Abstract. Europe frequently experiences by a wide range of extreme events and natural hazards, including heatwaves, extreme precipitation, droughts, cold spells, windstorms, and storm surges. Many of these events do not occur as single extreme events, but rather show a multivariate character, known as compound events. We investigate the interactions between extreme weather events, their characteristics, changes in intensity, frequency, as well as uncertainties in the past, present and future. We also explore their impacts on various socio-economic sectors in Germany and Central Europe. This contribution highlights several

41 case studies with special focus on 2018, a year marked by an exceptional sequence of compound events across large parts of
42 Europe, resulting in severe impacts on human lives, ecosystems, and infrastructure. We provide new insights into the drivers
43 of spatially and temporally compound events, such as heat and drought and heavy precipitation combined with extreme winds,
44 and their adverse effects on ecosystems and society, using large-scale atmospheric patterns. We also examine the interannual
45 influence of droughts on surface water, and the impact of water scarcity and heatwaves on agriculture and forests. we assess
46 projected changes in compound events at different current and future global surface temperature levels, demonstrating the need
47 for improved quantification of future extreme events to support adaptation planning. Finally, we address research gaps and
48 future directions, stressing the importance of defining composite events primarily in terms of their impacts prior to their
49 statistical characterisation.

50

51 **1 Introduction**

52 Extreme temperatures, strong extratropical low pressure systems and their associated extreme winds and heavy precipitation
53 events can have devastating socio-economic impacts. Moreover, the combination of otherwise regular climate and weather
54 phenomena can unfold their effects beyond the individual events (Ridder et al., 2020) and have devastating consequences and
55 impacts (Ridder et al., 2022; Bevacqua et. al., 2017, 2021, 2023 and references therein). Thus, human and natural systems that
56 are usually able to handle the impacts of single extreme events are challenged by the co-occurrence of two or more extremes
57 (compound events, CE) which severely increase the risk of loss and damage (Toreti et al., 2019a). Events with additive and
58 multiplicative effects are of utmost importance and can result from mutually reinforcing cycles/positive feedback between
59 individual events. Interrelated events, e.g., through land surface-atmosphere interactions or atmospheric moisture conditions,
60 modify extreme events (Wang et al., 2022). The effects may develop also through atmospheric dynamics that connect features
61 such as the 2010 Russian heatwave and the flood in Pakistan (Barriopedro et al., 2011; Lau et al., 2012; Zscheischler et al.,
62 2018) or through induced responses at distant areas of significant impact to the global system (Vogel et al., 2019).

63 The Intergovernmental Panel on Climate Change (IPCC; Seneviratne et al., 2012) defines CEs as 1) two or more extreme
64 events occurring simultaneously or successively, 2) a combination of extreme events with underlying conditions that amplify
65 the impact of the events, or 3) a combination of events that are not themselves extremes but lead to an extreme event or impact
66 when combined. This definition is embedded within the IPCC risk framework under the umbrella of a combination of multiple
67 drivers and/or hazards that contribute to societal or environmental risks. Also embedded in this framework is the understanding
68 that response to an imminent risk can, in its own right, serve to reduce or to increase future risks. CEs often lead to
69 disproportionate impacts on people and ecosystems (Seneviratne et al., 2012; Leonard et al., 2014; Caldeira et al., 2015; Bastos
70 et al., 2021). To quantify the probability of CEs in today's and future climate is of great importance specifically for adaptation
71 planning for various sectors including agriculture, fisheries, river transport, energy supply, tourism, etc. (Zscheischler and
72 Fischer, 2020). Recently, Zscheischler et al. (2020) extended the definition and classified CEs into 1) preconditioned events,

