## Abstract.

Dimethyl sulfide (DMS), a gas produced by phytoplankton, is the largest source of atmospheric sulfur over marine areas. DMS  
15 undergoes oxidation in the atmosphere to form a range of oxidation products, out of which sulfuric acid (SA) is well-known for participating in the formation and growth of atmospheric aerosol particles, and the same is also presumed for methanesulfonic acid (MSA). Recently, a new oxidation product of DMS, hydroperoxymethyl thioformate (HPMTF) was discovered and later also measured in the atmosphere. Little is still known about the fate of this compound and its potential to partition to the particle phase. In this study, we present a full year (2020) of concurrent gas- and particle-phase observations  
20 of HPMTF, MSA, SA and other DMS oxidation products at the Zeppelin Observatory (Ny-Ålesund, Svalbard) located in the Arctic. This is the first time HPMTF has been measured in Svalbard and attempted to be observed in atmospheric particles. The results show that gas-phase HPMTF concentrations largely follow the same pattern as MSA during the sunlit months (April–September), indicating production of HPMTF around Svalbard. However, HPMTF was not observed in significant amounts in the particle phase, despite high gas-phase levels. Particulate MSA and SA were observed during the sunlit months,  
25 although the highest median levels of particulate SA were measured in February, coinciding with the highest gaseous SA levels with assumed anthropogenic origin. We further show that gas- and particle-phase MSA and SA are coupled in May–July, whereas HPMTF lies outside of this correlation due to the low particulate concentrations. These results provide more

information about the relationship between HPMTF and other DMS oxidation products in a part of the world where these have not been explored yet, and about HPMTF's ability to contribute to particle growth and cloud formation.

## 30 **1 Introduction**

Oceanic dimethyl sulfide (DMS) is one of the largest contributors to atmospheric sulfur (17.6-34.4 Tg S yr<sup>-1</sup>, Lana et al., 2011) and the most important source in marine areas. The global natural DMS emissions vary largely between the southern and the northern hemisphere. On a global average, around 42% of the natural sulfur emissions can be traced back to DMS (Simó, 2001), which is equal to at least 50% of the total amount from anthropogenic sources (Simó, 2001; Klimont et al., 2013). DMS  
35 is a gas produced by algal communities when sea surface temperatures and sunlight conditions are favorable for primary production (Liss et al., 1993). When emitted to the atmosphere, DMS is oxidized to a range of gas-phase (g) sulfuric chemical species (Yin et al., 1990; Barnes et al., 2006). Some of these have a low enough volatility to condense to the particle phase (p), and have been shown to be able to participate in new particle formation (NPF, e.g. Lovejoy et al., 2004; Beck et al., 2021; Rosati et al., 2021) or contribute to the growth of aerosol particles. This has implications for the particles' ability to act as  
40 cloud condensation nuclei (CCN, see e.g. review by Ayers and Gillett, 2000), i.e. to form clouds in the atmosphere.

Clouds are important for the Earth's climate as they influence the radiation balance. In the Arctic, the common cloud type is low-level and mixed-phase (consisting of both liquid droplets and ice crystals) stratocumulus (e.g., Shupe, 2011; Tjernström et al., 2012). Stratocumulus clouds are considered to be an important factor (Serreze and Barry, 2011; Wendisch et al., 2019) in the rapid increase of average surface temperature that has been observed in the Arctic region during the last  
45 decades (two to four times larger than the global average of +1°C compared to preindustrial times) (Rantanen et al., 2022). A more detailed understanding of aerosol and CCN chemistry, sources and seasonal variability in the Arctic is therefore needed to be able to make better predictions of future climate change (Schmale et al., 2021).

The oxidation scheme of DMS is highly complex, and represented in a poor or very limited manner in many atmospheric chemistry models. The scheme can however be described as mainly a two-route mechanism (Fig. 1): the addition  
50 pathway, where either a hydroxyl (OH), nitrate (NO<sub>3</sub>) or halogen radical (e.g. bromine oxide, BrO, or chlorine, Cl) is added, or hydrogen abstraction pathway, in which a hydrogen (H) atom is removed. Main products in the abstraction pathway are the

inorganic compound sulfuric acid (SA,  $\text{H}_2\text{SO}_4$ ) (via sulfur dioxide,  $\text{SO}_2$  or methanesulfonate ( $\text{CH}_3\text{SO}_3^-$ ), and sulfur trioxide,  $\text{SO}_3$ ), and the organic compound methanesulfonic acid (MSA,  $\text{CH}_3\text{SO}_3\text{H}$ ). The first stable product in the addition pathway is dimethyl sulfoxide (DMSO,  $\text{CH}_3\text{SOCH}_3$ ), followed by methanesulfinic acid (MSIA,  $\text{CH}_3\text{S(O)OH}$ ) (Barnes et al., 2006). MSIA  
55 can either undergo reactive uptake to the particle phase or oxidize further via methanesulfonate to MSA and SA, although the abstraction pathway is normally considered more important for the production of these two species. The different oxidation pathways further depend on the ambient temperature, where the abstraction mechanism has been shown to be favored at higher temperatures and the addition mechanism at lower temperatures (Hoffmann et al., 2021; Wollesen de Jonge et al., 2021). It is therefore plausible that the addition pathway is of higher importance in the Arctic, where temperatures are generally low.

60 Recently, a new oxidation product of DMS was discovered in situ during an aircraft campaign by Veres et al. (2020), hydroperoxymethyl thioformate (HPMTF,  $\text{C}_2\text{H}_3\text{OSO}_2\text{H}$ ) (see Fig. 1). This compound is produced via the H-abstraction pathway, leading to the methylthiomethyl-peroxy radical ( $\text{CH}_3\text{SCH}_2\text{OO}^\bullet$ ), quickly followed by an H-shift to form intermediate radicals and then HPMTF (Berndt et al., 2019; Wu et al., 2015, 2022). It was found to be ubiquitous (frequently  $> 50$  ppt) in the lowest kilometers of the troposphere in both spring (April–May) and autumn (September–October), and was detected up  
65 to 14 km altitude over large parts of the world’s oceans between  $80^\circ\text{N}$  and  $85^\circ\text{S}$  latitudes. It was further shown to be readily removed through cloud uptake and there was no apparent relationship between HPMTF and MSA in the gas phase. The study also speculated that HPMTF could contribute to NPF or particle growth.

**Figure 1.** Simplified oxidation scheme of dimethyl sulfide (DMS) in the atmosphere. DMS is produced by microbiological activity in the ocean and emitted to the atmosphere, where it is oxidized through two main routes: 1) *addition* of a radical to produce dimethyl sulfoxide (DMSO) and methanesulfinic acid (MSIA), and further via methanesulfonate (CH<sub>3</sub>SO<sub>3</sub>) to methanesulfonic acid (MSA) and/or sulfuric acid (SA) either via sulfur dioxide (SO<sub>2</sub>) and sulfur trioxide (SO<sub>3</sub>) or via methanesulfonate and SO<sub>3</sub>; 2) *abstraction* of a hydrogen (H) atom to produce MSA, hydroperoxymethyl thioformate (HPMTF; marked with a box) and/or SA via SO<sub>2</sub> and SO<sub>3</sub>. The figure was created using information from Barnes et al. (2006) and R. Wu et al. (2015). The addition pathway is shown in orange arrows, the abstraction pathway in green arrows, and DMS oxidation products that are part of both pathways are indicated with black arrows.

Since the discovery of HPMTF, it has inspired several new studies (e.g., Vermeuel et al., 2020; Khan et al., 2021; Novak et al., 2021; Wollesen de Jonge et al., 2021).

