Abstract.

Dimethyl sulfide (DMS), a gas produced by phytoplankton, is the largest source of atmospheric sulfur over marine areas. DMS
15 undergoes oxidation in the atmosphere to form a range of oxidation products, out of which ~~methanesulfonic acid (MSA) and~~
sulfuric acid (SA) ~~are~~ is well-known for participating in the formation and growth of atmospheric aerosol particles, and the
same is also presumed for methanesulfonic acid (MSA). Recently, a new oxidation product of DMS, hydroperoxymethyl
thioformate (HPMTF) was discovered and later also measured in the atmosphere. Little is still known about the fate of this
compound and its potential to partition to the particle phase. In this study, we present a full year (2020) of concurrent gas- and
20 particle-phase observations of HPMTF, MSA, SA and other DMS oxidation products at the Zeppelin Observatory (Ny-
Ålesund, Svalbard) located in the Arctic. This is the first time HPMTF has been measured in Svalbard and attempted to be
observed in atmospheric particles. The results show that gas-phase HPMTF concentrations largely follow the same pattern as
MSA during the sunlit months (April–September), indicating production of HPMTF around Svalbard. However, HPMTF was
not observed in significant amounts in the particle phase, despite high gas-phase levels. Particulate MSA and SA were observed
25 during the sunlit months, although the highest median levels of particulate SA were measured in February, coinciding with the
highest gaseous SA levels with assumed anthropogenic origin. We further show that gas- and particle-phase MSA and SA are
coupled in May–July, whereas HPMTF lies outside of this correlation due to the low particulate concentrations. These results

provide more information about the relationship between HPMTF and other DMS oxidation products in a part of the world where these have not been explored yet, and about HPMTF's ability to contribute to particle growth and cloud formation.

30 **1 Introduction**

Oceanic dimethyl sulfide (DMS) is one of the largest contributors to atmospheric sulfur (17.6-34.4 Tg S yr⁻¹, Lana et al., 2011) and the most important source in marine areas. Up to The global natural DMS emissions vary largely between the southern and the northern hemisphere. On a global average, around 42% of ~~global the~~ natural sulfur emissions can be traced back to DMS (Simó, 2001), which is equal to at least 50% of the total amount from anthropogenic sources (Simó, 2001; Klimont et al., 2013). DMS is a gas produced by algal communities when sea surface temperatures and sunlight conditions are favorable for primary production (Liss et al., 1993). When emitted to the atmosphere, DMS is oxidized to a range of gas-phase (g) sulfuric chemical species (Yin et al., 1990; Barnes et al., 2006). Some of these have a low enough volatility to condense to the particle phase (p), and have been shown to be able to participate in new particle formation (NPF, e.g. Lovejoy et al., 2004; Beck et al., 2021; Rosati et al., 2021) or contribute to the growth of aerosol particles. This has implications for the particles' ability to act as cloud condensation nuclei (CCN, see e.g. review by Ayers and Gillett, 2000), i.e. to form clouds in the atmosphere.

Clouds are important for the Earth's climate as they influence the radiation balance. In the Arctic, the common cloud type is low-level and mixed-phase (consisting of both liquid droplets and ice crystals) stratocumulus (e.g., Shupe, 2011; Tjernström et al., 2012). Stratocumulus clouds are considered to be an important factor (Serreze and Barry, 2011; Wendisch et al., 2019) in the rapid increase of average surface temperature that has been observed in the Arctic region during the last decades (two to four times larger than the global average of +1°C compared to preindustrial times) (Rantanen et al., 2022). A more detailed understanding of aerosol and CCN chemistry, sources and seasonal variability in the Arctic is therefore needed to be able to make better predictions of future climate change (Schmale et al., 2021).

The oxidation scheme of DMS is highly complex, and represented in a poor or very limited manner in many atmospheric chemistry models. The scheme can however be described as mainly a two-route mechanism (Fig. 1): the addition pathway, where either a hydroxyl (OH), nitrate (NO₃) or halogen radical (e.g. bromine oxide, BrO, or chlorine, Cl) is added,

or hydrogen abstraction pathway, in which a hydrogen (H) atom is removed. Main products in the abstraction pathway are the inorganic compound sulfuric acid (SA, H₂SO₄) (via sulfur dioxide, SO₂ or methanesulfonate (CH₃SOOO[•]), and sulfur trioxide, SO₃), and the organic compound methanesulfonic acid (MSA, CH₃SO₃H). The first stable product in the addition pathway is 55 dimethyl sulfoxide (DMSO, CH₃SOCH₃), followed by methanesulfinic acid (MSIA, CH₃S(O)OH) (Barnes et al., 2006). MSIA can either undergo reactive uptake to the particle phase or oxidize further via methanesulfonate to MSA and SA, although the abstraction pathway is normally considered more important for the production of these two species. The different oxidation pathways further depend on the ambient temperature, where the abstraction mechanism has been shown to be favored at higher temperatures and the addition mechanism at lower temperatures (Hoffmann et al., 2021; Wollesen de Jonge et al., 2021). It is 60 therefore plausible that the addition pathway is of higher importance in the Arctic, where temperatures are generally low.

Recently, a new oxidation product of DMS was discovered in situ during an aircraft campaign by Veres et al. (2020), hydroperoxymethyl thioformate (HPMTF, C₂H₃OSO₂H) (see Fig. 1). This compound is produced via the H-abstraction pathway, leading to the methylthiomethyl-peroxy radical (CH₃SCH₂OO[•]), quickly followed by an H-shift to form intermediate radicals and then HPMTF (Berndt et al., 2019; Wu et al., 2015, 2022). It was found to be ubiquitous (frequently > 50 ppt) in 65 the lowest kilometers of the troposphere in both spring (April–May) and autumn (September–October), and was detected up to 14 km altitude over large parts of the world’s oceans between 80°N and 85°S latitudes. It was further shown to be readily removed through cloud uptake and there was no apparent relationship between HPMTF and MSA in the gas phase. The study also speculated that HPMTF could contribute to NPF or particle growth.

Figure 1. Simplified oxidation scheme of dimethyl sulfide (DMS) in the atmosphere. DMS is produced by microbiological activity in the ocean and emitted to the atmosphere, where it is oxidized through two main routes: 1) *addition* of a radical to produce dimethyl sulfoxide (DMSO) and methanesulfinic acid (MSIA), and further via methanesulfonate (CH_3SO_3) to methanesulfonic acid (MSA) and/or sulfuric acid (SA) either via sulfur dioxide (SO_2) and sulfur trioxide (SO_3) or via methanesulfonate and SO_3 ; 2) *abstraction* of a hydrogen (H) atom to produce MSA, hydroperoxymethyl thioformate (HPMTF; marked with a box) and/or SA via SO_2 and SO_3 . The figure was created using information from Barnes et al. (2006) and R. Wu et al. (2015). The addition pathway is shown in orange arrows, the abstraction pathway in green arrows, and DMS oxidation products that are part of both pathways are indicated with black arrows.