73 where a weather-driven or climate-driven precondition aggravates the impacts of a climatic impact-driver; 2) multivariate
74 events, where multiple drivers and/or climatic impact-drivers lead to an impact; 3) temporally compounding events, where a
75 succession of hazards leads to an impact; and 4) spatially compounding events, where hazards in multiple connected locations
76 cause an aggregated impact. Drivers include processes, variables, and phenomena in the climate and weather domain that may
77 span over multiple spatial and temporal scales (Zscheischler et al., 2020). Current research on weather and climate impacts,
78 risks and damages often underestimates the influence of CEs (Ridder et al., 2021). It is therefore essential to adapt research
79 strategies and tools, such as models, to integrate compound weather and climate events, enabling a more accurate assessment
80 of uncertainties, impacts and risks. Further, anthropogenic climate change is expected to influence the frequency and intensity
81 of CEs, and thus future planning for such changes requires reliable climate models, which can represent these hazards, their
82 underlying drivers as well as their combinations. Despite this importance, studies evaluating climate model representation of
83 CEs are still rare (Aalbers et al., 2013; Bevacqua et al., 2023; Manning et al., 2023). Further, the impact of climate change to
84 dynamic changes in the atmosphere and consequently to the location and magnitude of extreme events and its compounds is
85 less well understood and thus characterised as low confidence by the IPCC (IPCC, 2021). This holds true also for CEs, which
86 are naturally even more complex due to their multivariate character, also in terms of the complexity of the atmospheric
87 circulation state. For instance, the COVID-19 pandemic has brought dynamics of compound hazards and risk-response
88 feedback to the forefront of hydrometeorological hazard response and preparedness (Simpson et al., 2021; Zaitchik et al.,
89 2022). Compound hazards are rare, and those for instance that involve a disease such as COVID-19 have no recent precedent.
90 The more complex CEs become, the clearer are the limitations of the conventional statistical approaches to risk assessment
91 (Zaitchik et al., 2022).

92 The development of integrated research on CEs is the objective of the European COST Action DAMOCLES
93 (<http://www.damocles.compoundevents.org>) that bundled research efforts in this field, and towards which several of the
94 authors actively contribute. One of the main knowledge gaps identified concerns how the compound character of events is
95 changing in a warming world and will continue to change during future decades. The question on how and why extreme
96 weather events affecting specifically Germany and Central Europe may change in a warming climate is the major topic of the
97 climXtreme project (<https://climxtreme.net/>), in the frame of which this work has been conducted, aiming to analyze and
98 understand the dynamics of extreme climate events, their impacts, and potential future trends in a changing climate. To analyse
99 hot and dry compounds, a variety of research questions and approaches are explored: at the global scale, the precursors of
100 spatially and temporally CEs are analysed using large-scale atmospheric patterns and jet stream states. At the European scale,
101 the detection and identification of events and the spatial representation of key climate variables in relation to heatwaves are
102 investigated. Focusing on Germany, the interannual influence of droughts on surface water is analysed and the impact of water
103 scarcity and heatwaves on agriculture and forests is studied. Further, the CEs including precipitation and/or wind as a hazard
104 are analysed focusing on a series of windstorms and convective storms with adverse impacts on ecosystems and society.

105 All case studies presented in this paper are selected from the calendar year 2018, which is of particular interest given the
106 prolonged and persistent dry and hot conditions across large parts of Europe as well as featured storms Eleanor and David