Fung et al. (2022) developed an understanding of where certain DMS oxidation products can dominate in the world due to variation in dominating DMS oxidation mechanisms. This clarified why the highest HPMTF concentrations were found  
80 over tropical oceans with a high degree of OH oxidation through the abstraction pathway, and lower over equally microbiologically productive waters with a relatively higher degree of oxidation through the addition pathway, such as the North Atlantic and Canadian Arctic (Veres et al., 2020; Fung et al., 2022).

Wollesen de Jonge et al. (2021) showed in a model study based on chamber experiments that HPMTF accumulates in the gas phase during cloud-free conditions, but does not significantly partition to the particle phase and is unlikely to  
85 contribute to NPF. However, it was speculated in this study that HPMTF could indirectly contribute to growth of aerosol particles through increased aqueous-phase production of sulfate ( $\text{SO}_4^{2-}$ ). This does not necessarily happen where DMS concentrations are locally high, as HPMTF might be transported large distances before taking part in these partitioning and oxidation processes, depending on OH concentrations, cloud occurrence and ambient temperatures (Vermeuel et al., 2020; Khan et al., 2021; Novak et al., 2021).

90 In the Arctic, where aerosol-climate interactions are especially poorly understood (Schmale et al., 2021) and DMS emissions are expected to increase in the near future due to higher sea temperatures (Land et al., 2014), more measurements of HPMTF during different seasons and atmospheric conditions could help to improve our knowledge of DMS oxidation and aerosol formation in this region. Hence, in this study we present observations of atmospheric DMS oxidation products, including HPMTF, from the Zeppelin Observatory in Ny-Ålesund, Svalbard (79 °N) throughout the year of 2020. The  
95 measurements were made using a high-resolution time-of-flight chemical ionization mass spectrometer with a filter inlet for gases and aerosols (FIGAERO-CIMS, Lopez-Hilfiker et al., 2014) and iodide as the reagent ion. With the FIGAERO-CIMS, gas- and particle-phase measurements can be made concurrently, which provides a unique possibility to study sources and phase-transition mechanisms at time resolutions of seconds to hours. In this project, we were able to study this over all seasons. To our knowledge, this is the first time ambient HPMTF has been measured in Svalbard and the first time HPMTF detection  
100 in the particle phase has been attempted in the ambient atmosphere.

## 2 Methods

### 2.1 The measurement site

The results presented in this study were derived from measurements made during the Ny-Ålesund Aerosol Cloud Experiment (NASCENT) campaign in 2019–2020. The data presented in this study was collected between 2020-01-01 and 2020-12-17  
105 (where entire August is missing due to malfunctioning instrumentation) at the Zeppelin Observatory atop Mt. Zeppelin (474 m a.s.l), 2 km south of Ny-Ålesund, Svalbard (78.9° N, 11.9° E) (Platt et al., 2022), see Fig. 2. A detailed description of the entire campaign and overview on first results can be found in Pasquier et al. (2022). Here follows a description of the instrumentation and methods used for this particular study. Our FIGAERO-CIMS setup at the Zeppelin Observatory yielded two types of datasets: one on the aerosol particle composition that acted as CCN or INPs (also termed cloud residuals, reported  
110 in Gramlich et al. (2022), and one on the ambient aerosol particle and gas phase composition, which is reported in this study.

**Figure 2.** (a) Map of Svalbard, where Ny-Ålesund is marked with a red circle. (b) Mt. Zeppelin with the Zeppelin Observatory in relation to Ny-Ålesund (maps generated using Python's Matplotlib Basemap toolkit and ©OpenStreetMap contributors 2023, distributed under the Open Data Commons Open Database License (ODbL) v1.0). ## 2.2 Chemical composition of gaseous and particulate atmospheric compounds

The chemical composition of atmospheric compounds in the gas-, particle-, and cloud phase was determined at molecular level with a FIGAERO-CIMS (Aerodyne Research Inc., USA), with iodide ( $I^-$ ) as the reagent ion. This setup allows for detection of mainly polar and oxygenated organic compounds, due to the clustering mechanism of  $I^-$  (Lee et al., 2014). The FIGAERO-CIMS recorded data every second (1 Hz) until mid-February, and every two seconds (0.5 Hz) during the rest of the year. The

gas phase was sampled with a ¼ inch outer diameter (O.D.) and ~5 m long polytetrafluoroethylene (PTFE) tubing sticking out ~50 cm through a hole in the northern wall of the Zeppelin Observatory and with the tip protected by an attached funnel. The aerosol particles were sampled through a gently heated whole-air inlet, which follows the guidelines of the World Calibration Centre for Aerosol Physics (WCCAP) at the Leibniz Institute for Tropospheric Research, Germany (Wiedensohler et al., 2013). The inlet samples all aerosol and cloud particles smaller than approx. 40 µm at wind speeds up to 20 m s<sup>-1</sup> (Weingartner et al., 1999), and is located at ~480 m a.s.l.. The aerosol inlet was connected to the FIGAERO-CIMS by stainless steel tubing (O.D. ½ inch, length: ~6 m) through a three-way switching valve. During cloudy conditions, defined as when the visibility (visibility sensor from Belfort, Model 6400, at approx. 480 m a.s.l.) at the observatory was < 1000 m (World Meteorological Organization definition of fog (WMO, 2018)), the three-way valve switched to sampling cloud particles (> 6–7 µm in diameter) through a ground based counterflow virtual impactor (GCVI; Brechtel Manufacturing Inc., USA, Model 1205) inlet (Karlsson et al., 2021). After drying of the cloud particles, the chemical composition of the remaining cloud residuals was measured with FIGAERO-CIMS. The results of this analysis are reported in Gramlich et al. (2022).

The FIGAERO inlet is designed in a way that enables alternating gas- and particle-phase measurements (Lopez-Hilfiker et al., 2014; Thornton et al., 2020). Particles are deposited on a PTFE filter for a specified period of time, during which gaseous compounds are sampled via the gas-phase inlet. When enough particulate matter has been collected onto the filter, the gas-phase inlet is blocked and the filter moved into place in front of the instrument's inlet to enable particle-phase analysis. This mechanism makes it possible to compare the two phases at the same point in time.

During NASCENT, a FIGAERO-CIMS measurement cycle was 210 min (Fig. A1 and Table A1), where the first 150 min were made up by gas-phase measurements: 3x40 min of ambient atmosphere measurements and 2x15 min of background measurements with ultra-pure air ("zero air") from a generator (Teledyne API, USA, Model 701H), and simultaneous particle deposition on the PTFE filter. The last 60 min of the measurement cycle consisted of particle desorption, where the compounds collected on the filter were evaporated by a stream of ultrapure nitrogen (N<sub>2</sub>) from a generator (Peak Scientific, UK, Model NG5000), gradually heated during 20 min from room temperature to ~200°C. The temperature was then kept at this level for another 20 min, allowing all compounds to evaporate completely off the filter and their corresponding signal return to background levels. This means that compounds that are not volatile enough to evaporate at ≤ 200°C (e.g. sea salt) (Rasmussen

et al., 2017) or that decompose at these temperatures are not directly measurable by the FIGAERO-CIMS. Particle-phase blanks (background signal) were collected every third cycle by sampling through another particle filter, which removed particles from the sampling flow upstream of the sample filter.

150 The desorbed compounds were ionized by  $I^-$  and separated by their time-of-flight (ToF) in the mass spectrometer. The mass-to-charge ratio ( $m/z$ ) of each compound was determined from the ToF by using known ions as calibrants, from which their molecular compositions were determined.

