinct
143 continental collision evolutionary paths were recognized: (I) continuous subduction and (II) continental subduction with a
144 slab break-off. All the simulations are summarized in Table S2.

145 **3.1 Continuous subduction without slab break-off (Mode I)**

146 Figure 2 shows the development of the continuous subduction mode, and it takes the Model m2 (reference model,
147 Table S2) as an example. The model started with a relative shallow angle subduction characterized by the oceanic plate dips
148 downward along the low-viscosity weak zone (Fig. 2a1, 3 Myr). During this stage, a portion of oceanic sediment was
149 scraped off and stacked at the surface, accompanied by the slight uplift of the retrocontinental foreland (Fig. 2a2, 2c). As the
150 subduction goes on, the dipping angle of the slab in depth gradually steepens due to the increasing slab pull (Fig. 2a2, 9 Myr).
151 At ~11.5 Myr (Fig. 2a3), continents collide with each other after the full consumption of the oceanic plate. Under the
152 continued oceanic slab pulling, the procontinental lithosphere inherited the subduction, characterized by further subducting
153 angle steepening that resulted in the superposition of retrocontinental upper crust and oceanic sediment on the procontinental
154 forepart. With the proceeding of procontinental subduction, the collision wedge uplifted prominently (Fig. 2c). After that, a
155 large part of the oceanic sediment previously scraped off was then entrained and subducted with the procontinental crust,
156 followed by the rapid uplift at the retroside of the collision zone and the retroward advance of suture (Fig. 2c). From ~17.5
157 Myr on, the buoyant procontinental upper crust began to detach from the underlying lithosphere, mixed with the exhumated
158 oceanic sediment, accumulated together in the subduction channel (Figs. 2a4, 2a5). During this time, uplift within the
159 collision zone gradually expands to the retrocontinental interior (Fig. 2c).

