23 Abstract

24 Ozone (O₃) has become one of the most concerning air pollutants in China in recent
25 decades. In this study, based on surface observations, reanalysis data, global atmospheric
26 chemistry model simulations and multi-model future predictions, meteorological
27 characteristics conducive to extremesevere O₃ pollution in various regions of China are
28 investigated, and their historical changes and future trends are analyzed. During the most
29 severe O₃ polluted months, the chemical production of O₃ is enhanced under the hot and dry
30 conditions over the North China Plain (NCP) in June 2018 and Yangtze River Delta (YRD) in
31 July 2017, while the regional transport is the main reason causing the severe O₃ pollution over
32 Sichuan Basin (SCB) in July 2015 and Pearl River Delta (PRD) in September 2019. Over the
33 last four decades, the frequencies of high temperature and low relative humidity conditions
34 increased in 2000-2019 relative to 1980-1999, indicating that O₃ pollution in both NCP and
35 YRD became more frequent under the historical climate change. In SCB and PRD, the
36 occurrence of atmospheric circulation patterns similar to those during the most polluted months
37 increased, together with the more frequent hot and dry conditions, contributing to the increases
38 in severe O₃ pollution in SCB and PRD during 1980–2019. In the future (by 2100), the
39 frequencies of months with anomalous high temperature show stronger increasing trends in the
40 high forcing scenario (SSP5-8.5) compared to the sustainable scenario (SSP1-2.6) in China. It
41 suggests that high anthropogenic forcing will not only lead to slow economic growth and
42 climate warming, but also likely result in environmental pollution issues.

43 **1. Introduction**

44 Tropospheric ozone (O₃), one major air pollutant, is formed in photochemical reactions of
45 nitrogen oxides (NO_x) and volatile organic compounds (VOCs) when exposed to sunlight
46 (Finlayson-Pitts and Pitts, 1997; Silman, 1999). Enhanced O₃ pollution harms ecosystems and
47 human health (Fleming et al., 2018; Maji et al., 2019) by reducing crop yields (Ainsworth et
48 al., 2012; Mills et al., 2018) and aggravating cardiopulmonary disease (Ebi and McGregor,
49 2008; Liu et al. 2018). In recent years, near-surface ozone concentrations in many regions of
50 China have been increasing considerably (Verstraeten et al., 2015; Cheng et al., 2019; Zhang
51 et al., 2020, Li et al., 2019; Lu et al., 2018; Silver et al., 2018; Yin et al., 2019, Lu et al., 2020).
52 Lu et al. (2020) revealed that the daily maximum of 8-h average O₃ concentration (MDA8-O₃)
53 in China increased by 2.4 ppb per year (5.0% relative to the average) during April–September
54 over 2013–2019.

55 In addition to emissions, O₃ concentrations are influenced by meteorological factors such
56 as temperature, relative humidity, solar radiation, and winds (Mott et al., 2005; Fu and Tian,
57 2019; Gong and Liao, 2019; Li et al., 2019, 2020; Le et al., 2020; Zhao et al., 2020). Typically,
58 strong solar radiation, high surface air temperatures, and low relative humidity are conducive
59 to photochemical production of O₃, causing a raise of O₃ concentration (Peterson and Flowers,
60 1977; Xu, et al., 2011; Coates et al., 2016; Li et al., 2020; Dang et al., 2021). Wind speed is
61 negatively correlated with surface O₃ because low wind speed facilitates the accumulation of
62 O₃ upon production (Zhang et al., 2015; Wang et al., 2017; Liu and Wang, 2020). Han et al.
63 (2020) explored the impacts of various meteorological factors on the daily variation of summer
64 surface O₃ in eastern China based on a multiple linear regression method and suggested that

65 relative humidity is the primary factor affecting O₃ concentration in central and south parts of
66 eastern China, while temperature is the most important factor governing O₃ concentration in
67 north of eastern China. Gong and Liao (2019) reported that the meteorological characteristics
68 of O₃ pollution events in North China during 2014–2017 were the high daily maximum
69 temperature, low relative humidity, abnormal southerly winds and high pressure at 500 hPa.
70 These findings emphasize that meteorological factors play a crucial role in regulating O₃
71 pollution in China.

72 Atmospheric circulation patterns affect O₃ concentrations over China through changing
73 meteorological factors (Yang et al, 2014, 2022; Zhao and Wang, 2017; Shu et al., 2019; Dong
74 et al., 2020; Zhou et al., 2022). Zhao and Wang (2017) examined the influence of the Western
75 Pacific Subtropical high (WPSH) on O₃ over eastern China based on observations and
76 reanalysis data from 2014 to 2016. They found that stronger WPSH enhanced the moisture
77 transport to southern China, which was detrimental to the photochemical reaction of O₃,
78 leading to a decrease in surface O₃ concentration in southern China, whereas O₃ concentrations
79 in northern China increased under the stronger WPSH related to the dry and hot conditions
80 favoring O₃ production. On the basis of observational O₃ data and ERA5 reanalysis data during
81 2014–2018, Dong et al. (2019) analyzed the impact of synoptic patterns on summertime O₃
82 pollution in the North China Plain and revealed that the most severe O₃ pollution weather
83 pattern is associated with anomalous southwesterly winds, which carry dry, warm air from
84 inland southern China to the North China Plain and favor the chemical production of O₃. Zhou
85 et al. (2022) explored the impacts of Asian summer monsoon on the interannual variation of
86 O₃ concentrations based on surface measurements and GEOS-Chem model simulations. They

87 showed that the East Asian summer monsoon strength was positively correlated with O₃
88 concentration in south-central China and South Asian summer monsoon has complex effects
89 on O₃ pollution in China, mainly through changing transboundary transport related to large-
90 scale circulations.