### 2.2.1 Data processing

The FIGAERO-CIMS raw data were pre-averaged to 30 s time resolution. After mass calibration, the signals were normalized  
155 to the sum of the reagent ion signal ( $I^-$ ,  $m/z$ : 126.905) and the cluster of iodide and water ( $H_2OI^-$ ,  $m/z$ : 144.916). Inclusion of  $H_2OI^-$  in the normalization accounts for changes in the water vapor content of the ambient air, and the humidity difference between the ambient gas-phase measurement compared to the particle desorption using dry  $N_2$ , which influences sensitivity of iodide adduct ionization (Lee et al., 2014).

The time period between two particle heatings was identified as the “sampling period”, during which the gas-phase  
160 measurements took place (see Fig. A1 and Table A1). The sampling period was usually interrupted twice by two background measurements of 15 min each. The 30 first data points (~15 min) of the gas-phase signal were removed from each sample segment, since the signal took some time to stabilize after each shift (as is visible from the  $HNO_3I^-$  signal in Fig. A1). Similarly, to assure no inclusion of background signal in the averaged data of the sample, the 15 last data points (~7.5 min) were removed as well. Around 18 min of gas-phase data were used for analysis from each sample segment (represented by the green circles  
165 in Fig. A1). The segments were averaged individually, and the segment averages within the same sampling period were in turn averaged to a single data point for that period (dark-green triangles in Fig. A1). The average background signal (orange triangles in Fig. A1) of each sampling period was calculated in the same way, where only three data points (1.5 min) at the end of each background period were used (yellow diamonds in Fig. A1). The background signal was thereafter subtracted from the sample signal to give two sets of timeseries: 1) a background-subtracted average of the sampling period (using the values  
170 represented by the dark-green and orange triangles in Fig. A1), which was used for comparison to the particle-phase signal of the same period; 2) background-subtracted data with the full time-resolution of 30 s, to use when not comparing to particle-

phase data. The FIGAERO-CIMS was not calibrated to any known substance, and the unit of the gas-phase data is [number of detected ions s<sup>-1</sup>], i.e. not atmospheric concentration. The data can be used for qualitative analysis and for relative quantification between measured gaseous compounds. To achieve atmospheric concentrations, calibration of the FIGAERO-  
175 CIMS with known gaseous compounds is recommended for future studies.

The particle-phase signal was calculated as the signal integrated across time from the start of the heating (when the temperature starts ramping up) until the end of the desorption time (when the temperature starts decreasing again) (see the red line in Fig. A1). The signal was thereafter normalized to the sampled volume, as the sampling time could sometimes differ between samples. Particle backgrounds were calculated as the interpolated time-integrated signal between two consecutive  
180 particle blanks, which was in turn subtracted from the time-integrated particle sample signal. Handling blanks were not needed as the FIGAERO operated automatically. However, the first particle sample after the filter had been exchanged was excluded from the analysis due to the risk of contamination. Since the particle-phase data was time-integrated and normalized to the sampled volume, the unit is therefore [number of detected ions per liter of sampled air], and the data can be used in the same way as the gas-phase data (qualitative analysis and for relative quantification between measured particulate compounds). More  
185 details on the processing of the particle-phase data is given by Gramlich et al. (2022).

For the results presented in Sect. 3.1, 3.2 and 3.4, we only consider cloud-free conditions and visibilities > 5 km (measured by the GCVI), since the presence of cloud water and ice could influence the chemical composition of gaseous and particulate compounds. The data not considered in these sections are however included in the results of Sect. 3.3, where the effect of visibility and relative humidity (RH) is investigated.

### 190 **2.2.2 Peak resolution and separation**

The mass resolving power of the ToF mass spectrometer used for this study was ~5000  $m/\Delta m$ , which does not allow for full peak separation of the ions contributing to nominal  $m/z$  235. The closest neighbor of HPMTF ( $m/z$  234.893) is nitrogen pentoxide ( $N_2O_5I^-$ ,  $m/z$  234.885).  $N_2O_5$  and HPMTF luckily rarely coexist in the lower troposphere, as HPMTF is produced during the sunlit months when  $N_2O_5$  production is suppressed and vice versa (Veres et al., 2020). Although  $N_2O_5$  is a highly  
195 reactive gaseous compound, it can partition to the particle phase but then largely dissociates (Gržinić et al., 2017). The second-

closest neighbor to HPMTF is a cluster of acetic acid with an iodate ion ( $\text{IO}_3^-\text{CH}_3\text{COOH}$ ,  $m/z$  234.910) (Veres et al., 2020). Calculations of the statistical precision ( $\sigma_B$ ) of the peak intensities (Cubison and Jimenez, 2015) of these two overlapping peaks for four example cases are presented in Fig. B1 and Table B1: (a) HPMTF as single ion (in practice meaning a high HPMTF/ $\text{IO}_3^-\text{H}_3\text{COOH}$  ratio); (b) HPMTF as the larger (parent) peak and  $\text{IO}_3^-\text{CH}_3\text{COOH}$  as the smaller (child) peak; (c) equal intensities of HPMTF and  $\text{IO}_3^-\text{CH}_3\text{COOH}$ ; (d)  $\text{IO}_3^-\text{CH}_3\text{COOH}$  as the parent peak and HPMTF as the child peak. As expected,  $\sigma_B$  is the highest in (a) (51%) and the lowest in (d) (2.9%). However, it should be noted that the peak intensities of HPMTF and  $\text{IO}_3^-\text{CH}_3\text{COOH}$  (p) seemingly are much too low ( $< 10$  ions  $\text{s}^{-1}$ ) to even be covered by the analysis in Cubison and Jimenez (2015).

### 2.3 Other particle measurements

A condensation particle counter (CPC; TSI Inc., USA, Model 3772) behind the whole-air inlet was used to measure the total particle number concentration (1 Hz data averaged to 1 min time resolution, lower cut-off size 5 nm, upper cut-off size approx. 40  $\mu\text{m}$ ). An optical particle size spectrometer (FIDAS 200S, Palas GmbH, Germany) was used to measure particulate mass concentrations (PM1, PM2.5, PM4 and PM10 averaged to 1 h time resolution). The instrument was installed on the terrace of Zeppelin Observatory and was equipped with its own heated inlet and additional RH and temperature (T) sensors to ensure that all values were measured at dry conditions.

### 2.4 Trajectories and meteorological data

Backward trajectories (10 days, out of which 5 days were used for this study) were calculated with HYSPLIT (Stein et al., 2015) using 3-hourly archive data from the National Center for Environmental Prediction's (NCEP) Global Data Assimilation System (GDAS) with 1 degree horizontal grid resolution, starting from the Zeppelin Observatory at 474 m a.s.l.. Since gas- and aerosol emissions from the surface (ocean) would be considered for the analysis, data within the model mixed-layer height were distinguished from the data points above the mixed layer. The average monthly mixed-layer was around 260 m, 380 m, and 390 m, in January, May and October, respectively. Monthly chlorophyll-*a* data from the Aqua/MODIS satellite were retrieved from NASA Earth Observatory (Hu et al., 2012).

Meteorological data (air temperature, atmospheric pressure and relative humidity) with 1 h time resolution were  
220 downloaded from the EBAS data base (Norwegian Institute for Air Research). More meteorological details are presented in  
Pasquier et al. (2022).