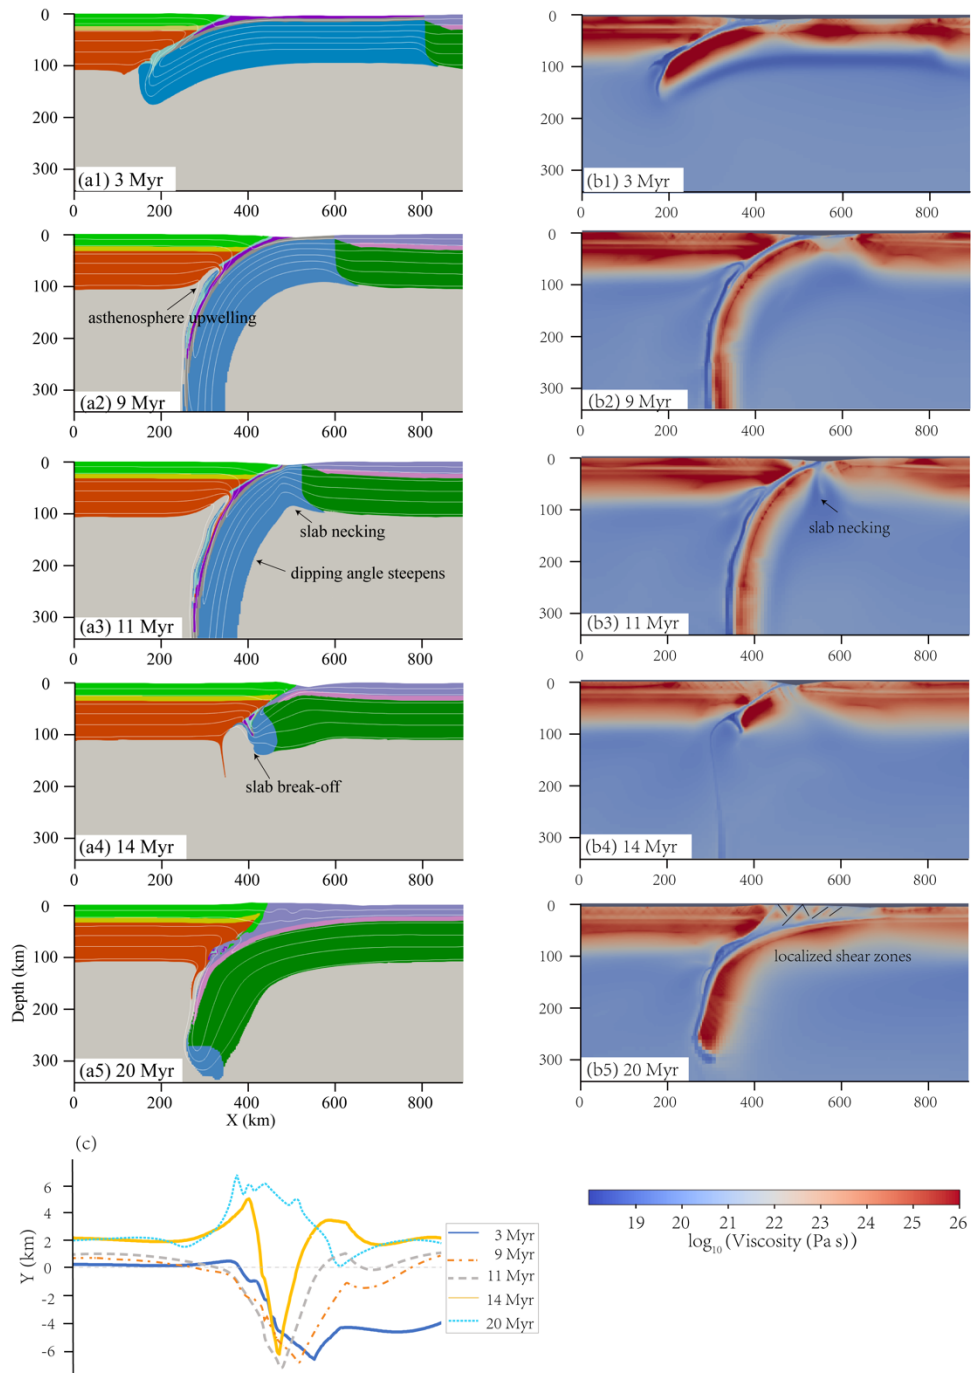

160

161 **Figure 2.** Time evolution of Model m2. Snapshots of compositional fields (a1 - a5), viscosity (b1 - b5) and topography (c)

162 for selected model times are shown. The lithologies and isotherms are the same as in Fig 1.

163 **3.2 Continental subduction with a slab break-off (Mode II)**

164 In Model m7, both the pro- and retro- continent have higher T_{moho} than Model m2 (Table S2). The lithospheric
165 deformation behaviors and the evolution of the model during the oceanic subduction phase are quite similar to those
166 observed in Model m2 (Fig. 3a1). The only difference is that the slab steepened more rapidly at a later stage, which gave rise
167 to the decoupling between the retrocontinental lithosphere and the oceanic plate. Such a process created an ideal space for
168 the asthenospheric upwelling and resulted in the significant weakening of the retrocontinental lithosphere (Fig. 3a2, 8.5 Myr).
169 After ~10.2 Myr, combined effect of the increasing slab pull and asthenosphere upwelling promoted necking around the
170 oceanic-procontinental lithospheric transition zone (Fig. 3a3, 11 Myr). The procontinental lithosphere then arrived at the
171 trench and initiated subducting along the inclined weak zone, accommodating most of the ongoing convergence. During this
172 stage, the continuous compression and rebound after slab break-off significantly uplifted the collision zone. Later on, the
173 upper part of the retrocontinental lithosphere indented into the procrust, scraping off most of the procontinental upper crust,
174 causing significant thickening and localized shear zones there while leaving the residual little portion to subduct with the
175 lithosphere. Subsequently, the accumulated orogenic wedge gradually grew into a relatively wide surface uplift.