Since the discovery of HPMTF, it has inspired several new studies (e.g., Vermeuel et al., 2020; Khan et al., 2021; Novak et al., 2021; Wollesen de Jonge et al., 2021).

Fung et al., (2022) developed an understanding of where certain DMS oxidation products can dominate in the world due to variation in dominating DMS oxidation mechanisms. This clarified why the highest HPMTF concentrations were found over tropical oceans with a high degree of OH oxidation through the abstraction pathway, and lower over equally microbiologically productive waters with a relatively higher degree of oxidation through the addition pathway, such as the North Atlantic and Canadian Arctic (Veres et al., 2020; Fung et al., 2022).

Wollesen de Jonge et al. (2021) showed in a model study based on ~~a~~ chamber study-experiments that HPMTF accumulates in the gas phase during cloud-free conditions, but does not significantly partition to the particle phase and is unlikely to contribute to NPF. However, it was speculated in this study that HPMTF could indirectly contribute to growth of aerosol particles through increased aqueous-phase production of sulfate (SO_4^{2-}). This does not necessarily happen where DMS concentrations are locally high, as HPMTF might be transported large distances before taking part in these partitioning and oxidation processes, depending on OH concentrations, cloud occurrence and ambient temperatures (Vermeuel et al., 2020; Khan et al., 2021; Novak et al., 2021).

In the Arctic, where aerosol-climate interactions are especially poorly understood (Schmale et al., 2021) and DMS emissions are expected to increase in the near future due to higher sea temperatures (Land et al., 2014), more measurements of HPMTF during different seasons and atmospheric conditions could help to improve our knowledge of DMS oxidation and aerosol formation in this region. Hence, in this study we present observations of atmospheric DMS oxidation products, including HPMTF, from the Zeppelin Observatory in Ny-Ålesund, Svalbard (79 °N) throughout the year of 2020. The

measurements were made using a high-resolution time-of-flight chemical ionization mass spectrometer with a filter inlet for gases and aerosols (FIGAERO-CIMS, Lopez-Hilfiker et al., 2014) and iodide as the reagent ion. With the FIGAERO-CIMS, gas- and particle-phase measurements can be made concurrently, which provides a unique possibility to study sources and phase-transition mechanisms at time resolutions of seconds to hours. In this project, we were able to study this over all seasons. To our knowledge, this is the first time ambient HPMTF has been measured in Svalbard and the first time HPMTF detection in the particle phase has been attempted in the ambient atmosphere.

2 Methods

2.1 The measurement site

The results presented in this study were derived from measurements made during the Ny-Ålesund Aerosol Cloud Experiment (NASCENT) campaign in 2019–2020. The data presented in this study was collected between 2020-01-01 and 2020-12-17 (where entire August is missing due to malfunctioning instrumentation) at the Zeppelin Observatory atop Mt. Zeppelin (474 m a.s.l), 2 km south of Ny-Ålesund, Svalbard (78.9° N, 11.9° E) (Platt et al., 2022), see Fig. 2. A detailed description of the entire campaign and overview on first results can be found in Pasquier et al. (2022). Here follows a description of the instrumentation and methods used for this particular study. Our FIGAERO-CIMS setup at the Zeppelin Observatory yielded two types of datasets: one on the aerosol particle composition that acted as CCN or INPs (also termed cloud residuals, reported in Gramlich et al., (2022)), and one on the ambient aerosol particle and gas phase composition, which is reported in this study.

2.2 Chemical composition of gaseous and particulate atmospheric compounds

The chemical composition of atmospheric compounds in the gas-, particle-, and cloud phase was determined at molecular level with a FIGAERO-CIMS (Aerodyne Research Inc., USA), with iodide (I^-) as the reagent ion. This setup allows for detection of mainly polar and oxygenated organic compounds, due to the clustering mechanism of I^- (Lee et al., 2014). The FIGAERO-

125 CIMS recorded data every second (1 Hz) until mid-February, and every two seconds (0.5 Hz) during the rest of the year. The gas phase was sampled with a ¼ inch outer diameter (O.D.) and ~5 m long polytetrafluoroethylene (PTFE) tubing sticking out ~50 cm through a hole in the northern wall of the Zeppelin Observatory and with the tip protected by an attached funnel. The aerosol particles were sampled through a gently heated whole-air inlet, [which follows the guidelines of the World Calibration Centre for Aerosol Physics \(WCCAP\) at the Leibniz Institute for Tropospheric Research, Germany](#) (Wiedensohler et al., 2013).
130 [The inlet \(which samples all aerosol and cloud particles smaller than approx. 40 µm at wind speeds up to 20 m s⁻¹ \(Weingartner et al., 1999\)\), and is located](#) at ~480 m a.s.l.. The aerosol inlet was connected to the FIGAERO-CIMS by stainless steel tubing (O.D. ½ inch, length: ~6 m) through a three-way switching valve. During cloudy conditions, defined as when the visibility [\(visibility sensor from Belfort, Model 6400, at approx. 480 m a.s.l.\)](#) at the observatory was ≤ 1000 m ([World Meteorological Organization definition of fog](#) (WMO, 2018)), the three-way valve switched to sampling cloud particles (> 6–7 µm in diameter)
135 through a ground based counterflow virtual impactor (GCVI; Brechtel Manufacturing Inc., USA, Model 1205) inlet (Karlsson et al., 2021). After drying of the cloud particles, the chemical composition of the remaining cloud residuals was measured with FIGAERO-CIMS. The ~~first~~ results of this analysis are reported in Gramlich et al. (2022).

The FIGAERO inlet is designed in a way that enables alternating gas- and particle-phase measurements (Lopez-Hilfiker et al., 2014; Thornton et al., 2020). Particles are deposited on a PTFE filter for a specified period of time, during which
140 gaseous compounds are sampled via the gas-phase inlet. When enough particulate matter has been collected onto the filter, the gas-phase inlet is blocked and the filter moved into place in front of the instrument's inlet to enable particle-phase analysis. This mechanism makes it possible to compare the two phases at the same point in time.

During NASCENT, a FIGAERO-CIMS measurement cycle was 210 min (Fig. A1 and Table A1), where the first 150 min were made up by gas-phase measurements: 3x40 min of ambient atmosphere measurements and 2x15 min of background
145 measurements with ultra-pure air (“zero air”) from a generator (Teledyne API, USA, Model 701H), and simultaneous particle deposition on the PTFE filter. The last 60 min of the measurement cycle consisted of particle desorption, where the compounds collected on the filter were evaporated by a stream of ultrapure nitrogen (N₂) from a generator (Peak Scientific, UK, Model NG5000), gradually heated during 20 min from room temperature to ~200°C. The temperature was then kept at this level for another 20 min, allowing all compounds to evaporate completely off the filter and their corresponding signal return to

150 background levels. This means that compounds that are not volatile enough to evaporate at $\leq 200^{\circ}\text{C}$ (e.g. sea salt) (Rasmussen et al., 2017) or that decompose at these temperatures are not directly measurable by the FIGAERO-CIMS. Particle-phase blanks (background signal) were collected every third cycle by sampling through another particle filter, which removed particles from the sampling flow upstream of the sample filter.