### 3 Results and discussion

#### 3.1 Seasonal pattern of DMS oxidation products

The high-resolution FIGAERO-CIMS data revealed the presence of seven compounds uniquely or potentially related to DMS  
225 oxidation: (HPMTF:  $C_2H_3OSO_2H$ , MSA:  $CH_3SO_3H$ , SA:  $H_2SO_4$ , sulfur dioxide:  $SO_2$ , sulfur trioxide:  $SO_3$ , bisulfate:  $HSO_3$ ,  
and disulfuric acid:  $H_2O_7S_2$ ). This is largely similar to earlier findings of particle-phase DMS oxidation products in the High  
Arctic with FIGAERO-CIMS (Siegel et al., 2021). The two organic compounds MSA and HPMTF have no other precursors  
than DMS, whereas the five inorganic compounds (SA,  $SO_2$ ,  $SO_3$ ,  $HSO_3$ , and  $H_2O_7S_2$ ) can originate from DMS oxidation but  
also from other sources, such as anthropogenic (e.g., ship fuel emissions) or other non-marine natural  $SO_2$  sources (e.g.,  
230 volcanic activity) (Barnes et al., 2006; Wu et al., 2015; Berndt et al., 2019). Here, we present the results of the gas- and particle-  
phase measurements of the DMS-related compounds.

##### 3.1.1 Gas-phase DMS oxidation products

Phytoplankton need solar radiation in order to produce DMS. Due to the large seasonal changes in the Arctic with the 24 h of  
darkness in winter and 24 h of sunlight in summer, it is of interest to compare the occurrence of DMS oxidation products  
235 throughout a full year.

In Figure 3a, c and e we show boxplots (monthly medians and percentiles) of the temporal evolution of the inorganic  
compound SA and the organic HPMTF and MSA in the gas phase between 2020-01-01 and 2020-12-17. A full time series,  
also including  $SO_2$ ,  $SO_3$ ,  $HSO_3$  and  $H_2O_7S_2$ , can be found in Fig. C1.

The inorganic SA (g) (Fig. 3a), which could be linked both to DMS oxidation and anthropogenic sources, displays  
240 the highest levels in January–April, i.e. not during the Arctic bloom period. During this time, synoptic-scale meteorology is  
different than in summer, with air masses from lower latitudes being advected into the north polar region (e.g., Heintzenberg  
et al., 1981; Frossard et al., 2011). These air masses carry anthropogenic pollution with elevated concentrations of sulfuric and

other chemical species from e.g. industries, and are known as the Arctic haze phenomenon (Hansen and Rosen, 1984; Mitchell, 1957). The results in Fig. 3a indicate that wintertime anthropogenic sources are the main contributor of annual inorganic sulfur  
245 in Ny-Ålesund, in agreement to previous studies (e.g., Jang et al., 2021).

MSA (g) (Fig. 3b) follows the expected pattern for a compound with DMS as its only source, where the concentration is very low during the winter and beginning of spring (October–March) and then starts increasing in April, when DMS starts being produced in the vicinity of Svalbard (Jang et al., 2021). It should however be noted that the onset and variability of the spring blooms show large variability from year to year (Galí et al., 2019; Jang et al., 2021). MSA (g) peaks sometime in May–  
250 June, and thereafter decreases toward the end of summer (September).

The levels of HPMTF (g) (Fig. 3c) develop similarly to MSA (g) during some parts of the year, with low levels in March, an increase in April and a peak in May. However, the variability over the bloom period is larger than for MSA (g) (see Fig. C1), and the measured HPMTF (g) concentration in May–September is sometimes as low as before the DMS production onset. HPMTF (g) further displays elevated levels in January and throughout September–October, which are completely  
255 lacking for MSA (g). During January and end of October, the Arctic experiences very few to no sunlit hours and DMS is not produced in the immediate vicinity of Svalbard, meaning that the measured HPMTF (g) must have been transported from an area with DMS production during these months. Another possibility is that we instead of HPMTF (g) measured N<sub>2</sub>O<sub>5</sub> (g) in winter. This is further discussed in Sect. 3.3 and 3.4.

During April–June, when MSA (g) and HPMTF (g) evolve in a common way, the level of MSA (g) is around 5 times  
260 higher than HPMTF (g) (assuming they have the same sensitivity in the FIGAERO-CIMS). This ratio is similar to the simulation **AtmMain** presented in Wollesen de Jonge et al. (2021), which was used as a base run scenario for an air parcel moving along a trajectory in a marine environment. The run was in total 120 h and included eight in-cloud events during both day- and night-time, with the last in-cloud event also including a rain event. The temperature was 280 K (~7°C) and the RH = 90%, i.e. fairly similar to the conditions in summer during the NASCENT campaign (Fig. C2). Therefore, it can be  
265 assumed that this scenario is representative of our data during this time of the year.

Further, the fact that HPMTF (g) and MSA (g) appear to have a relatively strong interrelationship in April–June indicates that they were formed from a local DMS source during this period (e.g., Becagli et al., 2016). Hence, we can assume

that DMS was at least partly oxidized through the abstraction pathway (Fig. 1) during these months (Wu et al., 2015; Berndt et al., 2019), despite the low occurrence of this mechanism compared to the addition pathway in the Nordic Seas according to Fung et al. (2022). However, the discrepancies that exist in the monthly absolute signal between measured MSA (g) and HPMTF (g) in summer could also be a sign that HPMTF (g) is not produced as efficiently as MSA (g) close to Svalbard due to e.g. low occurrence of OH radicals and/or meteorological factors. This hypothesis is supported by the higher importance of OH-initiated DMS oxidation at lower latitudes in the study by Fung et al. (2022), and the DMS conversion yields of MSA (g) and HPMTF (g) in the different model runs by Wollesen de Jonge et al. (2021), where the HPMTF/MSA ratio was considerably lower in the **AtmMain** case compared to cases with higher temperature and lower RH. This could be both due to differing sources and sinks, such as dry/wet deposition of MSA (Bergin et al., 1995) and HPMTF (Khan et al., 2021), heterogeneous oxidation of MSA (g) (Mungall et al., 2018) and evaporation of MSA from the particle- to the gas phase (Baccarini et al., 2021).

280 **Figure 3.** Box-and-whisker plots (with outliers removed) of SA, MSA and HPMTF in the gas- (g) and particle (p) phase per month of 2020, analyzed by FIGAERO-CIMS (panel (a)-(f)). Dashed horizontal lines inside the boxes represent median values, boxes the 25<sup>th</sup> and 75<sup>th</sup> data percentiles, and whiskers the maximum and minimum values of the populations. Panel (g) shows the total particle number concentration. Panel (h) shows the total particle mass (PM) of particles with diameters 1, 2.5, 4 and 10 μm, where the box-and-whisker plots (left-side axis) correspond to the sum of the particle sizes and the red markers (right-side axis) represent the monthly means of each size.

### 285 3.1.2 Particle-phase DMS oxidation products

Monthly boxplots of particle-phase SA, MSA and HPMTF are shown Figure 3b, d and f.

For SA (p) (Fig. 3b), the highest concentrations were measured in February and April, i.e. during the haze period. Slightly elevated levels are also found during summer, likely connected to DMS oxidation. These results are largely supported by measurements of particulate sulfate using an aerosol chemical speciation monitor (ACSM; data not shown), where the  
290 concentrations are overall declining from the beginning to the end of the year, with a small increase in July–August.