91 As mentioned above, many previous studies have examined the meteorological
92 characteristics of O₃ pollution in China. However, they focused on O₃ pollution over limited
93 regions in China in each study (e.g., the North China Plain, southern China). These studies only
94 examined the meteorological characteristics of O₃ pollution in a short time period due to the
95 lack of observational data and did not consider the historical and future trends of these
96 meteorological factors. In this study, the meteorological characteristics conducive to the most
97 severe O₃ pollution in several polluted areas of China, including the North China Plain (NCP),
98 Yangtze River Delta (YRD), Sichuan Basin (SCB), and Pearl River Delta (PRD), are
99 respectively investigated based on the observed surface O₃ concentrations, reanalysis data, and
100 GEOS-Chem model simulations. Besides, the contributions from various chemical and
101 physical processes inducing regional O₃ pollution are quantified using an integrated process
102 rate (IPR) analysis method. The historical changes in these meteorological factors favoring the
103 most severe O₃ pollution over 1980–2019 are provided. Moreover, variations in future
104 meteorological patterns during 2021–2100 leading to severe O₃ pollution in China are
105 presented under the sustainable and high forcing scenarios according to the multi-model data
106 from the Coupled Model Intercomparison Project Phase 6 (CMIP6).

107 **2. Methods**

108 **2.1 Surface ozone observations and meteorological reanalysis**

109 Hourly surface O₃ concentrations are obtained from the Ministry of Ecology and
110 Environment (MEE) of China. The observational network was established in 2013 with 450
111 monitoring sites and increased to 1,500 monitoring sites by 2019, covering about 360 cities in
112 China. MDA8-O₃ are calculated based on hourly O₃ concentrations from April-September
113 during 2013 to 2020. In this study, O₃ pollution days are defined as the days when MDA8-O₃
114 exceeds 160 µg m⁻³ according to the China National Ambient Air Quality Standard (GB3095-
115 2012).

116 The meteorological fields are taken from the European Centre for Medium-Range
117 Weather Forecasts (ECMWF) ERA5 monthly reanalysis dataset during 1980–2020, with a
118 horizontal resolution of 0.25° × 0.25°. To explore the meteorological characteristics that are
119 conducive to O₃ pollution, sea level pressure (SLP), geopotential height (GPH) at 500 hPa,
120 wind fields at 850 hPa and 500 hPa, temperature at 2m (T2m) and surface relative humidity
121 (RH) are adopted, which can have significant impacts on O₃ variations in China (Jiang et al.,
122 2020; Dong et al., 2020; Le et al., 2020).

123 **2.2 GEOS-Chem model simulations**

124 O₃ concentrations and the related chemical and physical processes causing O₃ variations
125 over 1981–2020 are simulated in the global atmospheric chemistry model GEOS-Chem
126 (version V12.9.3), driven by the Modern-Era Retrospective analysis for Research and
127 Application, Version 2 (MERRA-2). Simulations are performed on 47 vertical layers from
128 surface to 0.01 hPa, and a horizontal grid of 2° latitude × 2.5° longitude. GEOS-Chem model
129 incorporates a fully coupled O₃-NO_x-hydrocarbon-aerosol chemical mechanism (Pye et al.,
130 2009; Mao et al., 2013; Sherwen et al., 2016). Boundary-layer mixing uses a non-local scheme

131 (Lin and McElroy, 2010), and stratospheric O₃ chemistry employs the linearized O₃
132 parameterization (LINOZ) (McLinden et al., 2000).

133 Global anthropogenic ~~aerosol and precursor gas~~ emissions driving the simulations are
134 from the Community Emissions Data System (CEDS, Hoesly et al., 2018) and biomass burning
135 emissions are from the Global Fire Emissions Database, Edition 4 (GFED4, Van der Werf et
136 al., 2017). VOCs emissions from biogenic sources are provided offline by the Model of
137 Emissions of Gases and Aerosols from Nature version 2.1 (MEGAN V2.1, Guenther et al.,
138 2012). Lightning and soil emissions are specified in the model (Hudman et al., 2012; Ott et al.,
139 2010). Anthropogenic emissions in China are updated with the Multi-resolution Emission
140 Inventory (MEIC), a localized emission dataset for China. Anthropogenic, biomass burning,
141 ~~biological-biogenic~~ and other natural emissions are kept at 2017 levels during the simulations,
142 so as to eliminate the influence of emission changes on the interannual variation and trends of
143 O₃. Simulated O₃ distributions with the same configuration in GEOS-Chem have been
144 extensively evaluated in many studies, and the model has been reported to capture O₃
145 concentrations well in China (e.g., Li et al., 2019; Lu et al., 2019; Ni et al., 2018).

146 **2.3 CMIP6 multi-model simulations**

147 The multi-model simulations from historical and the Scenario Model Intercomparison
148 Project (ScenarioMIP) in CMIP6 are used to analyze the historical variations and future trends
149 of meteorological conditions conducive to the most severe O₃ pollution. Two different future
150 scenarios of the Shared Socioeconomic Path (SSPs) are applied, including the sustainable
151 scenario (SSP1-2.6) and the high forcing scenario (SSP5-8.5). Totally simulations from 13
152 models (ACCESS-CM2, ACCESS-ESM1-5, CAS-ESM2-0, CMCC-CM2-SR5, CMCC-ESM2,

153 FGOALS-f3-L, FGOALS-g3, GFDL-ESM4, INM-CM4-8, INM-CM5-0, IPSL-CM6A-LR,
154 MPI-ESM1-2-HR, MPI-ESM1-2-LR) are analyzed in this study.

155 **3. Results**

156 **3.1 Meteorological characteristics conducive to regional ozone pollution**

157 To investigate the relationship between meteorological conditions and regional O₃
158 pollution in China, the frequencies of O₃ pollution days from April to October during 2013–
159 2020 are calculated for Beijing, Shanghai, Chengdu and Guangzhou, representing the typical
160 four polluted regions in China (i.e., NCP, YRD, SCB and PRD) (Figure 1). Observational data
161 show the highest frequencies of O₃ pollution days in June 2018, July 2017 and September 2019
162 in Beijing, Shanghai and Guangzhou, with pollution days up to 22, 20 and 19 days per month,
163 respectively. The top three highest frequencies of O₃ pollution days in Chengdu are in July
164 2016, July 2015 and July 2018 (16, 15 and 15 days per month, respectively). Variations in O₃
165 concentration in the real world are driven by changes in both meteorological factors and
166 emissions. With fixed emissions, the positive anomalies of near-surface O₃ concentrations over
167 NCP, YRD and PRD during their most polluted months can also be reproduced by the GEOS-
168 Chem model (Figure 2), suggesting that the O₃ pollutions during the most polluted months over
169 NCP, YRD and PRD are likely attributable to the anomalies of meteorological conditions. In
170 the top three O₃ polluted months in Chengdu, only in July 2015 the higher concentrations than
171 the long-term averages can be captured by the simulations with fixed emissions. Therefore, in
172 this study, we focus on the meteorological characteristics in June 2018, July 2017, July 2015
173 and September 2019, that were conducive to the most severe O₃ pollution over NCP, YRD,
174 SCB and PRD, respectively.