The desorbed compounds were ionized by I^- and separated by their time-of-flight (ToF) in the mass spectrometer. 155 The mass-to-charge ratio (m/z) of each compound was determined from the ToF by using known ions as calibrants, from which their molecular compositions were determined.

2.2.1 Data processing

The FIGAERO-CIMS raw data were pre-averaged to 30 s time resolution. After mass calibration, the signals were normalized to the sum of the reagent ion signal (I^- , m/z : 126.905) and the cluster of iodide and water (H_2OI^- , m/z : 144.916). Inclusion of 160 H_2OI^- in the normalization accounts for changes in the water vapor content of the ambient air, and the humidity difference between the ambient gas-phase measurement compared to the particle desorption using dry N_2 , which influences sensitivity of iodide adduct ionization (Lee et al., 2014).

The time period between two particle heatings was identified as the “sampling period”, during which the gas-phase measurements took place (see Fig. A1 and Table A1). The sampling period was usually interrupted twice by two background 165 measurements of 15 min each. The 30 first data points (~15 min) of the gas-phase signal were removed from each sample segment, since the signal took some time to stabilize after each shift (as is visible from the HNO_3I^- signal in Fig. A1). Similarly, to assure no inclusion of background signal in the averaged data of the sample, the 15 last data points (~7.5 min) were removed as well. Around 18 min of gas-phase data were used for analysis from each sample segment (represented by the green circles in Fig. A1). The segments were averaged individually, and the segment averages within the same sampling period were in turn 170 averaged to a single data point for that period (dark-green triangles in Fig. A1). The average background signal (orange triangles in Fig. A1) of each sampling period was calculated in the same way, where only three data points (1.5 min) at the end of each background period were used (yellow diamonds in Fig. A1). The background signal was thereafter subtracted from the sample signal to give two sets of timeseries: 1) a background-subtracted average of the sampling period (using the values represented by the dark-green and orange triangles in Fig. A1), which was used for comparison to the particle-phase signal of

175 the same period; 2) background-subtracted data with the full time-resolution of 30 s, to use when not comparing to particle-phase data. The FIGAERO-CIMS was not calibrated to any known substance, and the unit of the gas-phase data is [number of detected ions s⁻¹], i.e. not atmospheric concentration. The data can be used for qualitative analysis and for relative quantification between measured gaseous compounds. To achieve atmospheric concentrations, calibration of the FIGAERO-CIMS with known gaseous compounds is recommended for future studies.

180 The particle-phase signal was calculated as the signal integrated across time from the start of the heating (when the temperature starts ramping up) until the end of the desorption time (when the temperature starts decreasing again) (see the red line in Fig. A1). The signal was thereafter normalized to the sampled volume, as the sampling time could sometimes differ between samples. Particle backgrounds were calculated as the interpolated time-integrated signal between two consecutive particle blanks, which was in turn subtracted from the time-integrated particle sample signal. Handling blanks were not needed
185 as the FIGAERO operated automatically. However, the first particle sample after the filter had been exchanged was excluded from the analysis due to the risk of contamination. Since the particle-phase data was time-integrated and normalized to the sampled volume, the unit is therefore [number of detected ions per liter of sampled air], and the data can be used in the same way as the gas-phase data (qualitative analysis and for relative quantification between measured particulate compounds). More details on the processing of the particle-phase data is given by Gramlich et al. (2022).

190 For the results presented in Sect. 3.1, 3.2 and 3.4, we only consider cloud-free conditions and visibilities > 5 km (measured by the GCVI), since the presence of cloud water and ice could influence the chemical composition of gaseous and particulate compounds. The data not considered in these sections are however included in the results of Sect. 3.3, where the effect of visibility and relative humidity (RH) is investigated.

2.2.2 Peak resolution and separation

195 The mass resolving power of the ToF mass spectrometer used for this study was ~5000 m/Δm, which does not allow for full peak separation of the ions contributing to nominal m/z 235. The closest neighbor of HPMTF (m/z 234.893) is nitrogen pentoxide (N₂O₅I⁺, m/z 234.885). N₂O₅ and HPMTF luckily rarely coexist in the lower troposphere, as HPMTF is produced during the sunlit months when N₂O₅ production is suppressed and vice versa (Veres et al., 2020). Although N₂O₅ is a highly

reactive gaseous compound, it can partition to the particle phase but then largely dissociates (Gržinić et al., 2017). The second-
200 closest neighbor to HPMTF is a cluster of acetic acid with an iodate ion ($\text{IO}_3^-\text{CH}_3\text{COOH}$, m/z 234.910) (Veres et al., 2020).
Calculations of the statistical precision (σ_B) of the peak intensities (Cubison and Jimenez, 2015) of these two overlapping peaks
for four example cases are presented in Fig. B1 and Table B1: (a) HPMTF as single ion (in practice meaning a high
HPMTF/ $\text{IO}_3^-\text{H}_3\text{COOH}$ ratio); (b) HPMTF as the larger (parent) peak and $\text{IO}_3^-\text{CH}_3\text{COOH}$ as the smaller (child) peak; (c) equal
intensities of HPMTF and $\text{IO}_3^-\text{CH}_3\text{COOH}$; (d) $\text{IO}_3^-\text{CH}_3\text{COOH}$ as the parent peak and HPMTF as the child peak. As expected,
205 σ_B is the highest in (a) (51%) and the lowest in (d) (2.9%). However, it should be noted that the peak intensities of HPMTF
and $\text{IO}_3^-\text{CH}_3\text{COOH}$ (p) seemingly are much too low (< 10 ions s^{-1}) to even be covered by the analysis in Cubison and Jimenez
(2015).

2.3 Other particle measurements

A condensation particle counter (CPC; TSI Inc., USA, Model 3772) behind the whole-air inlet was used to measure the total
210 particle number concentration (1 Hz data averaged to 1 min time resolution, lower cut-off size 5 nm, upper cut-off size approx.
40 μm). An optical particle size spectrometer (FIDAS 200S, Palas GmbH, Germany) was used to measure particulate mass
concentrations (PM1, PM2.5, PM4 and PM10 averaged to 1 h time resolution). The instrument was installed on the terrace of
Zeppelin Observatory and was equipped with its own heated inlet and additional RH and temperature (T) sensors to ensure
that all values were measured at dry conditions.