MSA (p) (Fig. 3d) follows a similar seasonal pattern in the particle and gas phase, where the highest levels are seen in June. The concentrations of HPMTF (p) (Fig. 3f) are much lower (2–3 orders of magnitude) than those of particulate MSA and SA and cannot be properly separated from the background. Hence, our conclusion is that the particulate amounts of HPMTF are negligible, and/or difficult to observe with the settings of our instrument. One reason for this is an extensive  
295 overlap with the peak  $\text{IO}_3^-$  ( $\text{CH}_3\text{COOH}$ ) (a cluster of acetic acid with an iodate ion, Veres et al., 2020), see Sect. 2.2.2. The signal of this cluster increased in the particle phase during the summer months relative to the winter, causing the time series of HPMTF (p) to appear very different from what is expected, with the lowest levels in summer and the highest in winter and spring. The statistical precision ( $\sigma_B$ ) of the peak intensities of these two ions (Cubison and Jimenez, 2015) (Fig. B1 and Table B1) show that the peak intensities of HPMTF (p) and  $\text{IO}_3^-$ - $\text{CH}_3\text{COOH}$  (p) in combination with our current level of mass  
300 resolution ( $\sim 5000$  m/ $\Delta$ m) were too low to be properly resolved (Sect. 2.2.2). This is in line with previous results from Wollesen de Jonge et al. (2021), which showed that HPMTF was an important gaseous DMS oxidation product, but that it does not contribute directly in significant amounts to particulate mass. However, it is possible that HPMTF (g) is taken up by particles, especially when these are wetted (Vermeuel et al., 2020), where it likely would quickly undergo peroxide oxidation or nucleophilic substitution (Jernigan et al., 2022). Similar to earlier observations by Veres et al. (2020) and Wollesen de Jonge  
305 et al. (2021), the levels of HPMTF (g) during NASCENT were seen to decrease as a function of increased atmospheric water content. This is further discussed in Sect. 3.3.

Further insights into the seasonality of the particle-phase DMS oxidation products can be obtained through comparison to the total particle number concentration (Fig. 3g) and concentrations of  $\text{PM}_x$  (particulate matter  $< x$   $\mu\text{m}$ ) (Fig. 3h). The highest PM concentrations (Fig. 3h) were measured during the winter and spring (November–April), and the

310 lowest during the summer months (June–September). The peak in July, likely influenced by a biomass burning event, is an exception. This pattern is in overall agreement to previous observations in Ny-Ålesund (Tunved et al., 2013). However, the summer months are known for higher particle number concentrations due to new particle formation (Tunved et al., 2013), driven by SA (g) with subsequent growth by condensation of SA (g) and MSA (g) (Beck et al., 2021; Xavier et al., 2022). Fig. 3g clearly shows that the particle number concentration peak in 2020 coincided with the summer peak of particulate DMS  
315 oxidation products, indicating that SA and MSA (but not HPMTF) were participating in the growth of the newly formed particles. This means that the measured SA (p) in winter most likely was of anthropogenic origin where SA (g) condensed onto pre-existing accumulation mode particles in the atmosphere, whereas in summer it was produced locally via DMS oxidation and subsequent condensation and at least partly via new particle formation.

### 3.2 Correlation between gas- and particle phase concentrations

320 As was discussed in the previous section, there appears to be a seasonal pattern of the DMS oxidation products, which is clearer for MSA and SA than for HPMTF, for both gas and particle phase. As MSA and SA are known to contribute to particle mass (e.g. Lovejoy et al., 2004; Sipilä et al., 2010), a correlation between the gas- and particle phase can give indications on the direct relationship between the two phases, which would be important for e.g. model simulations of particle growth. Previous studies from the Arctic pack ice region in summer, farther away from DMS sources, have shown that MSA and SA do not  
325 exhibit any correlation between the gas- and particle phase (Chang et al., 2011; Siegel et al., 2021), and similar results from Antarctica have been reported (Davis et al., 1998; Read et al., 2008).

In Fig. 4 we show scatterplots for the two phases per “season”, where January–April (JFMA, panel (a)) represent late winter–early spring, May–July (MJJ, panel (b)) represent late spring–summer, and September–December (SOND, panel (c)) represent early fall–early winter.

330 As expected from Fig. 3, HPMTF appears to have no relationship between the phases in either season. The same is true for SA (g) and (p). To some extent, a correlation between the gas and particle phase is visible for MSA in JFMA and MJJ (due to the increasing levels in April and high production during summer), but not at all in SOND (after the bloom season). Although no correlation is notable for MSA and SA individually in MJJ, a different pattern appears when combining the datasets. An orthogonal linear regression analysis (non-weighted) (Cantrell, 2008) of the combined MSA and SA data (both

335 gas- and particle-phase signals logarithmized) in MJJ results in a an  $R^2$  of 0.32 (Fig. 4b), which indicates a weakly positive linear relationship, and that MSA and SA have the same sources and are part of the same reaction process during these months. Due to the insignificant levels of HPMTF (p), HPMTF lies outside of this connected relationship.

Besides seasonal variation, diurnal cycles of DMS oxidation products have previously been reported (Vermeuel et al., 2020). However, no diurnal patterns were possible to see with our dataset, similarly to the study by Baccharini et al. (2021)  
340 in the Southern Ocean. Our hypothesis is that the large seasonal differences and fast changes around the equinoxes in Ny-Ålesund affect the pattern in a way that makes diurnal cycles difficult to identify.

**Figure 4.** Relationship between gas- and particle-phase MSA, SA and HPMTF per season: (a) January–April (JFMA), (b) May–July  
345 (MJJ), (c) September–December (SOND). The black line in panel (b) represents the orthogonal linear regression between the combined logarithmized MSA and SA datasets. The linear equation and correlation coefficient  $R^2$  are shown in the lower right corner.

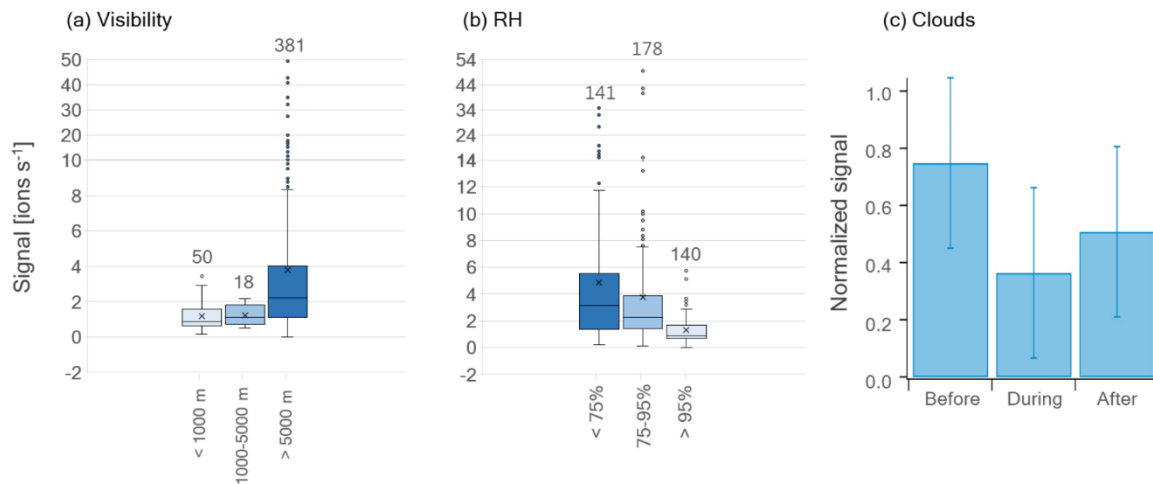

### 3.3 Correlation of HPMTF (g) with visibility and relative humidity

Previous studies have found gas-phase HPMTF to be readily taken up by clouds and hence suggested that wet scavenging is an important atmospheric sink (e.g., Khan et al., 2021; Novak et al., 2021). Therefore, we investigated the measured levels of  
350 HPMTF (g) as a function of visibility (vis, Fig. 5a) and RH (Fig. 5b) (averages per sampling period) during the summer months (MJJ). Cloudy conditions are represented by  $\text{vis} < 1$  km and cloud-free conditions by  $\text{vis} > 5$  km.  $\text{vis} = 1\text{--}5$  km be viewed as a “transition state” between these conditions, here referred to as “semi-cloudy”. Further, a high atmospheric water content

(referred to as “wet”) is here defined as  $RH > 95\%$ , whereas a low water content (referred to as “dry”) is set to  $< 75\%$ . Hence, the range 75–95% (“semi-wet”) refer to data points at neither high nor low RH.