107 (coined Burglind and Friederike in Germany and hereafter) in January 2018 and several weeks of thunderstorm activity in May
108 and June. 2018 was also characterized by strong wind gusts that co-occurred with heavy snowfall during the windstorm
109 Friederike (Vautard et al., 2019), a relatively dry spring with exceptionally high temperatures followed by an extremely dry
110 summer with very warm mean temperatures over large areas of Europe (Munich Re, 2019; Zscheischler and Fischer, 2020).
111 Total precipitation in central Europe was at the lowest percentiles relative to the 1976–2005 distribution; Germany experienced
112 a reduction of precipitation of ~53% in July and of ~46% in August compared to the period 1981-2010 (Deutscher
113 Wetterdienst, 2018). The summer in Germany was characterised by the most extreme combination of high temperatures, as
114 one of the warmest years on record (Kaspar et al., 2023) and low precipitation since 1881 (Zscheischler and Fischer, 2020).
115 The combination of the individual events caused tremendous adverse and detrimental impacts in larger areas of western Europe
116 with a peak over Germany and on a variety of sectors ranging from agriculture and society (Manning et al., 2018; Toreti et al.,
117 2019b; Zscheischler and Fischer, 2020; Conradt et al., 2023; Shyrokaya et al., 2024), forests (Bastos et al., 2020; Buras et al.,
118 2020; de Brito et al., 2020; Senf and Seidl, 2021), fires (Munich Re 2019; Bastos et al., 2020), ecology (Bastos et al., 2021),
119 soil and surface water (Liu et al., 2020; Brakkee et al., 2022; Hartick et al., 2021), marine environment (Kaiser et al., 2023),
120 traffic disruption, power outages, property damage by e.g. falling trees, fatalities (Vautard et al., 2019) as well as human health
121 (Matzarakis et al., 2020; Conradt et al., 2023). The exceptional heatwave of 2018 also caused many nuclear power plants to
122 shut down because the rivers could not provide sufficient cooling capacity for the reactors (Vogel et al., 2019). In addition,
123 Blauhut et al. (2022) surveyed stakeholders across Europe regarding their perceptions of the 2018–2019 drought and drought
124 risk management in their respective countries. Germany was identified as being aware of drought risks but among the least
125 prepared, lacking a formal management plan.

126 We study this exceptional year and the series of extremes and CEs in a sequence of the large scale, their detection and spatial
127 representation as well as the long term impacts on soil moisture both at the continental scale and the consequent agriculture
128 and forestry impacts at the national scale. The paper first outlines the data and methodologies used for analysing the selected
129 CEs in 2018, followed by a detailed analysis of each case study. These case studies are categorized into temperature-
130 precipitation and precipitation-wind CE storylines, along with an evaluation of their impacts in Germany.

131 **2 Data and Methods**

132 Different methodological approaches have been used, tailored to the different types of CEs, ranging from better understanding
133 of the selected event drivers to sectoral impact assessments. This section summarizes these approaches and provides a basis
134 for the study and analysis of the selected case studies separated in temperature-precipitation and precipitation-wind CEs. The
135 temperature-precipitation storyline includes analysis on drivers of the hot summer of 2018, detection of extreme events and
136 spatial patterns, assessment of the impact of the 2018 European drought on soil moisture and groundwater as well as sectoral
137 impacts on agriculture and forestry. The storyline is complemented with an assessment of model simulations to realistically
138 represent conditions as those of 2018 in Germany. The precipitation-wind storyline comprises the analysis of intense low

139 pressure systems in winter 2018, their life cycle and triggering role for compound precipitation and wind events, as well as
140 severe convective storms during the 2018 warm season. Considering the nature of the various case studies and events during
141 the warm season of 2018, and given the focus on compound events in this study, we aim to define the characteristics of the
142 events analysed and their interrelationships. Additionally, a range of relative thresholds, such as the 90th, 95th, and 98th
143 percentiles, appropriate for each variable and elaborated impact are used to define extremes, and we will provide explanations
144 for their application.
145

146 **2.1 Drivers of the hot summer of 2018**

147 To better understand the drivers of the hot summer of 2018, Rousi et al. (2022) identified jet states in the zonal mean zonal
148 wind over the Eurasian sector at different pressure levels for the summer months in ERA5 data (Hersbach et al., 2020) using
149 Self-Organizing Maps (SOMs, see Kohonen, 2013; Rousi et al., 2015). A comparative approach with different cluster numbers,
150 clustering algorithms and initializations of SOMs led to a robust cluster of double jet states. Increased persistence of those jet
151 states was connected to heatwave events (defined as a period of at least 3 consecutive days of daily maximum temperature
152 threshold exceedance > 90th percentile, following Fischer and Schär (2010) and a spatial extent over 40.000 km² within a 4°
153 x 4° spatial sliding window, similar to Stefanon et al. (2012) across western Europe (Rousi et al., 2022).