215 2.4 Trajectories and meteorological data

Backward trajectories (10 days, out of which 5 days were used for this study) were calculated with HYSPLIT (Stein et al.,
2015) using 3-hourly archive data from the National Center for Environmental Prediction's (NCEP) Global Data Assimilation
System (GDAS) with 1 degree horizontal grid resolution, starting from the Zeppelin Observatory at 474 m a.s.l.. Since gas-
and aerosol emissions from the surface (ocean) would be considered for the analysis, data within the model mixed-layer height
220 were distinguished from the data points above the mixed layer. The average monthly mixed-layer was around 260 m, 380 m,
and 390 m, in January, May and October, respectively. Monthly chlorophyll-*a* data from the Aqua/MODIS satellite were
retrieved from NASA Earth Observatory (Hu et al., 2012).

Meteorological data (air temperature, atmospheric pressure and relative humidity) with 1 h time resolution were downloaded from the EBAS data base (Norwegian Institute for Air Research). More meteorological details are presented in Pasquier et al. (2022).

3 Results and discussion

3.1 Seasonal pattern of DMS oxidation products

The high-resolution FIGAERO-CIMS data revealed the presence of seven compounds uniquely or potentially related to DMS oxidation: (HPMTF: $C_2H_3OSO_2H$, MSA: CH_3SO_3H , SA: H_2SO_4 , sulfur dioxide: SO_2 , sulfur trioxide: SO_3 , bisulfate: HSO_3 , and disulfuric acid: $H_2O_7S_2$). This is largely similar to earlier findings of particle-phase DMS oxidation products in the High Arctic with FIGAERO-CIMS (Siegel et al., 2021). The two organic compounds MSA and HPMTF have no other precursors than DMS, whereas the five inorganic compounds (SA, SO_2 , SO_3 , HSO_3 , and $H_2O_7S_2$) can originate from DMS oxidation but also from other sources, such as anthropogenic (e.g., ship fuel emissions) or other non-marine natural SO_2 sources (e.g., volcanic activity) (Barnes et al., 2006; Wu et al., 2015; Berndt et al., 2019). Here, we present the results of the gas- and particle-phase measurements of the DMS-related compounds.

3.1.1 Gas-phase DMS oxidation products

Phytoplankton need solar radiation ~~to be able~~ in order to produce DMS. Due to the large seasonal changes in the Arctic with the 24 h of darkness in winter and 24 h of sunlight in summer, it is of interest to compare the occurrence of DMS oxidation products throughout a full year.

In Figure 3a, c and e we show boxplots (monthly medians and percentiles) of the temporal evolution of the inorganic compound SA and the organic HPMTF and MSA in the gas phase ~~and~~ between 2020-01-01 and 2020-12-17. A full time series, also including SO_2 , SO_3 , HSO_3 and $H_2O_7S_2$, can be found in Fig. C1.

The inorganic SA (g) (Fig. 3a), which could be linked both to DMS oxidation and anthropogenic sources, displays the highest levels in January–April, i.e. not during the Arctic bloom period. During this time, synoptic-scale meteorology is different than in summer, with air masses from lower latitudes being advected into the north polar region (e.g., Heintzenberg et al., 1981; Frossard et al., 2011). These air masses carry anthropogenic pollution with elevated concentrations of sulfuric and

other chemical species from e.g. industries, and are known as the Arctic haze phenomenon (Hansen and Rosen, 1984; Mitchell, 1957). The results in Fig. 3a indicate that wintertime anthropogenic sources are the main contributor of annual inorganic sulfur in Ny-Ålesund, in agreement to previous studies (e.g., Jang et al., 2021).

250 ———MSA (g) (Fig. 3b) follows the expected pattern for a compound with DMS as its only source, where the concentration is very low during the winter and beginning of spring (October–March) and then starts increasing in April, when DMS starts being produced in the vicinity of Svalbard (Jang et al., 2021). It should however be noted that the onset and variability of the spring blooms show large variability from year to year (Galí et al., 2019; Jang et al., 2021). MSA (g) peaks sometime in May–June, and thereafter decreases toward the end of summer (September).

255 The levels of HPMTF (g) (Fig. 3c) develop similarly to MSA (g) ~~to some degree during some parts of the year~~, with low levels in March, an increase in April ~~to~~ and a peak in May. However, the variability over the bloom period is larger than for MSA (g) (see Fig. C1), and the measured HPMTF (g) concentration in May–September is sometimes as low as before the DMS production onset. HPMTF (g) further displays elevated levels in January and throughout September–October, which are completely lacking for MSA (g). During January and end of October, the Arctic experiences very few to no sunlit hours and
260 DMS is not produced in the immediate vicinity of Svalbard, meaning that the measured HPMTF (g) must have been transported from an area with DMS production during these months. Another possibility is that we instead of HPMTF (g) measured N₂O₅ (g) in winter. This is further discussed in Sect. 3.3 and 3.4.

During April–June, when MSA (g) and HPMTF (g) evolve in a common way, the level of MSA (g) is around 5 times higher than HPMTF (g) (assuming they have the same sensitivity in the FIGAERO-CIMS). This ratio is similar to the
265 simulation ~~–AtmMain~~ presented in Wollesen de Jonge et al. (2021), which was used as a base run scenario for an air parcel moving along a trajectory in a marine environment. The run was in total 120 h and included eight in-cloud events during both day- and night-time, with the last in-cloud event also including a rain event. The temperature was 280 K (~7°C) and the RH = 90%, i.e. fairly similar to the conditions in summer during the NASCENT campaign (Fig. C2). Therefore, it can be assumed that this scenario is representative of our data during this time of the year.

270 Further, the fact that HPMTF (g) and MSA (g) appear to have a relatively strong interrelationship in April–June indicates that they were formed from a local DMS source during this period (e.g., Becagli et al., 2016). Hence, we can assume

that DMS was at least partly oxidized through the abstraction pathway (Fig. 1) during these months (Wu et al., 2015; Berndt et al., 2019), despite the low occurrence of this mechanism compared to the addition pathway in the Nordic Seas according to Fung et al. (2022). However, the discrepancies that exist in the ~~relative temporal evolution~~ monthly absolute signal between measured MSA (g) and HPMTF (g) in summer could also be a sign that HPMTF (g) is not produced as efficiently as MSA (g) close to Svalbard due to e.g. low occurrence of OH radicals and/or meteorological factors. This hypothesis is supported by the higher importance of OH-initiated DMS oxidation at lower latitudes in the study by Fung et al. (2022), and the DMS conversion yields of MSA (g) and HPMTF (g) in the different model runs by Wollesen de Jonge et al. (2021), where the HPMTF/MSA ratio was considerably lower in the **AtmMain** case compared to cases with higher temperature and lower RH. This could be both due to differing sources and sinks, such as dry/wet deposition of MSA (Bergin et al., 1995) and HPMTF (Khan et al., 2021), heterogeneous oxidation of MSA (g) (Mungall et al., 2018) and evaporation of MSA from the particle- to the gas phase (Baccarini et al., 2021).