175 When O₃ pollution was the most severe over NCP in June 2018, an anomalous high
176 pressure occurred at 500 hPa over NCP (Fig. 3b), relative to the 40-year climatological
177 averages from 1980 to 2019, leading to positive T2m anomalies near the surface (Fig. 3c).
178 Anomalous lows located over northeastern China and northwestern Pacific (Fig. 3a) and the
179 associated anomalous northerly winds prevent the moisture moving from the ocean to NCP,
180 causing negative RH anomalies over NCP (Fig. 3d). The meteorological conditions with the
181 high T2m and low RH are favorable for the photochemical production of O₃. When the most
182 severe O₃ pollution occurred in July 2017, YRD was dominated by anomalous high pressure
183 in the lower and middle troposphere (Figs. 4a and 4b). Under the control of high pressure, the
184 meteorological conditions (e.g., high T2m and low RH) enhance the photochemical production
185 of O₃ (Figs. 4c and 4d). In the O₃ pollution event of SCB in July 2015, the negative T2m
186 anomaly is not conducive to the O₃ production (Fig. 5c), although the RH was low (Fig. 5d).
187 Meanwhile, the anomalous low over eastern China and northwestern Pacific in the middle
188 troposphere favors regional O₃ transport from the polluted source region over eastern China to
189 SCB (Fig. 5b) and the anomalous high over central-western China is conducive to the vertical
190 transport of upper tropospheric O₃ down to the lower troposphere (Fig. 5a). For the PRD in
191 September 2019, the anomalous high covering almost the entire China along with the
192 anomalous low over East China Sea generates northerly wind anomalies in the lower
193 troposphere over eastern China, which tend to transport polluted air from northern China and
194 weaken the inflow of oceanic clean air (Fig. 6). The temperature increase is much more
195 significant in the upwind regions as compared to PRD, suggesting that the strong regional
196 transport could be the primary reason causing this severe O₃ pollution event of PRD.

3.2 Physical and chemical mechanisms leading to regional ozone pollution

To further explore the mechanisms of meteorological changes leading to the severe O₃ pollution over the four typical polluted regions in China, contributions of individual chemical and physical processes to O₃ variations are quantified based on the IPR analysis from GEOS-Chem simulations and summarized in Table 1.

Consistent with the meteorological anomalies analyzed above, high temperature and low RH meteorological conditions in NCP are conducive to the photochemical production of O₃. During the polluted month over NCP, the chemical production of tropospheric O₃ is higher than the long-term average by 2.36 Gg day⁻¹, while the horizontal transport also contributes to the increase in O₃ mass by 1.58 Gg day⁻¹ (Table 1). Due to the enhanced northwesterly winds, the import of O₃ mass from the north and west of NCP was increased by 1.80 and 0.62 Tg, respectively (Table 2). In YRD, the chemical production (2.38 Gg day⁻¹) is also the dominant process that drives the O₃ concentration increase during the most severe polluted month, associated with the warm and dry conditions. Therefore, the anomalous chemical production is the major process that induced O₃ pollution in NCP and YRD during the most severe polluted months.

Different from NCP and YRD, horizontal transport is the main process that caused O₃ pollution in SCB and PRD during the most severe ~~polluted~~ months. It contributes to the rate of increase in O₃ mass by 5.10 and 6.67 Gg day⁻¹, respectively, over SCB and PRD, while other processes tend to decrease the O₃ mass (Table 1). Due to the anomalous northerly winds over SCB, more O₃ is transported into SCB from north (by 4.02 Tg), and the anomalous northeasterly winds enhance the O₃ transport from the north and east of PRD by 1.97 and 1.09

219 Tg, respectively, leading to the increase in O₃ concentrations over SCB and PRD during the
220 most severe ~~polluted~~ months relative to the climatological averages (Table 2). Note that, the
221 chemical production of tropospheric O₃ decreased in SCB and PRD during the most severe
222 ~~polluted~~ months. It could have been biased by the relatively coarse model resolution in this
223 study (2° latitude × 2.5° longitude), since that the SCB and PRD for calculating the chemical
224 and physical processes only cover limited grid boxes. Further studies should be performed
225 using a model with finer resolution or a nested simulation method.

226 **3.3 Historical and future changes in the meteorological conditions**

227 O₃ pollution has deteriorated in China during recent decades, which could be related to
228 the changes in meteorological conditions. Time series of T2m and RH anomalies in the polluted
229 months during the 1980–2019 and frequencies of high T2m and low RH months during 1980–
230 1999 and 2000–2019 over the four polluted regions in China based on ERA5 reanalysis data
231 are shown in Figure 7. Due to climate change, both the high temperature and low RH conditions
232 in NCP, YRD, SCB and PRD all increased during the past four decades (2000-2019 versus
233 1980-1999). Based on the analysis showing that chemical production is the dominant process
234 of the most severe O₃ pollution in NCP and YRD, the increases in the frequency of high
235 temperature and low RH indicate that severe O₃ pollution in both NCP and YRD has become
236 more frequent under the historical climate change. In SCB and PRD, the most severe O₃
237 pollution is more related to changes in regional transport. Similar to the analyzing method used
238 in previous studies (Li et al., 2018; Yang et al., 2021), the SLP and 500 hPa GPH over East
239 Asia and Western Pacific in the same month of each year similar to those during the most severe
240 ~~polluted~~ months in both SCB and PRD have increased (2000-2019 versus 1980-1999) (Figure

241 8), together with the more frequent hot and dry conditions (Figure 7), leading to the increases
242 in severe O₃ pollution in SCB and PRD during 1980–2019.