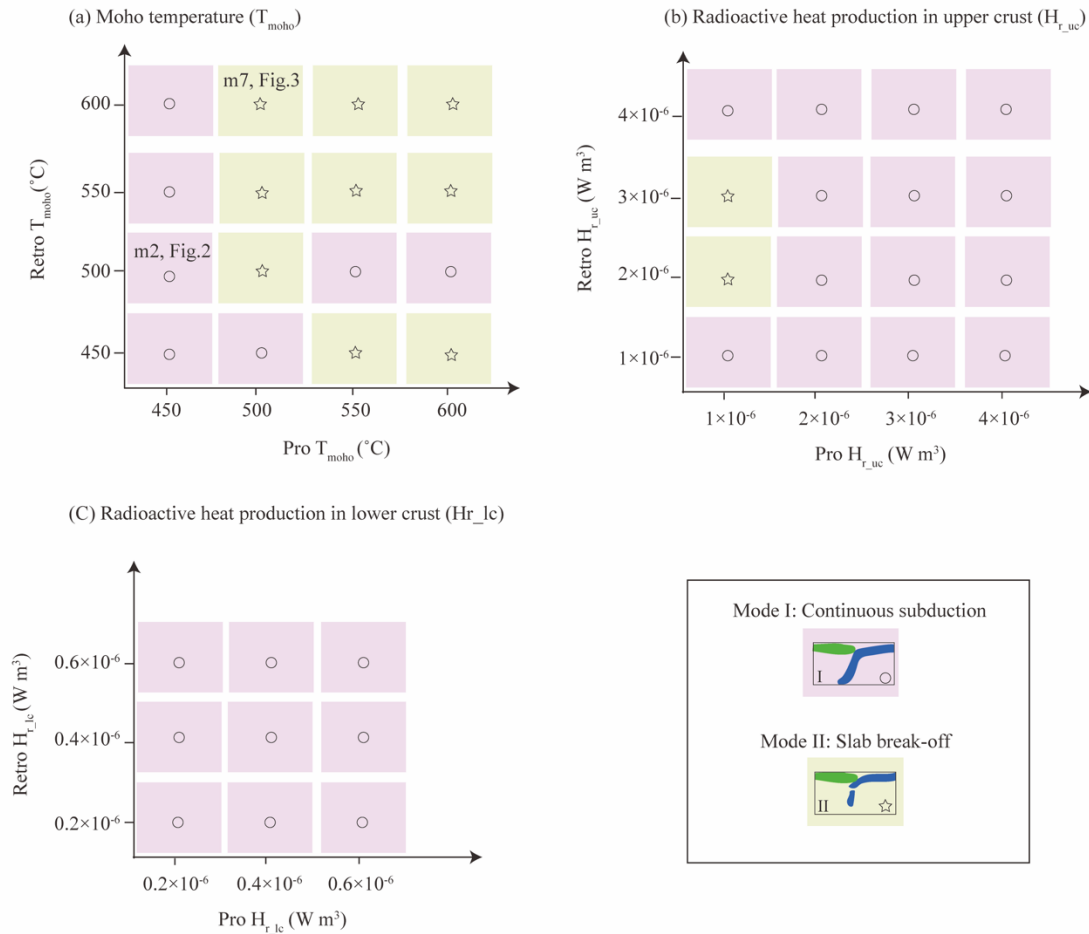

176

177 **Figure 3.** Results of Model m7. Snapshots of compositional fields (a1 - a5), viscosity (b1 - b5) and topography (c) for
 178 selected model times are shown. The lithologies and isotherms are the same as in Fig. 1.

179 **3.3 Sensitivity tests of continental lithospheric thermal structure on the evolution of continental convergence**

180 A regime diagram (Fig. 4) of all the models summarizes the template simulations investigating the effects of
 181 continental T_{moho} and H_r , and two contrasting end members of continental collision modes are identified. Models with a cold
 182 procontinental T_{moho} (≤ 450 °C) generally exhibit a continuous subduction mode without slab break-off. Meanwhile, the
 183 hotter the retrocontinental T_{moho} , the steeper the subducting angle is (Figs. 4a, 5a). In comparison, Mode II dominates among
 184 the models with a relative hot procontinental T_{moho} (≥ 500 °C), especially when the retrocontinental T_{moho} is greater than
 185 550 °C (Fig. 4a). In addition, H_r is a second-order controlling parameter compared to the T_{moho} , as it's more propensity to
 186 alter the upper part of lithospheric deformation styles than the continental collision mode (Figs. 6c - 6i).

187
 188 **Figure 4.** Schematic figures of models with different (a) continental T_{moho} , (b) upper and (c) lower crustal radioactive heat
 189 production (Table S2). The diagram in each panel shows the dependence of collision mode on the corresponding controlling
 190 parameters of both colliding plates.