154 **2.2 Detection of spatial patterns of extreme events**

155 The analysis of the large-scale temperature and precipitation deficit patterns and their expression during the 2018 heatwave at
156 the European scale is based on the cross-Tail Pairwise Dependence Matrix (cross-TPDM) and Extreme Pattern Index (EPI)
157 proposed by Szemkus and Friederichs (2024). Typical spatial patterns of common extremes are derived by singular value
158 decomposition of the cross-TPDM. The cross-TPDM is a measurement of extremal dependence, rooted in extreme value theory
159 and has comparable statistical properties to the cross-covariance matrix (Szemkus and Friederichs, 2024; Cooley and Thibaud,
160 2019). The singular vectors of cross-TPDM represent pairs of spatial patterns in which extremes in two variables are likely to
161 occur simultaneously. Consequently, the expansion coefficients provide a time series for each singular vector that summarise
162 the occurrence of extreme events within the respective pattern. The first 10 left and right expansion coefficients are then
163 summarised in the EPI that is high when individual patterns or a linear combination of leading patterns are particularly strongly
164 pronounced. This pattern-based analysis thus provides a robust measurement for the heatwave and drought intensity over
165 Europe. Before calculating the cross-TPDM and EPI, the ERA5 daily 2m temperature and precipitation deficits for the summer
166 months (June-August) of 2018 are standardised and the annual cycle is removed. Precipitation deficits are calculated as the
167 inverse of the 90-day accumulated precipitation.

168 **2.3 Surface water storage of the dry summer of 2018**

169 To analyse the drought characteristics of the summer of 2018, an ensemble of simulations for the hydrological year 2018/19
170 is used (Hartick et al., 2021). The hydrological year 2018/2019 was initialised with land surface and subsurface conditions
171 from the end of the hydrological year 2018 and simulated using different atmospheric boundary conditions. The proposed
172 approach investigates the impact of hydrologic initialization, and soil and groundwater memory on water storage anomalies
173 against the background of atmospheric variability and uncertainty on an interannual time scale. The varying atmospheric initial
174 conditions were derived from the ERA-Interim data for each individual year between 1996 and 2018 and resulted in 22
175 realisations as the number of individual years within that period. Thus, the ensemble of realisations of the hydrological year
176 2018/2019 accounts for a large part of the atmospheric uncertainty. The analysis was performed for 20 European river basins.
177 The 2018 drought was defined as the driest 10% of the total water storage anomalies (S) occurring in 2018 within the
178 climatological time series. Surface water availability for the 2018/2019 hydrological year was represented by surface water
179 storage (S_u), categorised into dry, $S_{u,d}$, and wet, $S_{u,w}$, anomalies. To ensure that an increased probability of $S_{u,d}$ in the
180 hydrological year 2018/2019 was outside of regular climate variability, we compared the $S_{u,d}$ probability distribution of the
181 described hydrological year 2018/2019 ensemble (Case A) with the probability distribution of $S_{u,d}$ within the climatological
182 time series (Case B), see also the corresponding section below. Two beta distributions were generated, one for each case, by
183 applying a prior with no information. We sampled each beta distribution 10,000 times and calculated the probability of Case
184 $A > Case B$ to determine the confidence that the probability of a $S_{u,d}$ after a drought is greater than the climatological variability.
185 In addition, we obtained the uncertainty of the confidence intervals by bootstrapping 1000 times over the climatological time
186 series. The methodology provides a probabilistic insight into the impact of a groundwater drought on future surface water
187 resources on an interannual time scale.