355 In Fig. 5a, the average HPMTF (g) level is lower during cloudy and semi-cloudy compared to cloud-free conditions. However, these data are too unequally distributed (see the number of data points above each box-and-whisker plot) and skewed (especially  $> 5$  km) to make a statistical analysis meaningful. The data related to RH in Fig. 5b are more equally distributed; however, they are skewed, as seen on the outliers towards higher HPMTF (g) levels. A statistical evaluation using the Wilcoxon rank-sum test for skewed data (two-tailed) of the three RH ranges, where the  $p$ -values are summarized in Table C1, shows that  
360 the largest differences lie in the HPMTF (g) data between the wet case and the semi-wet/dry cases. These are statistically different at a 99% confidence level, whereas the data of the wet and semi-wet cases are statistically different at a 90% confidence level. The  $p$ -values of the analyses involving the wet case are, however, much smaller ( $3.9 \times 10^{-18}$  and  $3.0 \times 10^{-19}$ ) than between the semi-wet and dry cases (0.059), showing that HPMTF (g) is most effectively scavenged when  $RH > 95\%$ .

Nevertheless, one must keep in mind that changes in RH could be a sign of an air mass shift, which likely has an  
365 influence on the atmospheric composition. Hence, it is difficult to conclude whether the RH or air mass origin is the main reason for the lower HPMTF (g) concentration at high RH. However, during the cloud events studied in Gramlich et al. (2022), HPMTF (g) levels were lower compared to right before and right after the cloudy period (Fig. 5c). These cloudy periods also correspond to the time with the highest RH values, hence, this demonstrates that cloudy and wet conditions do reduce HPMTF (g) levels in the atmosphere in Svalbard during summer. However, we did not detect HPMTF nor any of its possible  
370 reaction products (e.g.,  $C_2H_4SO_2$ ,  $C_2H_6SO_2$ ) (Jernigan et al., 2022) in significant amounts in any of the cloud residual samples (data not shown) (Gramlich et al., 2022). Therefore, we cannot make a conclusive statement about the fate of HPMTF in the particle phase with our dataset.

**Figure 5.** Box-and-whisker plots of HPMTF (g) levels during MMJ divided into (a) visibility ranges, (b) RH ranges (averages per sampling period). The horizontal lines inside the boxes correspond to the median and cross markers to the mean of each population. Quartiles are represented by the box borders, maximum and minimum values of the populations are represented by the whiskers, and outliers are shown as individual points outside the whisker ranges. The number of data points in each population is written above the plots. Panel (c) shows the average signal of HPMTF (g) before, during and after cloud events during May and June 2020. The error bars correspond to the standard deviation. The signals were normalized to the maximum HPMTF (g) signal of the individual cloud cases (combining the signals before, during and after) before computing the average and standard deviation.

### 3.4 Source regions of observed HPMTF

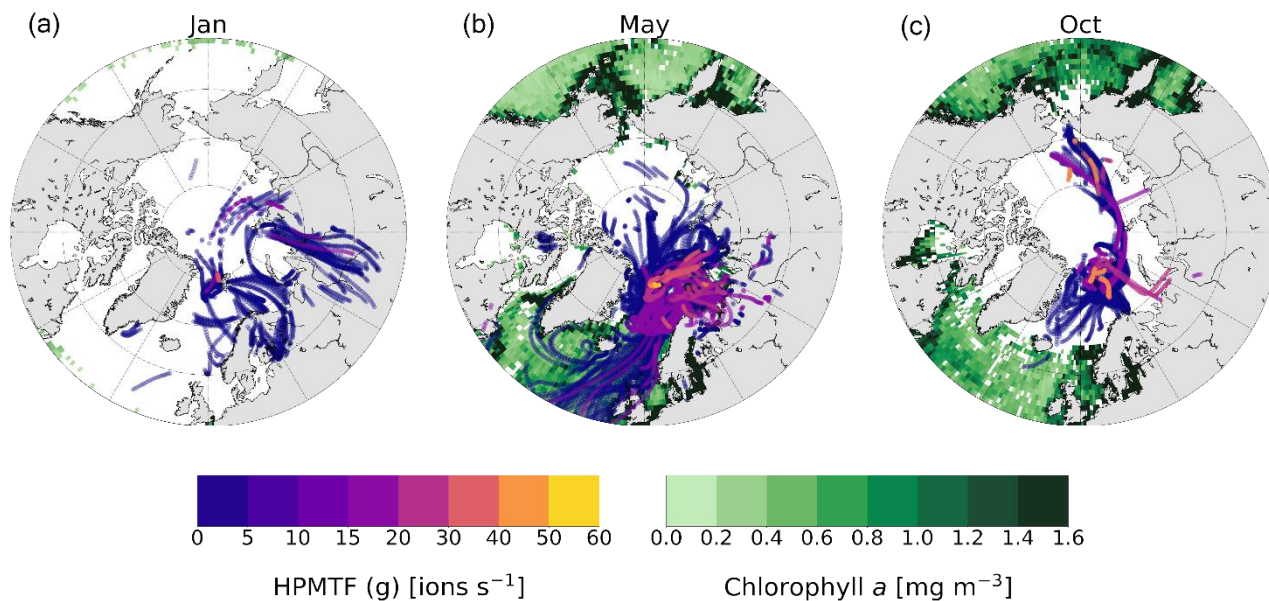

DMS is not produced close to Ny-Ålesund during wintertime due to the lack of sunlight, and the relatively high observed levels of presumed HPMTF (g) in January and high levels in October (Fig. 3e) are surprising. To investigate the possibilities of measuring high HPMTF concentrations during the dark and sunlit months, we analysed the HPMTF (g) content carried by

385 air masses to Ny-Ålesund in January, May and October using 5-day backward trajectories and satellite observations of marine chlorophyll-*a*, used as a proxy for DMS production (Fig. 6).

In May, the chlorophyll-*a* concentration was high in the coastal areas around Svalbard, and essentially all air masses arriving to Ny-Ålesund carried some HPMTF. The highest concentrations appear to originate from the Barents Sea, which is in line with previous results by Park et al. (2021).

390 In October, there were still some algal blooms at the Norwegian coast, south of Iceland and Greenland. However, the trajectories show that the air masses in October had spent the last 5 days before arriving to Ny-Ålesund within the Arctic region, far away from DMS-producing areas at lower latitudes. Several studies have shown that long-range transport of HPMTF is possible (Vermeuel et al., 2020; Khan et al., 2021; Novak et al., 2021); however, it seems unlikely as of the efficient scavenging of HPMTF by clouds (e.g., Khan et al., 2021; Novak et al., 2021). This is supported by the simulation case in the  
395 study by Wollesen de Jonge et al. (2021), which could be said to represent our measurement conditions (Sect. 3.1.1) and included both in-cloud events and a rain event. Although it seems unlikely, the possibility that HPMTF was transported to Svalbard in October cannot be ruled out.

In January there was almost no chlorophyll-*a* in the surface waters  $> 50^\circ$  N, and most of the air masses originated from Europe and Siberia. As the Arctic is experiencing polar night and low temperatures in January, and the trajectories indicate  
400 that the air masses were arriving from terrestrial areas, another hypothesis is that these peaks should instead be attributed to  $N_2O_5$ , as has been observed previously in Alaska during wintertime (Ayers and Simpson, 2006). This hypothesis is partly supported by the fact that  $N_2O_5$  was a better fit in the high-resolution mass spectrum than HPMTF during the second half of January (Fig. C3), although more directed measurements (such as in the study from Alaska) would be needed to verify this.