191

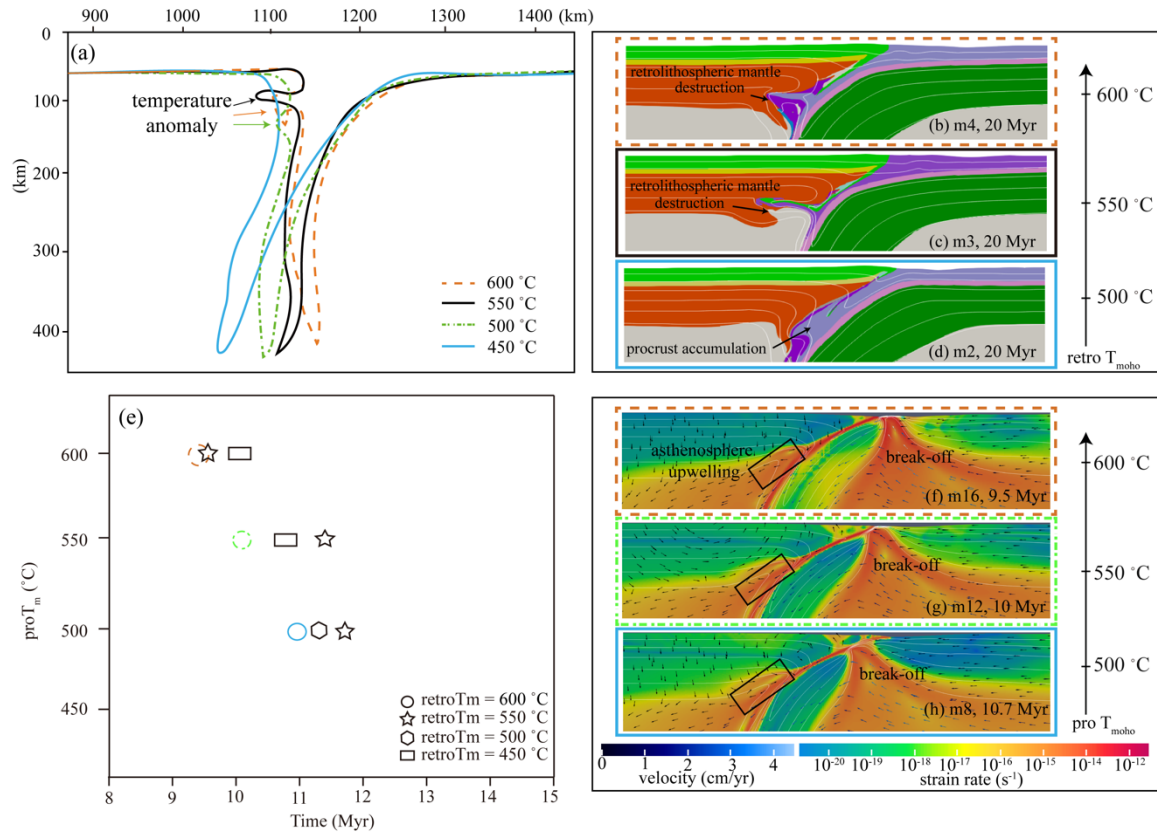

192 4 Discussions

193 4.1 How continental moho temperature influences the trajectory of the collision system?

194 As mentioned above, models incorporating a cold prolithosphere generally evolve into continuous subduction
195 without slab break-off. It may come from the fact that a cold prolithosphere is strong enough to maintain its strength, and
196 also keeps coupling with the retrolithosphere during plate convergence. Thus, the prolithosphere suffers moderate roll-back,
197 under the condition that the stress is not sufficient to yield the lithosphere and generate break-off (Fig. 2, Fig. S1 in
198 Supporting Information). Based on further analysis of this mode of models, we notice that the subducting angle increases as
199 the retrocontinental T_{moho} increases, accompanied by much more procrust accumulation at shallow and intense
200 retrolithospheric mantle destruction (Figs. 5a - 5d). The mechanism behind this is that increasing the retrocontinental T_{moho}
201 can weaken the retrolithosphere and increase the thermal structural difference between the two continents, which may lead to
202 plate decoupling. As a consequence, it is more likely for the prolithosphere to roll back as the magnitude of decoupling
203 increases. Besides, weakening of the retrolithosphere may also offer a favorable condition for the intrusion of accumulated
204 procrustal material into it.