243 Many studies have reported that future climate change will have significant influences
244 on O₃ pollution in China through changing meteorological factors (e.g., Li et al., 2023; Wang
245 et al., 2022). Here, the frequencies of extreme months with high T2m and low RH and the
246 frequencies of extreme months with SLP and 500 hPa GPH that have moderate to high
247 correlation to those in the most polluted months in the four regions of China, under the
248 sustainable (SSP1-2.6) and high forcing (SSP5-8.5) scenarios during 2021–2100 from CMIP6
249 multi-model results, are presented in Figures 9 and 10, respectively. Unlike the historical
250 changes in the meteorological conditions that caused the severe O₃ pollution through chemical
251 production and regional transport, future variations in meteorological conditions conducive to
252 the severe O₃ pollution are more related to the global warming process that enhances the O₃
253 production in China. The frequencies of months with anomalous high temperature show
254 obvious upward trends in both SSP1-2.6 and SSP5-8.5 scenarios over the four regions, and the
255 increasing trends in SSP5-8.5 are much more significant than in SSP1-2.6. Frequencies of low
256 RH months show downward trends in NCP, YRD and SCB, especially under SSP5-8.5, while
257 there is an upward trend in PRD. Note that the trends in frequencies of low RH months are
258 much less significant than in high temperature months. The frequencies of extreme months
259 with SLP and 500 hPa GPH that are similar to those in the most severe O₃ pollution months in
260 the four regions do not show significant trends in the SSPs. Hence, the future climate change
261 may aggregate O₃ pollution in China by enhancing the chemical production related to
262 temperature increases. The O₃ pollution exacerbation is projected to be less significant in the

263 sustainable scenario due to the moderate temperature increase than in the high forcing scenario,
264 suggesting that the sustainable scenario is the optimal path to retaining clean air in China. High
265 anthropogenic radiative forcing will not only lead to slow economic growth and climate
266 warming, but also result in the environmental pollution.

267 **4. Conclusions and Discussions**

268 O₃ pollution harms ecosystems and human health. In recent years, near-surface O₃
269 concentrations in many regions of China have been increasing considerably. Base on
270 observational O₃ data, ERA5 reanalysis data and GEOS-Chem model simulations,
271 meteorological characteristics conducive to ~~extremesevere~~ O₃ pollution in different regions of
272 China are investigated in this study. Contributions from various chemical and physical
273 processes inducing O₃ pollution are quantified using ~~the an integrated process rate (IPR)~~
274 analysis method. Furthermore, historical changes and future trends of meteorological
275 conditions leading to severe O₃ pollution in China are explored based on the meteorological
276 reanalysis and CMIP6 multi-model future predictions, which is of great implication for the
277 mitigation and prevention of O₃ pollution over China.

278 In this study, June 2018, July 2017, July 2015 and September 2019 are identified as the
279 most severe O₃ pollution months influenced by meteorological factors over NCP, YRD, SCB
280 and PRD, respectively. Severe O₃ pollution in June 2018 over NCP and in July 2017 over YRD
281 is mainly due to enhanced chemical production related to hot and dry conditions. The chemical
282 production of O₃ in the ~~most~~ severe ~~polluted~~ months over NCP and YRD are 2.36 Gg day⁻¹ and
283 2.38 Gg day⁻¹, respectively, higher than the climatological averages. Different from NCP and
284 YRD, regional transport is the main process leading to the high O₃ concentration in SCB and

285 PRD during the respective severely polluted months, which contributes to the rate of increase
286 in O₃ mass by 5.10 and 6.67 Gg day⁻¹, respectively, over SCB and PRD. During the most
287 ~~severely polluted~~ months, related to large-scale circulation patterns, anomalous northerly winds
288 transport more O₃ into SCB from north, and anomalous northeasterly winds enhance the O₃
289 transport from the north and east into PRD.

290 Over the last four decades (2000-2019 versus 1980-1999), the frequencies of high
291 temperature and low RH increased, indicating that O₃ pollution in both NCP and YRD has
292 become more frequent under the historical climate change. In SCB and PRD, the occurrence
293 of atmospheric circulation patterns similar to those during the most polluted months in both
294 SCB and PRD has increased, together with the more frequent hot and dry conditions, leading
295 to the increases in severe O₃ pollution in SCB and PRD during 1980–2019. In the future (by
296 2100), the frequencies of months with anomalous high temperature show obvious upward
297 trends in both sustainable (SSP1-2.6) and high forcing (SSP5-8.5) scenarios over the four
298 regions, and the increasing trends in SSP5-8.5 are much more significant than in SSP1-2.6.
299 This suggests that high anthropogenic radiative forcing will not only lead to slow economic
300 growth and climate warming, but also likely result in environmental pollution issues. The
301 sustainable scenario is the optimal path to retaining clean air in China.

302 There are some limitations and uncertainties in this work that can be further addressed in
303 future studies. For example, the model only captures the high O₃ concentrations in July 2015
304 in Chengdu among its top three polluted months. It is probably because the emissions are kept
305 at 2017 levels during the simulations. The high O₃ anomalies in July 2016 and July 2018 are
306 more likely influenced by the interannual changes in local precursor emissions in the

307 background of country-level increases in O₃ concentration in recent years. However, we also
308 can not rule out the possible inaccuracy in the model simulations to interpret severe O₃
309 pollution events in the SCB, which deserves further investigation with multi-model simulations.
310 In addition, this study focuses on the most extreme O₃ pollution in several polluted areas of
311 China. However, many other meteorological conditions can also cause O₃ pollution, although
312 they may not be as extreme as the cases analyzed in this study, which requires comprehensive
313 analysis for individual regions in future studies. Although the historical changes in the
314 meteorological patterns causing severe O₃ pollution are in accordance with the elevated O₃
315 levels in China in the recent decade, the quantitative analysis of meteorological impacts needs
316 full consideration of factors leading to O₃ pollution, including changes in anthropogenic and
317 natural emissions of its precursors, O₃ chemical regime, other meteorological factors conducive
318 to O₃ pollution, and stratosphere-troposphere exchange.

585 **Table 1.** Anomalies in net rate of changes in tropospheric O₃ mass (Gg day⁻¹) over NCP (115°–
 586 120°E, 38°–44°N), YRD (120°–125°E, 28°–32°N), SCB (102.5°–105°E, 30°–32°N) and PRD
 587 (110°–115°E, 22°–26°N) due to physical and chemical processes in the most polluted months
 588 (June 2018, July 2017, July 2015 and September 2019, respectively) relative to the same
 589 months averaged during 1981–2019.