405

**Figure 6.** 5-day backwards trajectories arriving at the Zeppelin Observatory in (a) January, (b) May and (c) October, colored by measured HPMTF content in the gas phase [ $\text{ions s}^{-1}$ ]. Only trajectory points corresponding to times below the mixed-layer height are shown. The green areas show marine chlorophyll *a* concentration (monthly mean), indicative of DMS production.

#### 4 Summary and conclusions

410 We present a full year (2020) of gas- and particle phase observations of DMS oxidation products obtained with FIGAERO-CIMS at the Zeppelin Observatory, Svalbard. We focus especially on the newly discovered DMS oxidation product hydroperoxymethyl thioformate (HPMTF) (Veres et al., 2020), for which in situ observations are still limited. It has never been measured in Svalbard or attempted to be observed in atmospheric particulate matter.

Our results indicate that HPMTF is produced in large amounts in the vicinity of Svalbard during summer (April–  
 415 September), and can be measured in October possibly as a result of transportation from lower latitudes. In summer, HPMTF follows the seasonal increase of MSA in the gas phase to some extent, but it could not be measured in the particle phase in significant amounts. This is in line with previous laboratory results by Wollesen de Jonge et al. (2021), stating that HPMTF did not contribute directly to particle growth despite high concentrations in the gas phase. Elevated levels in the gas phase

were also measured in January; however, due to the lack of DMS sources within a radius reasonable for long-range transport, we speculate that this could instead be  $\text{N}_2\text{O}_5$ , which cannot be fully separated from HPMTF with the resolution of the mass spectrometer deployed.

MSA follows a clear evolution pattern in both the gas- and particle phase, with an onset in April and fast decrease towards the end of Arctic summer (~September), similar to earlier findings in Ny-Ålesund (Jang et al., 2021). Sulfuric acid (SA) was found in high concentrations during the winter/spring months (January–April) in both phases, assumed to be a result of condensation onto accumulation mode particles from lower latitudes which are commonly found in the Arctic during the spring haze period (e.g., Tunved et al., 2013). Particle-phase SA was also measured in summer when the total particle mass concentrations were low but number concentrations high, indicating DMS oxidation and new particle formation as a source.

Due to the insignificant amounts of HPMTF in the particle phase, no correlation between the two phases could be seen in any of the seasons. For MSA and SA, no correlation was visible in fall–winter–spring (~September–April), but a clear relationship emerged during the sunlit months with DMS production (~May–July). The relationship between the phases of MSA and SA also appeared to be connected, where MSA was more abundant in both phases during summer.

As has been seen in several previous studies (e.g., Veres et al., 2020; Vermeuel et al., 2020; Wollesen de Jonge et al., 2021), we also noticed a decrease in HPMTF (g) levels during periods of cloud occurrence (visibility < 1 km) and high RH (> 95%) in May–June. This shows that cloud removal is an efficient sink for HPMTF (g) also in Ny-Ålesund during summer.

With this study, we aimed to investigate the links between the relatively well-known seasonal patterns of MSA and SA (Leaitch et al., 2013; Becagli et al., 2016; Jang et al., 2021) and the almost unknown one of HPMTF. We concluded that there is a relationship between gas-phase MSA and HPMTF in summer, indicative of an apparent contribution of the abstraction pathway to DMS oxidation. SA and HPMTF have a low correlation, partly due to SA's preference for the particle phase and HPMTF for the gas phase.

Future studies should focus on quantification of the measured levels of HPMTF in both gas- and particle phase. This information could be used for modelling of DMS oxidation and would thereby increase quantitative knowledge about oxidation pathways and sinks of HPMTF in the Arctic. For the particle-phase measurements in particular, it would be useful to investigate the possibility of a better peak separation between HPMTF and mainly the acetic acid-iodate cluster  $\text{IO}_3^- \text{CH}_3\text{COOH}$  in the

FIGAERO-CIMS. This can be achieved by e.g. using a mass spectrometer with a higher resolution or concurrent measurements  
445 of N<sub>2</sub>O<sub>5</sub> and acetic acid. The possibility for indirect contributions of HPMTF to particulate mass, such as an increase of sulfate  
due to HPMTF oxidation in the aqueous phase as reported by Wollesen de Jonge et al. (2021), should also be investigated in  
association to typical atmospheric conditions in the Arctic throughout the year.

### **Data availability**

The data of this study is available upon request to the corresponding author and will be made available at a later stage on the  
450 Bolin Centre Database (<https://bolin.su.se/data/>). The meteorological data is available on the EBAS data base (Tørseth et al.,  
2012).

### **Author contribution**

CM, PZ and RK were responsible for funding and conceptualization. YG, KS, SH and CM performed the FIGAERO-CIMS  
measurements. YG, KS and SH wrote code for FIGAERO-CIMS analysis. RK, PZ and GF operated the GCVI and provided  
455 the GCVI data. PZ provided the CPC and the FIDAS data. KS and YG analyzed and visualized the FIGAERO-CIMS data,  
and visualized the GCVI and CPC data. KS visualized the trajectories, and wrote the manuscript with input from CM. CM was  
responsible for supervision. All co-authors have read and commented on the manuscript.

### **Competing interests**

Some of the authors are co-editors at ACP.

authors also thank Chris Lunder and Ian (Gang) Chen for providing the ACSM data.

Details on the FIGAERO-CIMS measurement cycles, referring to the text in Sect. 2.2.