205 As to mode II, models with hot procontinental $T_{\text{moho}} (\geq 500^\circ\text{C})$ always evolve into continental subduction following
206 a slab break-off. In these models, when the retrocontinental T_{moho} is determined, (1) as the procontinental T_{moho} decreases, the
207 procontinental lithosphere becomes cold, which results in a rheologically strong lithosphere that can be subjected to greater
208 deformation; the slab thus breaks off much latter (Fig. 5e). This is consistent with many of the previous numerical studies
209 (van de Zedde and Wortel, 2001; van Hunen and Allen, 2011; Duretz et al., 2011). However, it appears that Duretz and
210 Gerya (2013) proposed an apparent opposite tendency. It may come from the fact that these models do not use a layered
211 crust. In consequence, a strong crust is more likely to result in strong crust-mantle coupling and a deeper slab break-off
212 under slower convergence, while a weak crust leads to crust-mantle decoupling that may evolve into delamination. (2) The
213 depth of slab break-off in our models is between $\sim 30 - 60$ km, which is in the range indicated by Davies and von
214 Blanckenburg (1995), Li et al. (2002), Duretz et al. (2011), and Duretz and Gerya (2012). (3) After slab break-off, the
215 buoyant continental lithosphere experiences a rebound accompanied by strong surface uplift within a short duration (Fig. 3c),
216 which coincides with Duretz and Gerya (2013) and Magni et al. (2017). Slab break-off is often considered an early process
217 of continental collision, and numerous numerical simulations have been conducted to investigate it. Comparing their results
218 with our models, we suggest that slab break-off is closely related to the rheological strength of the lithospheres. Therefore,
219 the parameters that have prominent impacts on it, such as oceanic plate age, convergence velocity, continental crustal
220 structure, layered crustal rheological strength, the strength of the interface between the subducting and overriding plates, etc.
221 (Gerya et al., 2004; Burov, 2011; Duretz et al., 2011; Magni et al., 2017; Koptev et al., 2022), may significantly influence
222 the evolutionary path of slab break-off.

223 In conclusion, we propose that continental T_{moho} is an important parameter in shaping the continental collision
 224 system, especially influencing the fate of subduction. The hotter the procontinent, the weaker and easier it is to evolve into a
 225 slab break-off. The hotter either the procontinent or the retrocontinent, the less coupled it is with the adjacent plate. In
 226 addition, as a result of ongoing subduction, the slab rolls back rapidly, which may generate a gap between the adjacent plates.
 227 The asthenosphere then upwells into it, which in turn aggravates the rollback. This contributes to the development of intense
 228 strain localization in the pro-lithosphere and finally leads to slab break-off (Figs. 3, S2, 5f, 5g, 5h).