Figure 3. Box-and-whisker plots (with outliers removed) of SA, MSA and HPMTF in the gas- (g) and particle (p) phase per month of 2020, analyzed by FIGAERO-CIMS (panel (a)-(f)). Dashed horizontal lines inside the boxes represent median values, boxes the 25th and 75th data percentiles, and whiskers the maximum and minimum values of the populations. Panel (g) shows the total particle number concentration. Panel (h) shows the total particle mass (PM) of particles with diameters 1, 2.5, 4 and 10 μm, where the box-and-whisker plots (left-side axis) correspond to the sum of the particle sizes and the red markers (right-side axis) represent the monthly means of each size.

3.1.2 Particle-phase DMS oxidation products

290 Monthly boxplots of particle-phase SA, MSA and HPMTF are shown Figure 3b, d and f.

For SA (p) (Fig. 3b), the highest concentrations were measured in February and April, i.e. during the haze period. Slightly elevated levels are also found during summer, likely connected to DMS oxidation. These results are largely supported by measurements of particulate sulfate using an aerosol chemical speciation monitor (ACSM; data not shown), where the concentrations are overall declining from the beginning to the end of the year, with a small increase in July–August.

295 MSA (p) (Fig. 3d) follows a similar seasonal pattern in the particle-~~to the~~ and gas phase, where the highest levels are seen in June. The concentrations of HPMTF (p) (Fig. 3f) are much lower (2–3 orders of magnitude) than those of particulate MSA and SA and cannot be properly separated from the background. Hence, our conclusion is that the particulate amounts of HPMTF are negligible, and/or difficult to observe with the settings of our instrument. One reason for this is an extensive overlap with the peak IO_3^- (CH_3COOH) (a cluster of acetic acid with an iodate ion, Veres et al., 2020), see Sect. 2.2.2. The
300 signal of this cluster increased in the particle phase during the summer months relative to the winter, causing the time series of HPMTF (p) to appear very different from what is expected, with the lowest levels in summer and the highest in winter and spring. The statistical precision (σ_B) of the peak intensities of these two ions (Cubison and Jimenez, 2015) (Fig. B1 and Table B1) show that the peak intensities of HPMTF (p) and IO_3^- - CH_3COOH (p) in combination with our current level of mass resolution ($\sim 5000 \text{ m}/\Delta\text{m}$) were too low to be properly resolved (Sect. 2.2.2). This is in line with previous results from Wollesen
305 de Jonge et al. (2021), which showed that HPMTF was an important gaseous DMS oxidation product, but that it does not contribute directly in significant amounts to particulate mass. However, it is possible that HPMTF (g) is taken up by particles, especially when these are wetted (Vermeuel et al., 2020), where it likely would quickly undergo peroxide oxidation or nucleophilic substitution (Jernigan et al., 2022). Similar to earlier observations by Veres et al. (2020) and Wollesen de Jonge et al. (2021), the levels of HPMTF (g) during NASCENT were seen to decrease as a function of increased atmospheric water
310 content. This is further discussed in Sect. 3.3.

Further insights into the seasonality of the particle-phase DMS oxidation products can be obtained through comparison to the total particle number concentration (Fig. 3g) and concentrations of PM_x (particulate matter $< x \mu\text{m}$) (Fig. 3h). The highest PM concentrations (Fig. 3h) were measured during the winter and spring (November–April), and the

lowest during the summer months (June–September). The peak in July, likely influenced by a biomass burning event, is an
315 exception. This pattern is in overall agreement to previous observations in Ny-Ålesund (Tunved et al., 2013). However, the
summer months are known for higher particle number concentrations due to new particle formation (Tunved et al., 2013),
~~driven by SA (g) with subsequent growth by condensation of SA (g) and MSA (g) where condensation of SA from DMS
oxidation and formation of MSA are the main drivers~~ (Beck et al., 2021; Xavier et al., 2022). Fig. 3g clearly shows that the
particle number concentration peak in 2020 coincided with the summer peak of particulate DMS oxidation products, indicating
320 that SA and MSA (but not HPMTF) were participating in the growth of the newly formed particles. This means that the
measured SA (p) in winter most likely was of anthropogenic origin ~~and where SA (g)~~ condensed onto pre-existing accumulation
mode particles in the atmosphere, whereas ~~it~~ in summer it was produced locally via DMS oxidation and subsequent
condensation and at least partly via new particle formation.

3.2 Correlation between gas- and particle phase concentrations

325 As was discussed in the previous section, there appears to be a seasonal pattern of the DMS oxidation products, which is clearer
for MSA and SA than for HPMTF, for both gas and particle phase. As MSA and SA are known to contribute to particle mass
(e.g. Lovejoy et al., 2004; Sipilä et al., 2010), a correlation between the gas- and particle phase can give indications on the
direct relationship between the two phases, which would be important for e.g. model simulations of particle growth. Previous
studies from the Arctic pack ice region in summer, farther away from DMS sources, have shown that MSA and SA do not
330 exhibit any correlation between the gas- and particle phase (Chang et al., 2011; Siegel et al., 2021), and similar results from
Antarctica have been reported (Davis et al., 1998; Read et al., 2008).

In Fig. 4 we show scatterplots for the two phases per “season”, where January–April (JFMA, panel (a)) represent late
winter–early spring, May–July (MJJ, panel (b)) represent late spring–summer, and September–December (SOND, panel (c))
represent early fall–early winter.

335 As expected from Fig. 3, HPMTF appears to have no relationship between the phases in either season. The same is
true for SA (g) and (p) ~~in JFMA and SOND. In MJJ a correlation can be noted between the gas and particle phase for both
MSA and SA (Fig. 4b)~~. To some extent, ~~this~~ correlation between the gas and particle phase is visible for MSA also in JFMA
and MJJ for MSA (due to the increasing levels in April and high production during summer), but not at all in SOND; (after

the bloom season). Although no correlation is notable for MSA and SA individually in MJJ, a different pattern appears when combining the datasets. Furthermore, there appears to be a connection between the MSA and SA correlations in MJJ, indicating that they have the same sources and are part of the same reaction processes. An orthogonal linear regression analysis (non-weighted) (Cantrell, 2008) of the combined MSA and SA dataset (both gas- and particle-phase signals logarithmized) in MJJ results in a an R^2 of 0.32 (Fig. 4b), which indicates a weakly positive linear relationship, and that MSA and SA have the same sources and are part of the same reaction process during these months. Due to the insignificant levels of HPMTF (p), HPMTF lies outside of this connected relationship.

Besides seasonal variation, diurnal cycles of DMS oxidation products have previously been reported (Vermeuel et al., 2020). However, no diurnal patterns were possible to see with our dataset, similarly to the study by Baccharini et al. (2021) in the Southern Ocean. Our hypothesis is that the large seasonal differences and fast changes around the equinoxes in Ny-Ålesund affect the pattern in a way that makes diurnal cycles difficult to identify.