590

	Beijing	Shanghai	Chengdu	Guangzhou
Chemical reaction	2.36	2.38	-2.80	-1.52
Horizontal transport	1.58	-1.18	5.10	6.67
Diffusion and dry deposition	0.29	0.24	-0.73	-0.93

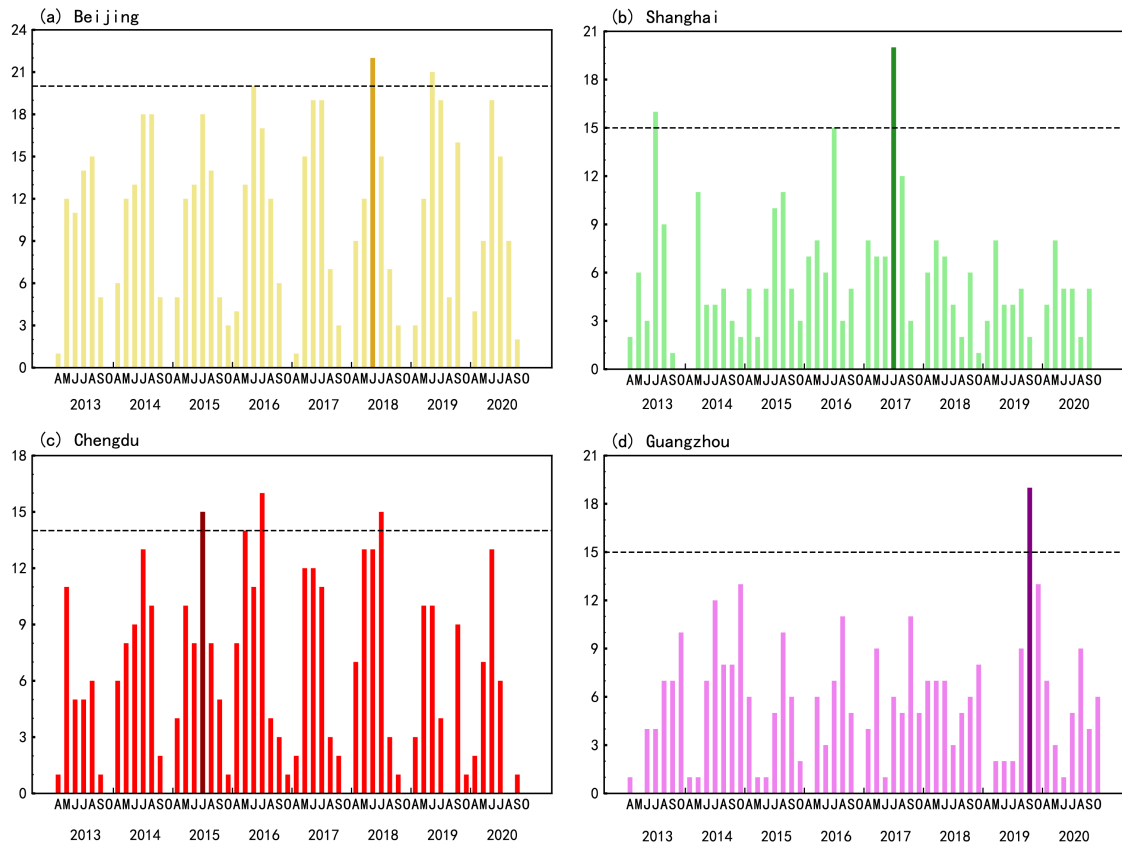

591

592

593 **Table 2.** Horizontal mass transport (Tg) of O₃ from the surface to 500 hPa over NCP (115°–
594 120°E, 38°–44°N), YRD (120°–125°E, 28°–32°N), SCB (102.5°–105°E, 30°–32°N) and PRD
595 (110°–115°E, 22°–26°N) areas in the severe polluted months (June 2018, July 2017, July 2015
596 and September 2019, respectively) and averaged over the same months of a year during 1981–
597 2019, as well as their differences. Positive values indicate incoming fluxes and negative values
598 indicate outgoing fluxes.
599

	Polluted month	Average	Anomalies
NCP			
North	4.43	2.62	1.80
South	-2.22	-1.42	-0.81
East	-12.30	-11.31	-0.99
West	11.83	11.20	0.62