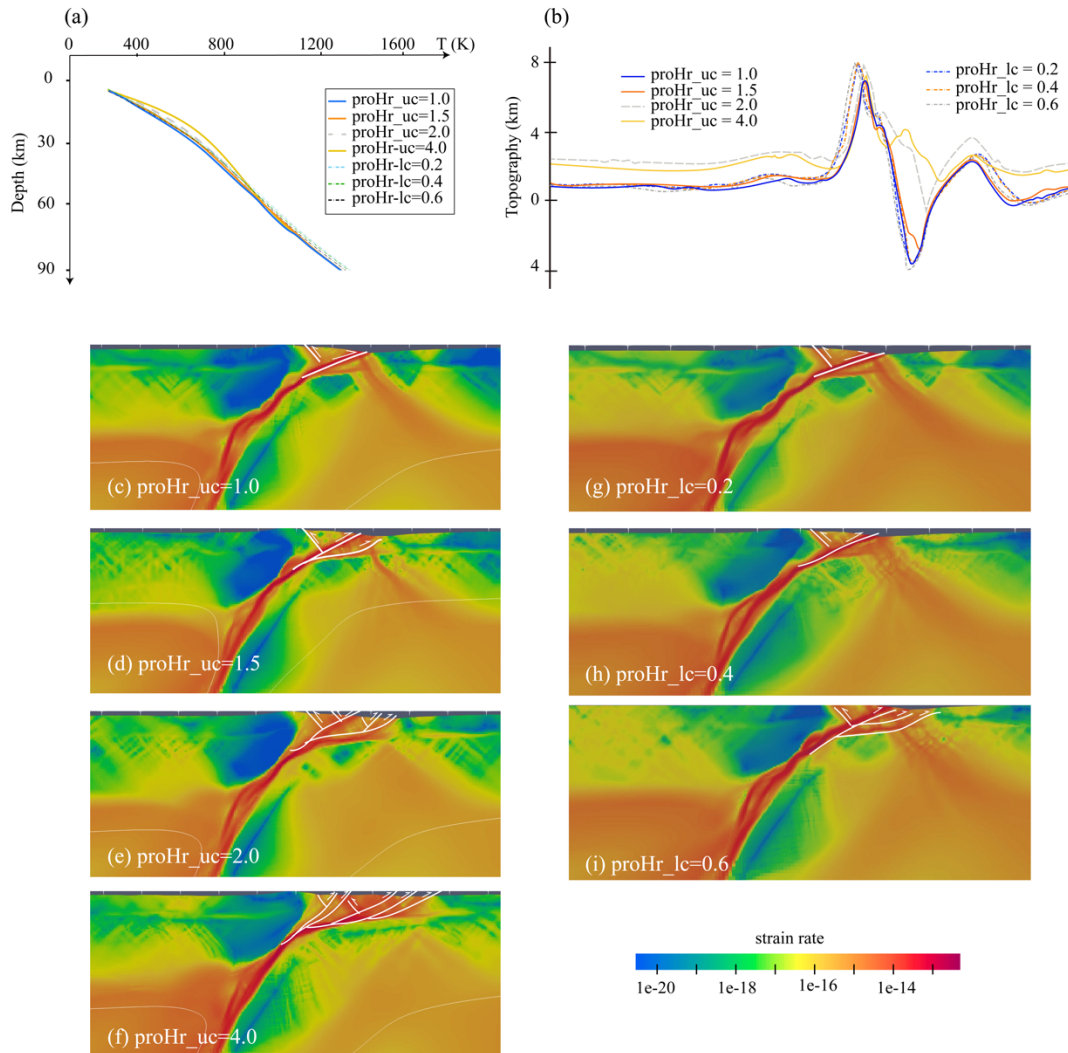

229
 230 **Figure 5.** (a) Geometries of subducting plate in models with different retrocontinental T_{moho} outlined by 800 °C isotherms.
 231 Compositional fields of models with decreasing retrocontinental T_{moho} , (b) m4, retro $T_{\text{moho}} = 600^\circ\text{C}$, (c) m12, retro $T_{\text{moho}} =$
 232 550°C , (d) m8, retro $T_{\text{moho}} = 500^\circ\text{C}$. White lines denote the isotherms (200 °C increments). (e) shows the relationship
 233 between the times of slab break-off and continental T_{moho} . (f)-(h) are strain rate of models with various procontinental T_{moho} .

234 4.2 How crustal radioactive heat production influences the trajectory of the collision system

235 Radioactive elements are thought to mainly exist in the continental crust, and the radioactive heat production that
 236 originates from their decay is one of the important internal heat sources in the earth, which influences the continental
 237 lithospheric thermal structure significantly (Turcotte and Schubert, 2002; Faccenda et al., 2008). According to our model

238 results, increasing the upper crustal H_r can distinctly increase the thermal gradient of the lithospheric upper part, under the
 239 effect of which the steep surface topography built at the early stage of continental collision would tend to be relatively gentle.
 240 In comparison, varying lower crustal H_r has much less influence on the variation of the continental lithospheric thermal
 241 gradient and the evolution of surface topography. Moreover, as the H_r in the crust increases, the lithospheric rheological
 242 strength decreases, which facilitates the growth of crustal shear zones. That is, the higher the crustal H_r , the more shear zones
 243 it may generate in the crust (Figs. 6c - 6i). In conclusion, crustal H_r is a crucial parameter in enhancing strain localization in
 244 the lithospheric upper part that is closely related to the growth of shear zones, while it exerts a second-order influence on
 245 altering the continental collision mode.

246
 247 **Figure 6.** Temperature profiles (a), topography (b) and strain rate (c-i, at 20 Myr) of models with different crustal H_r .
 248