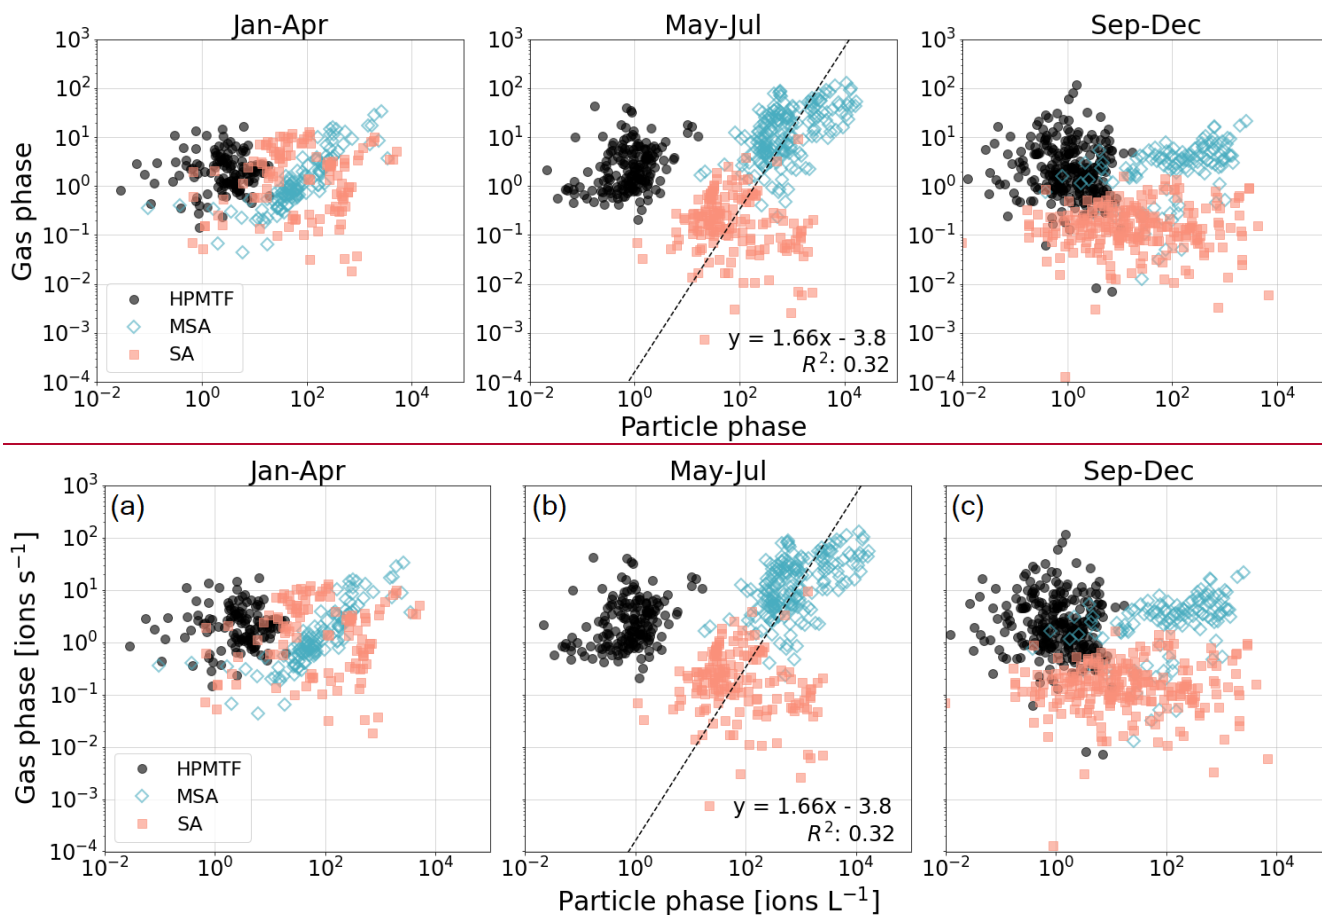

Figure 4. Relationship between gas- and particle-phase MSA, SA and HPMTF per season: (a) January–April (JFMA), (b) May–July (MJJ), (c) September–December (SOND). The black line in panel (b) represents the orthogonal linear regression between the combined logarithmized MSA and SA datasets. The linear equation and correlation coefficient R^2 are shown in the lower right corner.

3.3 Correlation of HPMTF (g) with visibility and relative humidity

Previous studies have found gas-phase HPMTF to be readily taken up by clouds and hence suggested that wet scavenging is an important atmospheric sink (e.g., Khan et al., 2021; Novak et al., 2021). Therefore, we investigated the measured levels of HPMTF (g) as a function of visibility (vis, Fig. 5a) and RH (Fig. 5b) (averages per sampling period) during the summer months (MJJ). Cloudy conditions are represented by vis < 1 km (the World Meteorological Organization’s definition of fog; WMO, 2018) and cloud-free conditions by vis > 5 km. Vis = 1–5 km be viewed as a “transition state” between these conditions, here

referred to as “semi-cloudy”. Further, a high atmospheric water content (referred to as “wet”) is here defined as $RH > 95\%$, whereas a low water content (referred to as “dry”) is set to $< 75\%$. Hence, the range 75–95% (“semi-wet”) refer to data points at neither high nor low RH.

365 In Fig. 5a, the average HPMTF (g) level is lower during cloudy and semi-cloudy compared to cloud-free conditions. However, these data are too unequally distributed (see the number of data points above each box-and-whisker plot) and skewed (especially > 5 km) to make a statistical analysis meaningful. The data related to RH in Fig. 5b are more equally distributed; however, they are skewed, as seen on the outliers towards higher HPMTF (g) levels. A statistical evaluation using the Wilcoxon rank-sum test for skewed data (two-tailed) of the three RH ranges, where the p -values are summarized in Table C1, shows that
370 the largest differences lie in the HPMTF (g) data between the wet case and the semi-wet/dry cases. These are statistically different at a 99% confidence level, whereas the data of the wet and semi-wet cases are statistically different at a 90% confidence level. The p -values of the analyses involving the wet case are, however, much smaller (3.9×10^{-18} and 3.0×10^{-19}) than between the semi-wet and dry cases (0.059), showing that HPMTF (g) is most effectively scavenged when $RH > 95\%$.

Nevertheless, one must keep in mind that changes in RH could be a sign of an air mass shift, which likely has an
375 influence on the atmospheric composition. Hence, it is difficult to conclude whether the RH or air mass origin is the main reason for the lower HPMTF (g) concentration at high RH. However, during the cloud events studied in Gramlich et al. (2022), HPMTF (g) levels were lower compared to right before and right after the cloudy period (Fig. 5c). These cloudy periods also correspond to the time with the highest RH values, hence, this demonstrates that cloudy and wet conditions do reduce HPMTF (g) levels in the atmosphere in Svalbard during summer. However, we did not detect HPMTF nor any of its possible
380 reaction products (e.g., $C_2H_4SO_2$, $C_2H_6SO_2$) (Jernigan et al., 2022) in significant amounts in any of the cloud residual samples (data not shown) (Gramlich et al., 2022). Therefore, we cannot make a conclusive statement about the fate of HPMTF in the particle phase with our dataset.