608

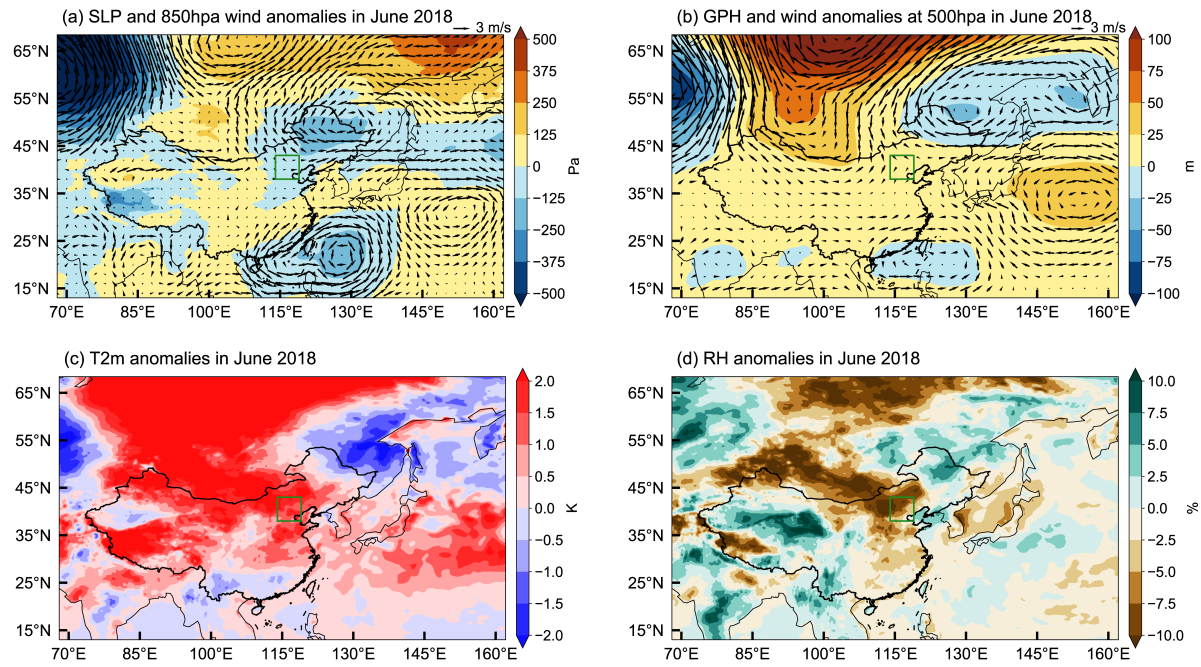

Figure 1. Time series of frequencies of severe O₃ pollution days (defined by daily maximum of 8-h average ozone (MDA8-O₃) concentration greater than 160 $\mu\text{g m}^{-3}$) in Beijing, Shanghai, Chengdu and Guangzhou (a–d) from April to October during 2013–2020. The dark-colored bars represent the most severe month (second most for Chengdu) that has the highest frequency of O₃ pollution days for the individual cities.

609

610 **Figure 2.** Spatial distribution of monthly O₃ concentration anomalies (part per billion, ppb) in
 611 June 2018 (a), July 2017 (b), July 2016 (c), July 2015 (d), July 2018 (e) and September 2019
 612 (f) relative to 40-year (1980–2019) monthly average for June (a), July (b, c, d, e) and September
 613 (f), simulated in the GEOS-Chem model. The green boxes mark NCP (a), YRD (b), SCB (c, d,
 614 e) and PRD (f).

615

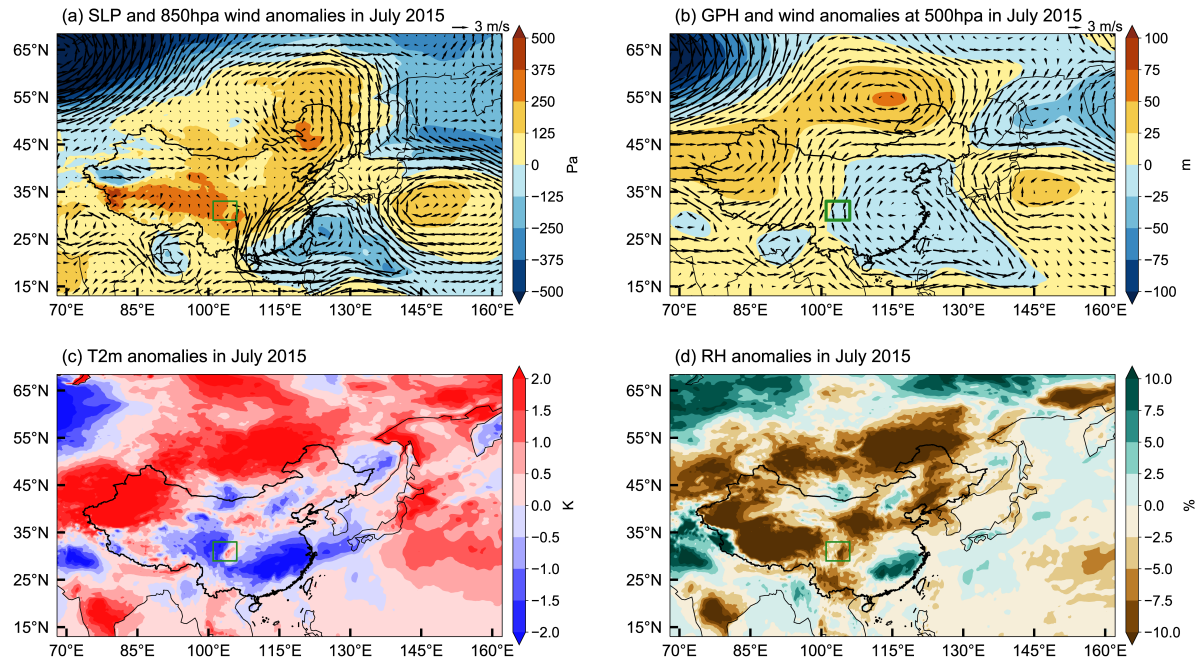

616

617 **Figure 3.** Anomalies in sea level pressure (SLP, Pa, shaded) and 850 hPa winds (m s^{-1} , vector)
 618 (a), geopotential height (GPH, m, shaded) and winds at 500 hPa (m s^{-1} , vector) (b), 2-meter air
 619 temperature (T2m, K) (c) and surface relative humidity (RH, %) (d) in June 2018 relative to
 620 the 40-year (1980–2019) monthly average for June. The green boxes mark NCP.
 621

622
 623
 624
 625

Figure 4. Same as Figure 3 but for the monthly anomalies in July 2017. The green boxes mark YRD.