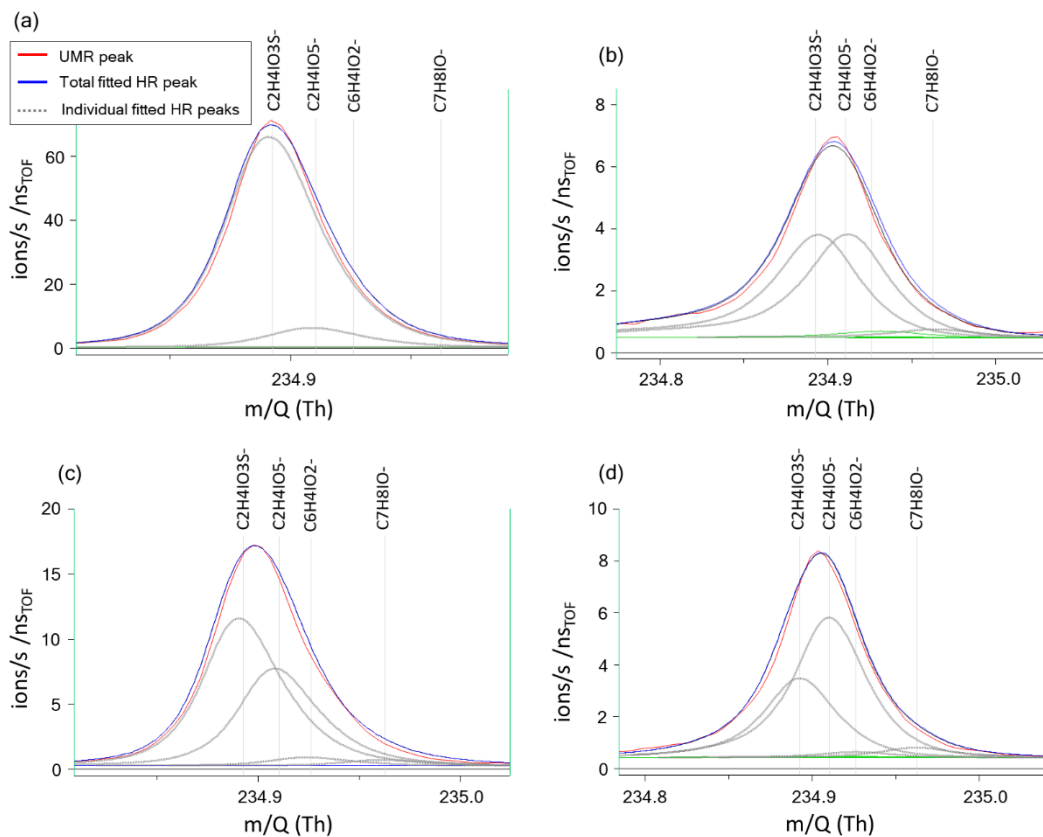

**Figure A1.** Example of a FIGAERO-CIMS sampling cycle, using the timeseries of the nitric acid iodide adduct ( $\text{HNO}_3\text{I}^-$ ), shown in black. The letter S represents a particle-phase sample and B a particle-phase blank. The blue boxes define the times of a sampling cycle, when gas-phase measurements are done while particles are deposited on a filter. The green circle markers show the gas-phase sample segments (normally 3 segments) and the yellow diamond markers the gas-phase background segments (normally 2) identified for each sampling period. The dark-green triangles represent the averaged gas-phase sample segments and the orange triangles the averaged gas-phase background segments. The solid red line shows the heater temperature, i.e. the temperature of the  $\text{N}_2$  flow passing through the filter.

485

**Table A1.** Scheme of the FIGAERO-CIMS measurement cycle during NASCENT. Every third such cycle was particle blank with an additional particle filter upstream of the particle sample filter. BG stands for background measurement.

Peak separation of HPMTF and its neighbor peaks.

**Figure B1.** Four example cases of the separation of the two peaks HPMTF (in figure: C<sub>2</sub>H<sub>4</sub>IO<sub>3</sub>S<sup>-</sup>) and the acetic acid/iodate cluster IO<sub>3</sub><sup>-</sup>CH<sub>3</sub>COOH (in figure: C<sub>2</sub>H<sub>4</sub>IO<sub>5</sub><sup>-</sup>) (Veres et al., 2020), as analyzed by FIGAERO-CIMS: (a) HPMTF as single ion (in practice a high HPMTF/IO<sub>3</sub><sup>-</sup>CH<sub>3</sub>COOH ratio), (b) HPMTF as the larger (parent) peak and IO<sub>3</sub><sup>-</sup>CH<sub>3</sub>COOH as the smaller (child) peak, (c) equal intensities of HPMTF and IO<sub>3</sub><sup>-</sup>CH<sub>3</sub>COOH, and (d) IO<sub>3</sub><sup>-</sup>CH<sub>3</sub>COOH as the parent peak and HPMTF as the child peak. The peak separation statistics are shown in Table B1. UMR = Unit Mass Resolution, HR = High Resolution.

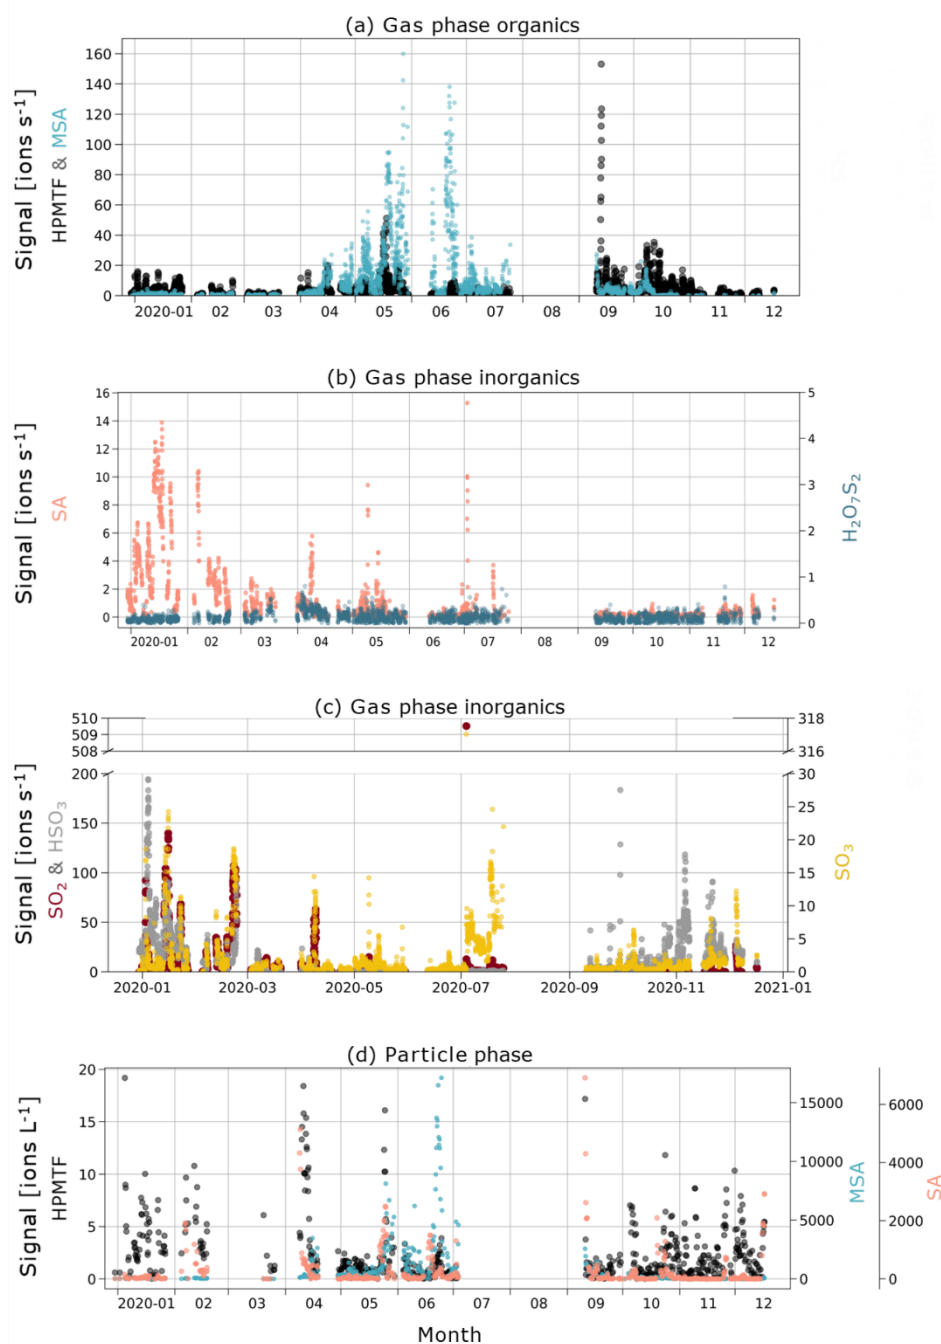

500 **Table B1.** Separation statistics of the two peaks HPMTF and the acetic acid/iodate cluster  $\text{IO}_3\text{CH}_3\text{COOH}$  (Cubison and Jimenez, 2015). The first column corresponds to the example cases shown in Fig. B1 (a)-(d). The parameter  $\chi$  shows the degree of separation of the two peaks, whereas  $\sigma_B$  shows the statistical precision of the peak intensities. When in bold font,  $\sigma_B$  corresponds to the precision of the HPMTF peak as parent/child. In case (c), HPMTF can be viewed as either the parent or child, and the precision is therefore in the range 3.2-5.4%.

Peak type	Fitted intensity [ions]	HPMTF % of UMR intensity	Ratio HPMTF/C2H4IO5	Peak separation ( $\chi$ )	$\sigma_B$ (parent) [%] <sup>*</sup>	$\sigma_B$ (child) [%] <sup>*</sup>	Regime <sup>**</sup>
Single ion (a)	212	91	11	0.7	<b>51</b>	2.9	Counting-error