Figure 5. Box-and-whisker plots of HPMTF (g) levels during MMJ divided into (a) visibility ranges, (b) RH ranges (averages per sampling period). The horizontal lines inside the boxes correspond to the median and cross markers to the mean of each population. Quartiles are represented by the box borders, maximum and minimum values of the populations are represented by the whiskers, and outliers are shown as individual points outside the whisker ranges. The number of data points in each population is written above the plots. Panel (c) shows the average signal of HPMTF (g) before, during and after cloud events during May and June 2020. The error bars correspond to the standard deviation. The signals were normalized to the maximum HPMTF (g) signal of the individual cloud cases (combining the signals before, during and after) before computing the average and standard deviation.

3.4 Source regions of observed HPMTF

DMS is not produced close to Ny-Ålesund during wintertime due to the lack of sunlight, and the relatively high observed levels of presumed HPMTF (g) in January and high levels in October (Fig. 3e) are surprising. To investigate the possibilities of measuring high HPMTF concentrations during the dark and sunlit months, we analysed the HPMTF (g) content carried by

395 air masses to Ny-Ålesund in January, May and October using 5-day backward trajectories and satellite observations of marine chlorophyll-*a*, used as a proxy for DMS production (Fig. 6).

In May, the chlorophyll-*a* concentration was high in the coastal areas around Svalbard, and essentially all air masses arriving to Ny-Ålesund carried some HPMTF. The highest concentrations appear to originate from the Barents Sea, which is in line with previous results by Park et al. (2021).

400 In October, there were still some algal blooms at the Norwegian coast, south of Iceland and Greenland. However, the trajectories show that the air masses in October had spent the last 5 days before arriving to Ny-Ålesund within the Arctic region, far away from DMS-producing areas at lower latitudes. Several studies have shown that long-range transport of HPMTF is possible (Vermeuel et al., 2020; Khan et al., 2021; Novak et al., 2021); however, it seems unlikely as of the efficient scavenging of HPMTF by clouds (e.g., Khan et al., 2021; Novak et al., 2021). This is supported by the simulation case in the
405 study by Wollesen de Jonge et al. (2021), which could be said to represent our measurement conditions (Sect. 3.1.1) and included both in-cloud events and a rain event. Although it seems ~~not likely~~ unlikely, the possibility that HPMTF was transported to Svalbard in October cannot be ruled out.

In January there was almost no chlorophyll-*a* in the surface waters $> 50^\circ$ N, and most of the air masses originated from Europe and Siberia. As the Arctic is experiencing polar night and low temperatures in January, and the trajectories indicate
410 that the air masses were arriving from terrestrial areas, another hypothesis is that these peaks should instead be attributed to N_2O_5 , as has been observed previously in Alaska during wintertime (Ayers and Simpson, 2006). This hypothesis is partly supported by the fact that N_2O_5 was a better fit in the high-resolution mass spectrum than HPMTF during the second half of January (Fig. C3), although more directed measurements (such as in the study from Alaska) would be needed to verify this.

415

Figure 6. 5-day backwards trajectories arriving at the Zeppelin Observatory in (a) January, (b) May and (c) October, colored by measured HPMTF content in the gas phase [ions s^{-1}]. Only trajectory points corresponding to times below the mixed-layer height are shown. The green areas show marine chlorophyll a concentration (monthly mean), indicative of DMS production.

4 Summary and conclusions

420 We present a full year (2020) of gas- and particle phase observations of DMS oxidation products obtained with FIGAERO-CIMS at the Zeppelin Observatory, Svalbard. We focus especially on the newly discovered DMS oxidation product hydroperoxymethyl thioformate (HPMTF) (Veres et al., 2020), for which in situ observations are still limited. It has never been measured in Svalbard or attempted to be observed in atmospheric particulate matter.

Our results indicate that HPMTF is produced in large amounts in the vicinity of Svalbard during summer (April–
 425 September), and can be measured in October possibly as a result of transportation from lower latitudes. In summer, HPMTF follows the seasonal increase of MSA in the gas phase to some extent, but it could not be measured in the particle phase in significant amounts. This is in line with previous laboratory results by Wollesen de Jonge et al. (2021), stating that HPMTF did not contribute directly to particle growth despite high concentrations in the gas phase. Elevated levels in the gas phase

were also measured in January; however, due to the lack of DMS sources within a radius reasonable for long-range transport, we speculate that this could instead be N_2O_5 , which cannot be fully separated from HPMTF with the resolution of the mass spectrometer deployed.

MSA follows a clear evolution pattern in both the gas- and particle phase, with an onset in April and fast decrease towards the end of Arctic summer (~September), similar to earlier findings in Ny-Ålesund (Jang et al., 2021). Sulfuric acid (SA) was found in high concentrations during the winter/spring months (January–April) in both phases, assumed to be a result of condensation onto accumulation mode particles from lower latitudes which are commonly found in the Arctic during the spring haze period (e.g., Tunved et al., 2013). Particle-phase SA was also measured in summer when the total particle mass concentrations were low but number concentrations high, indicating DMS oxidation and new particle formation as a source.

Due to the insignificant amounts of HPMTF in the particle phase, no correlation between the two phases could be seen in any of the seasons. For MSA and SA, no correlation was visible in fall–winter–spring (~September–April), but a clear relationship emerged during the sunlit months with DMS production (~May–July). The relationship between the phases of MSA and SA also appeared to be connected, where MSA was more abundant in both phases during summer.

As has been seen in several previous studies (e.g., Veres et al., 2020; Vermeuel et al., 2020; Wollesen de Jonge et al., 2021), we also noticed a decrease in HPMTF (g) levels during periods of cloud occurrence (visibility < 1 km) and high RH (> 95%) in May–June. This shows that cloud removal is an efficient sink for HPMTF (g) also in Ny-Ålesund during summer.

With this study, we aimed to investigate the links between the relatively well-known seasonal patterns of MSA and SA (Leaitch et al., 2013; Becagli et al., 2016; Jang et al., 2021) and the almost unknown one of HPMTF ~~one~~. We concluded that there is a relationship between gas-phase MSA and HPMTF in summer, indicative of an apparent contribution of the abstraction pathway to DMS oxidation. SA and HPMTF have a low correlation, partly due to SA's preference for the particle phase and HPMTF for the gas phase.

Future studies should focus on quantification of the measured levels of HPMTF in both gas- and particle phase. This information could be used for modelling of DMS oxidation and would thereby increase quantitative knowledge about oxidation pathways and sinks of HPMTF in the Arctic. For the particle-phase measurements in particular, it would be useful to investigate the possibility of a better peak separation between HPMTF and mainly the acetic acid-iodate cluster $\text{IO}_3\text{-CH}_3\text{COOH}$ in the

FIGAERO-CIMS. This can be achieved by e.g. using a mass spectrometer with a higher resolution or concurrent measurements
455 of N₂O₅ and acetic acid. The possibility for indirect contributions of HPMTF to particulate mass, such as an increase of sulfate
due to HPMTF oxidation in the aqueous phase as reported by Wollesen de Jonge et al. (2021), should also be investigated in
association to typical atmospheric conditions in the Arctic throughout the year.