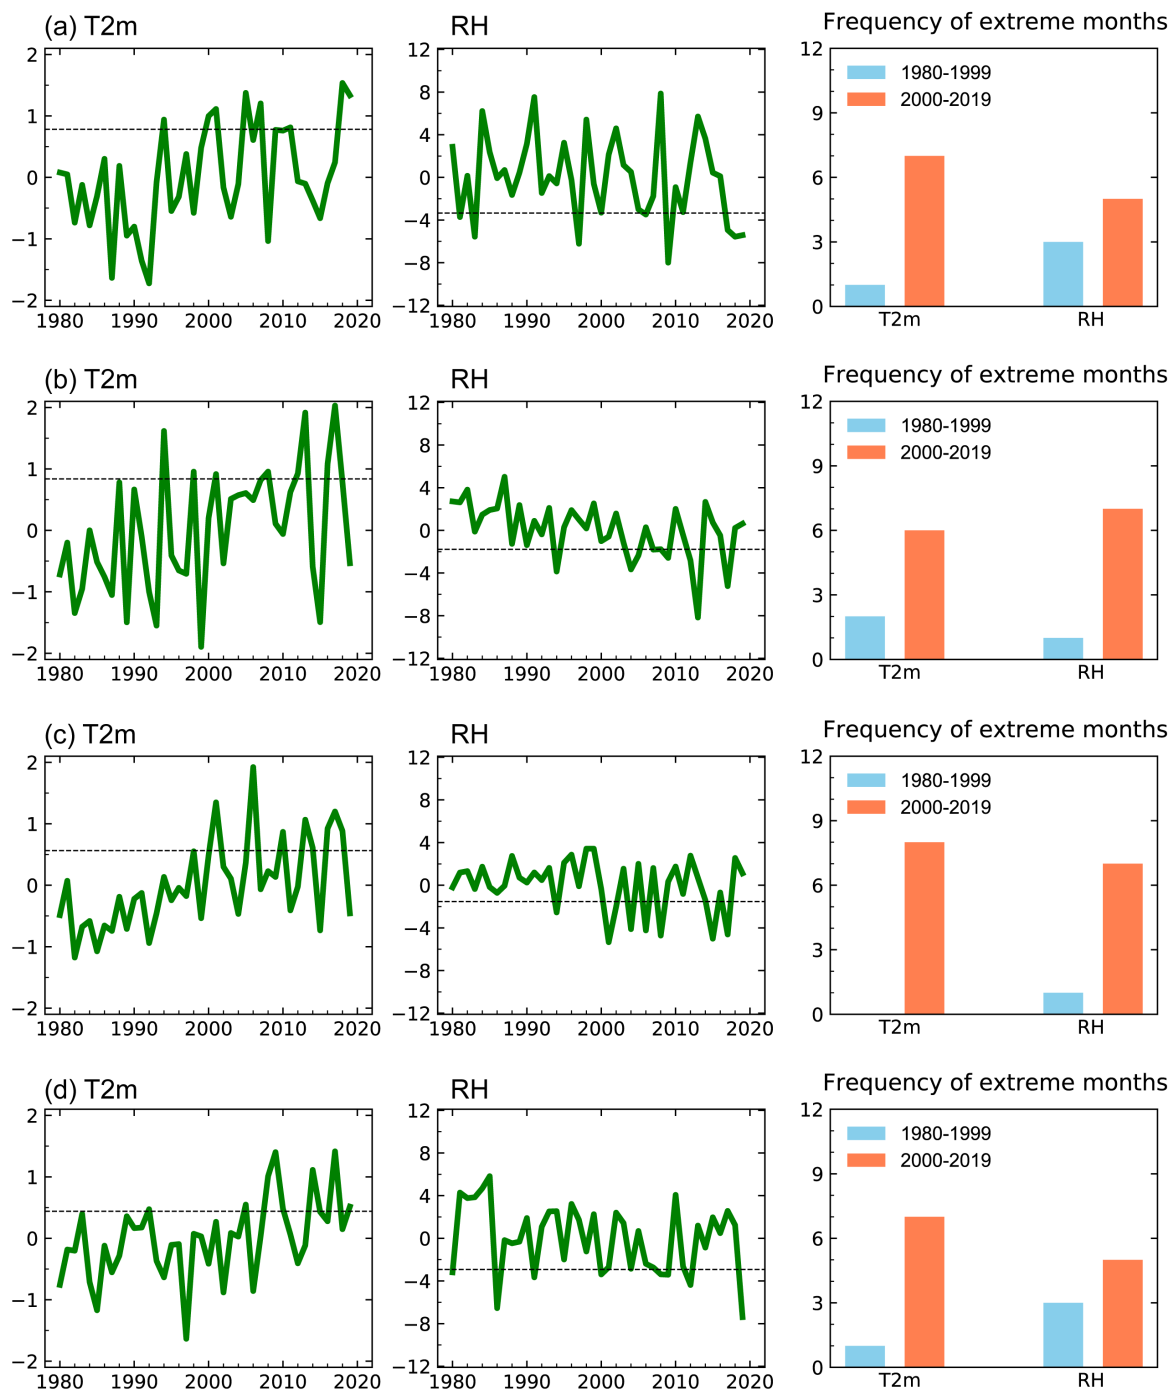

626
 627
 628
 629

Figure 5. Same as Figure 3 but for the monthly anomalies in July 2015. The green boxes mark SCB.