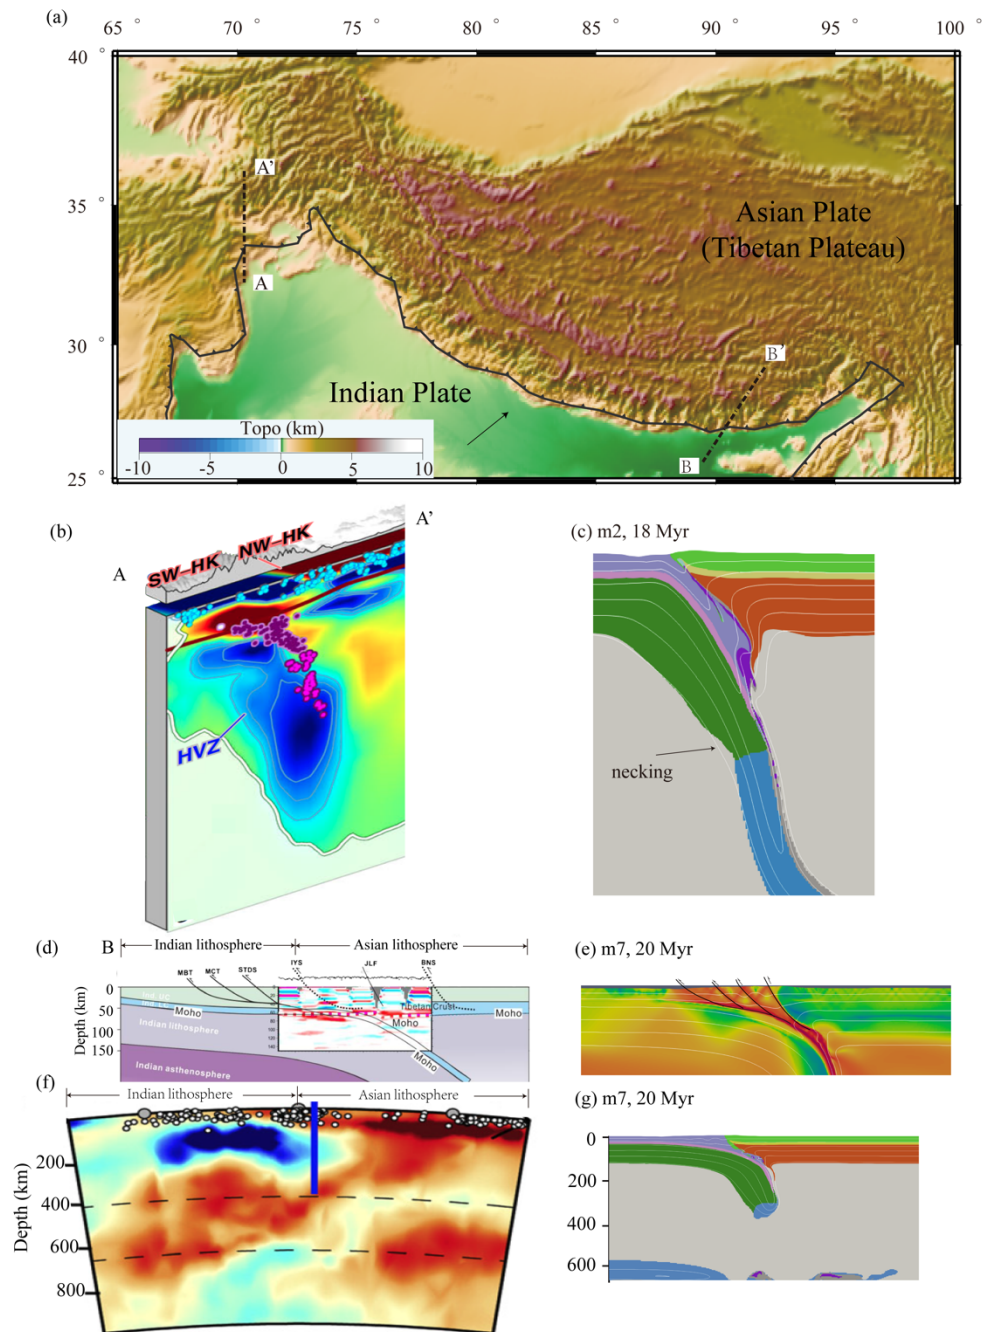

249 **4.3 Implications for the development of lateral heterogeneity of Indian-Asian collision**

250 ~2000 km-long east-west Himalayan-Tibetan orogenic system was created by continental collision from ~ 60 to 50
251 Ma, with the Nanga Parbat syntaxis as its west margin and the Namche Barwa syntaxis in the east (Chen et al., 2015). It has
252 been proven by contrasting along-strike lithospheric structures (Li et al., 2008; Chen et al., 2015; Kufner et al., 2021). By
253 comparison, our models are capable of providing several first-order fits of the crust-mantle deformation behaviors to this
254 natural collision system, especially at the Hindu-Kush profile and the eastern Tibet profile.