Data availability

The data of this study will be available on the Bolin Centre Database (<https://bolin.su.se/data/>). The meteorological data is
460 available on the EBAS data base (<https://ebas-data.nilu.no>).

Author contribution

CM, PZ and RK were responsible for funding and conceptualization. YG, KS, SH and CM performed the FIGAERO-CIMS
measurements. YG, KS and SH wrote code for FIGAERO-CIMS analysis. RK, PZ and GF operated the GCVI and provided
the GCVI data. ~~PZGF~~ provided the ~~DMPS-CPC and the FIDAS~~ data. KS and YG analyzed and visualized the FIGAERO-
465 CIMS data, and visualized the GCVI and ~~DMPS-CPC~~ data. KS visualized the trajectories, and wrote the manuscript with input
from CM. CM was responsible for supervision. All co-authors have read and commented on the manuscript.

Appendix A

485 Details on the FIGAERO-CIMS measurement cycles, referring to the text in Sect. 2.2.

490 **Figure A1.** Example of a FIGAERO-CIMS sampling cycle, using the timeseries of the nitric acid iodide adduct (HNO_3I^-), shown in black. The letter S represents a particle-phase sample and B a particle-phase blank. The blue boxes define the times of a sampling cycle, when gas-phase measurements are done while particles are deposited on a filter. The green circle markers show the gas-phase sample segments (normally 3 segments) and the yellow diamond markers the gas-phase background segments (normally 2) identified for each sampling period. The dark-green triangles represent the averaged gas-phase sample segments and the orange triangles the averaged gas-phase background segments. The solid red line shows the heater temperature, i.e. the temperature of the N_2 flow passing through the filter.

Appendix B

500 Peak separation of HPMTF and its neighbor peaks.

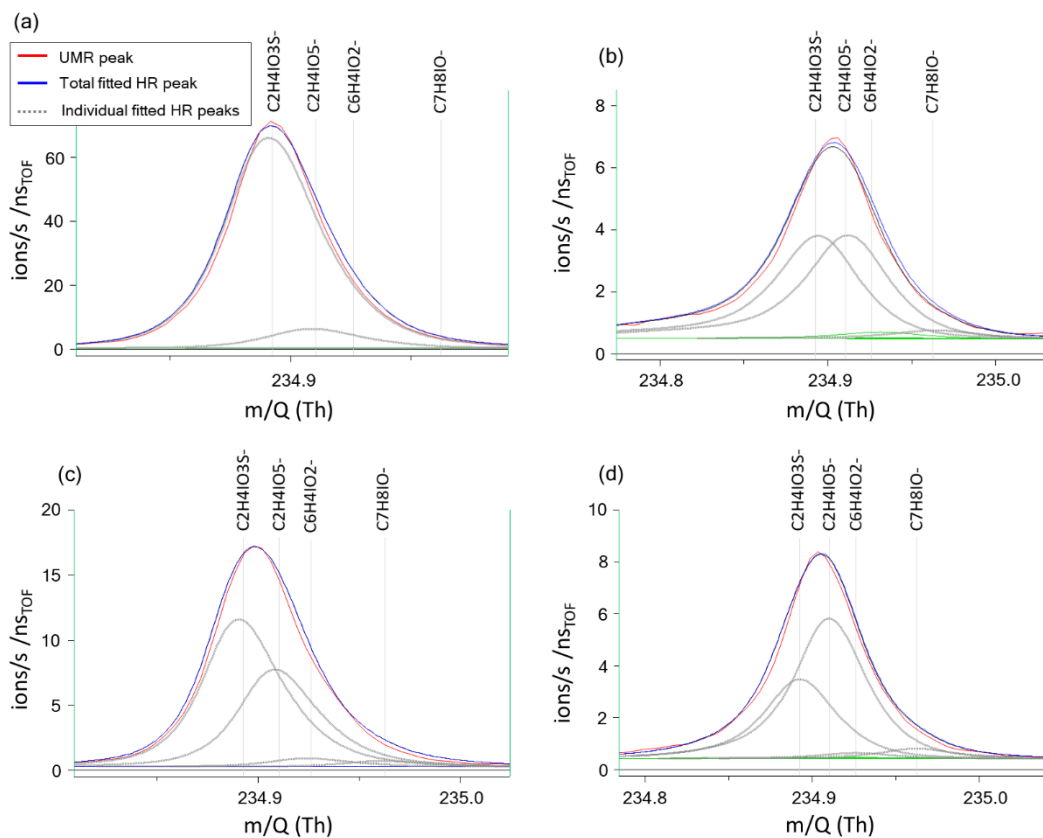

Figure B1. Four example cases of the separation of the two peaks HPMTF (in figure: C₂H₄IO₃S⁻) and the acetic acid/iodate cluster IO₃⁻CH₃COOH (in figure: C₂H₄IO₅⁻) (Veres et al., 2020), as analyzed by FIGAERO-CIMS: (a) HPMTF as single ion (in practice a high HPMTF/IO₃⁻CH₃COOH ratio), (b) HPMTF as the larger (parent) peak and IO₃⁻CH₃COOH as the smaller (child) peak, (c) equal intensities of HPMTF and IO₃⁻CH₃COOH, and (d) IO₃⁻CH₃COOH as the parent peak and HPMTF as the child peak. The peak separation statistics are shown in Table B1. UMR = Unit Mass Resolution, HR = High Resolution.

Table B1. Separation statistics of the two peaks HPMTF and the acetic acid/iodate cluster $\text{IO}_3^-\text{CH}_3\text{COOH}$ (Cubison and Jimenez, 2015).
 510 The first column corresponds to the example cases shown in Fig. B1 (a)-(d). The parameter χ shows the degree of separation of the two peaks, whereas σ_B shows the statistical precision of the peak intensities. When in bold font, σ_B corresponds to the precision of the HPMTF peak as parent/child. In case (c), HPMTF can be viewed as either the parent or child, and the precision is therefore in the range 3.2-5.4%.

Peak type	Fitted intensity [ions]	HPMTF % of UMR intensity	Ratio HPMTF/C2H4IO5	Peak separation (χ)	σ_B (parent) [%] [*]	σ_B (child) [%] [*]	Regime ^{**}
Single ion (a)	212	91	11	0.7	51	2.9	Counting-error
Parent (b)	37.6	57	1.5	0.8	6.3	2.5	Counting-error
Equal (c)	14.8	48	1.0	0.6	5.4	3.2	Counting-error (parent) Over-lapping counting error (child)
Child (d)	11.2	34	0.56	0.7	8.6	2.9	Overlapping counting-error

^{*} Calculated from eq. (3) and (4) in Cubison and Jimenez (2015), respectively.