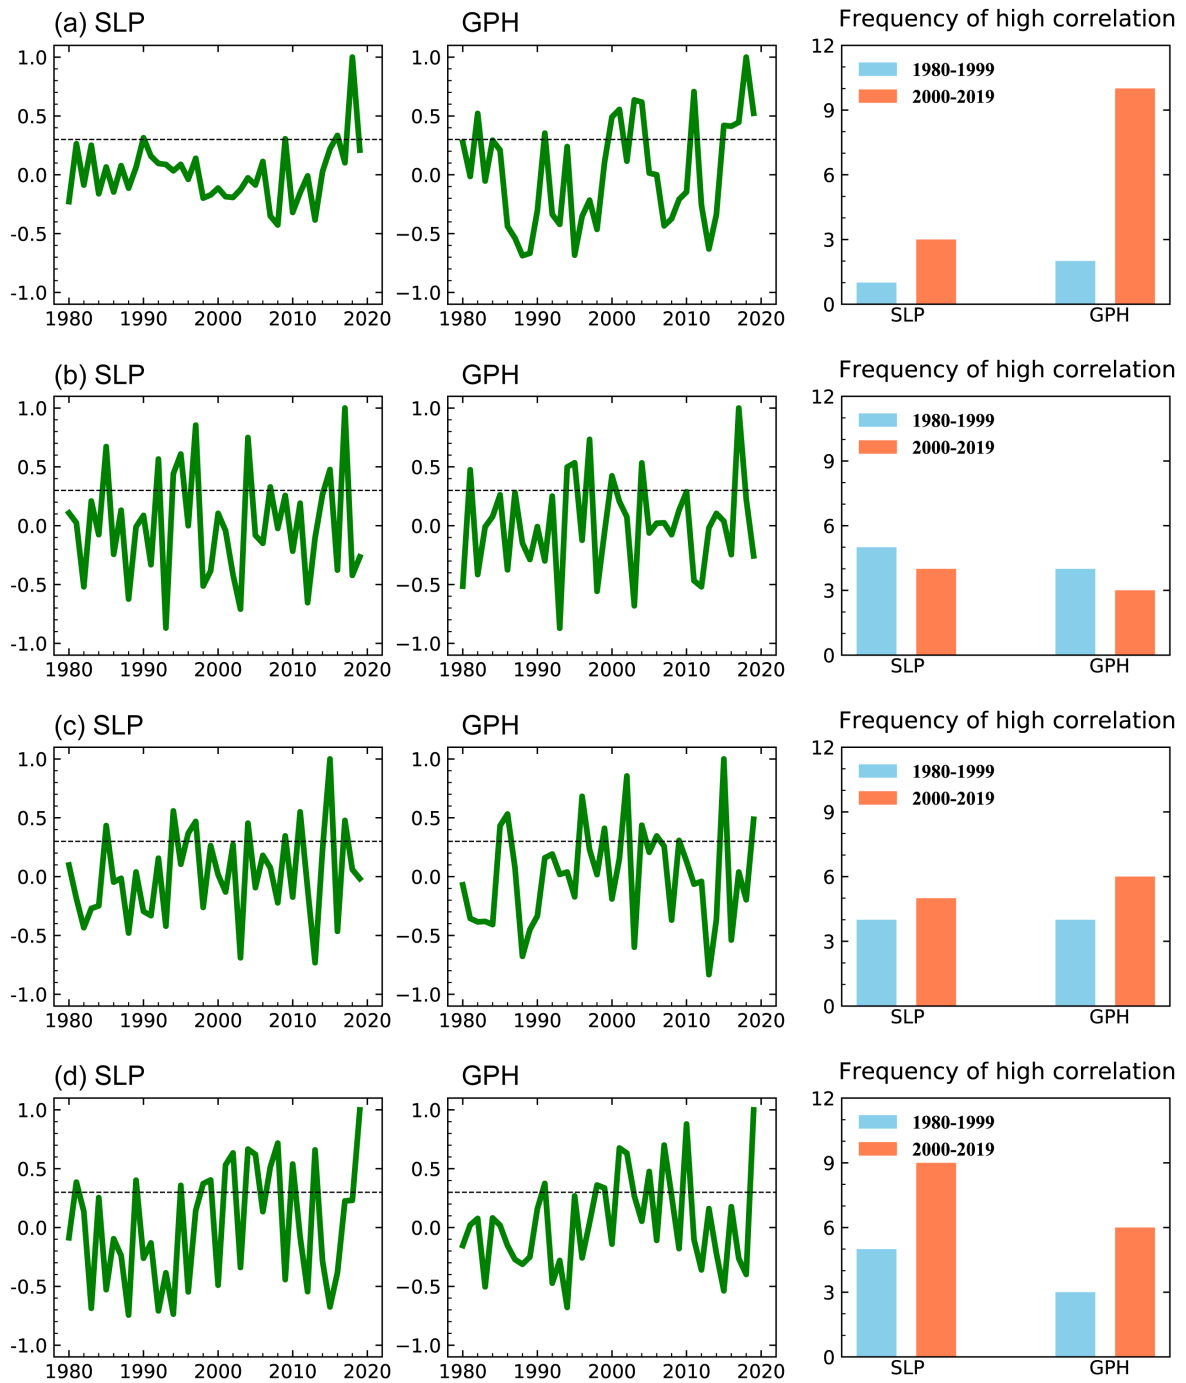

630

631 **Figure 6.** Same as Figure 3 but for the monthly anomalies in September 2019. The green boxes
 632 mark PRD.

633

634 **Figure 7.** Time series of anomalies of T2m (K, left) and surface RH (%), middle) over (a) NCP
 635 (115°–120°E, 38°–44°N), (b) YRD (120°–125°E, 28°–32°N), (c) SCB (102.5°–105°E, 30°–
 636 32°N) and (d) PRD (110°–115°E, 22°–26°N) in the most polluted months during 1980–2019.
 637 The dotted lines mark the 80th percentile of the distributions for T2m and 20th percentile for
 638 RH. The bar charts (right) represent the frequency of T2m above the 80th percentile and RH
 639 anomalies below the 20th percentile during 1980–1999 (blue) and 2000–2019 (orange).

640

641 **Figure 8.** Time series of spatial correlation in SLP (left) and 500 hPa GPH (middle) anomalies
 642 over East Asia and Western Pacific (EAWP, 90°–160°E, 20°–60°N) in June 2018 (a), July 2017
 643 (b), July 2015 (c) and September 2019 (d) and those in the same targeted month of each year
 644 during 1980–2019. The dotted lines mark the correlation coefficient of +0.3, which is used as
 645 a threshold to define “moderate to high correlation”. The bar chart (right) represents the
 646 frequency of SLP and 500 hPa GPH anomalies in the same months during 1980–1999 (blue)
 647 and 2000–2019 (orange) that have moderate to high correlation (>0.3) with those in June 2018,
 648 July 2017, July 2015 and September 2019.

649

650

651 **Figure 9.** Frequencies of extreme months with T2m or RH anomalies exceeding the 80th
 652 percentile or below the 20th percentile of the distributions over NCP (115°–120°E, 38°–44°N)
 653 (a, b), YRD (120°–125°E, 28°–32°N) (c, d), SCB (102.5°–105°E, 30°–32°N) (e, f) and PRD
 654 (110°–115°E, 22°–26°N) (g, h) in each 10-year interval during 2021–2100 under two SSPs
 655 future scenarios of 13 CMIP6 models. The two SSPs are SSP1-2.6 and SSP5-8.5. The slope
 656 and P values of the linear regression during 2021–2100 are shown in the upper right of each
 657 panel.

658

659 **Figure 10.** Frequencies of extreme months with SLP and 500 hPa GPH that have moderate to
 660 high correlation (>0.3) to those in June 2018 (a, b), July 2017 (c, d), July 2015 (e, f) and
 661 September 2019 (g, h) in each 10-year interval during 2021–2100 under two SSPs future
 662 scenarios of 13 CMIP6 models. The two SSPs are SSP1-2.6 and SSP5-8.5. The slope and P
 663 values of the linear regression during 2021–2100 are shown in the upper right of each panel.
 664 The linear trends of SLP and GPH in each model grid were removed before the correlation
 665 coefficient is calculated.