255 Hindu Kush is the westernmost end of the Himalayan-Tibetan orogen. Previous seismic tomography studies have
256 confirmed that there is a north-dipping, downward steepening, and thinning high-velocity anomaly (HVA), accompanied by
257 increasingly intense seismicity, underneath the region (Kufner et al., 2016; Kufner et al., 2021). The inclined HVA is
258 believed to be a subducting plate of Indian provenance and is part of the Indian-Asian collision system. The thinning of the
259 HVA is in the extent between 180-220 km, and was suggested to be at the transition zone between Indian continental
260 lithosphere and Neo-Tethys oceanic lithosphere. In agreement with the observations, Model m2 has a similar tectonic
261 background, and shows an analogous continuous subduction characterized by a nearly vertical dipping angle and a slab
262 necking at a depth of ~ 220 km. In addition, the relative narrow collision orogen in the model is also consistent with the
263 natural topography in this region (Figs. 7a, 2c). It's worth noticing that the observed inclined distribution of earthquakes
264 seems to coincide with the subducting continental crust. This may offer a possible explanation for the active intermediate
265 earthquakes beneath this region.

266 The main part of the Himalayan-Tibetan orogen is the product of a collision between the cold Indian craton and the
267 relative warm Asian continent after the closure of Neo-Tethys, the geological settings of which are quite analogous with our
268 Model m7. During the continental collision phase, the Yarlung Zangbo suture zone bordering the Indian and Asian
269 lithospheres moved significantly, creating an ~8 km mountain (the Himalayas) and a ~ 4 km plateau (the Tibetan Plateau)
270 (Yin and Harrison, 2000). Unlike continuous subduction underlying the Hindu Kush, geological and seismological evidence
271 shows that the eastern part of the profile is underlain by a shallower-angle subducting Indian lithosphere following a slab
272 break-off; these are also similar to the model results of Model m7 (Figs. 7b, 2c). Furthermore, previous field observations
273 have shown that the northern part of the Indian continental crust is abundant with radioactive elements (Vidal et al., 1982;
274 Scaillet et al., 1990; Macfarlane, 1992; Faccenda et al., 2008). Our sensitive tests have recognized that continental crust with
275 high radioactive heat production is much easier to generate brittle fractures and intense deformation of the lithospheric upper
276 part, which may lead to the development of new shear zones (Fig. 6). This resembles the tectonic characteristics of large
277 thrust fault zones in the Himalayas (Fig. 7b).

278 In consequence, we speculate that the continental lithospheric thermal structural difference may be one of the key
279 parameters that control the evolution of lateral heterogeneity along the Himalayan-Tibetan orogen and that the high content
280 of crustal radioactive elements is one of the significant factors that dominates the growth of large thrust fault zones in the
281 Himalayas.

282

283 **Figure 7.** (a) Geographic setting of Himalayan-Tibetan orogen. Schematic geologic cross-sections across the (b) western
 284 (Hindu Kush) (Kufner et al., 2021) and eastern Himalayan-Tibetan orogen (Li et al., 2008; Wang et al., 2019). (c) shows the
 285 compositional field of Model m2 (mode I), (e) and (g) are the strain rate and compositional field of Model m7 (mode II),
 286 respectively.

288 **5 Conclusions**

289 In this work, we systematically discuss the influences of the continental lithospheric thermal structure on the evolution
290 of the continental collision system based on high-resolution thermomechanical numerical experiments. The model results
291 demonstrate that:

292 Two end members of continental collision are obtained: the continuous subduction mainly occurs with a relative cold
293 overriding lithosphere ($T_{\text{moho}} \leq 450^\circ$), and as the retrocontinental T_{moho} increases, the subducting angle steepens. Slab break-
294 off dominates when the model has a relatively hot procontinental $T_{\text{moho}} (\geq 500^\circ\text{C})$, especially when the retrocontinental T_{moho}
295 is greater than 550°C . H_r is a second-order controlling parameter compared with T_{moho} in shaping the continental collision
296 mode, while it is more prone to facilitate the growth of crustal shear zones.

297 The continental lithospheric thermal structure may have played a significant role in the development of lateral
298 heterogeneity along the Himalayan-Tibetan orogenic belt. We suggest that the different evolutionary paths between the
299 continuous subduction underlying the Hindu Kush and the continental subduction beneath eastern Tibet may come from the
300 inherited lateral variation of the Indian lithospheric geothermal gradient. In addition, the high content of radioactive elements
301 in the continental crust may be one of the important reasons for the development of deep and large thrust fault zones in this
302 collision orogen.