188 **2.4 Soil moisture of the dry summer of 2018**

189 In addition to the dry surface water anomaly in Central Europe, soils showed moisture deficits (Liu et al., 2020; Bastos et al.,
190 2020; Rousi et al., 2023; Conradt et al., 2023). This likely caused low groundwater levels (Brauns et al., 2020; Conradt et al.,
191 2023), as infiltration of precipitation water is considered to be the most important groundwater source in Central Europe
192 (Brakkee et al., 2022). ERA5 soil moisture was evaluated for the four soil layers over the period 2018-2020 and compared
193 against the climatology averaged over 1991-2020 in order to assess the strength of the soil moisture deficit and its persistence
194 during the consecutive drought years 2018-2020. For this analysis, time series of daily means as well as centred 92-day running
195 means were computed for all land points of the study area 4°-16° E and 45°-55° N, covering Germany and adjacent regions.
196 The evaluation of soil moisture in the lowest soil layer also gives an indication of the groundwater reservoir as it interacts with
197 the aquifer in the modelling system (Cerlini et al., 2021).

198 **2.5 Agricultural and hydrological drought of the year 2018**

199 Lack of sufficient soil moisture, resulting from shortage of precipitation and excess evapotranspiration leads to agricultural
200 drought. Lack of run-off and surface water result in hydrological drought (streamflow deficits) (Seneviratne et al., 2021). To
201 estimate the severity of agricultural and hydrological droughts across Europe during summer 2018, we employed the nitrogen
202 version of the vegetation, crop, and hydrology model LPJmL (Schaphoff, et al., 2018; von Bloh et al., 2018; Lutz et al., 2019;
203 Herzfeld et al., 2021). The analysis is based on 69 years (1951-2019) obtained from model simulations driven with daily
204 temperature, precipitation, and radiation data from the GSWP-W5E5 dataset (Kim, 2017; Cucchi et al., 2020; Lange et al.,
205 2022) at 0.5 arc-degree resolution. To assess agricultural drought, the evapotranspiration deficit calculated as the ratio of actual
206 evapotranspiration to potential evapotranspiration (ET/PET ratio) over the growing season of maize in each year is determined
207 and a generalised beta distribution (a three-parameter probability distribution for variables in a bounded interval) is fitted to
208 the 69 annual values in each grid cell. An ET/PET ratio of less than 1 indicates water deficit or water stress. For the assessment
209 of the hydrological drought, the average river discharge (Dis) during the summer months (June, July, and August) of each year
210 is determined and a generalized gamma distribution (a three-parameter probability distribution for non-negative variables) is
211 fitted to the 69 annual values in each grid cell. Using the fitted distributions, the return period of the conditions in 2018 is
212 determined. To support comparability with other drought indices such as the Standardized Precipitation Evapotranspiration
213 Index (SPEI), the drought severity is also calculated, which is the probability (inverse of return period) of a given year
214 expressed as its distance from the mean (in number of standard deviations) in a standard normal distribution (McKee et al.,
215 1993; Vicente-Serrano et al., 2010). For example, a return period of 44 years is equivalent to the 2.28th percentile, which is
216 -2 standard deviations away from the mean and would be assigned a drought severity of -2.

217 **2.6 Impact on the agricultural production of 2018**

218 In comparison with the past three decades, the year 2018 was identified as a year with severe winter wheat yield losses
219 estimated using a compilation of LOESS (locally estimated scatterplot smoothing; to take into account improvement of
220 agricultural practises (Zampieri et al., 2017)) detrended and gap-filled yield data at county level aggregated from a variety of
221 sources including the Regionaldatenbank Deutschland (Statistische Ämter des Bundes und der Länder, 2021) and the Statistical
222 Offices of the federal states of Germany (Ellsäßer and Xoplaki 2022abc; Ellsäßer and Xoplaki, 2024). The resulting annual
223 gridded yield data was evaluated using the Standardized Yield Anomaly Index (SYAI) that expresses yield anomalies in terms
224 of standard deviation from a 30-year time series. The analysis is based on the Heat Magnitude Index (HMD) (Zampieri et al.,
225 2017), the drought index SPEI (Vicente-Serrano et al., 2010) and the Combined Stress Index (CSI) (Zampieri et al., 2017) that
226 accounts for stress compounds of heat and drought through a (ride-regression based) superimposition of HMD and SPEI, using
227 the temperature and precipitation series from E-OBS (Comes et al., 2018). In order to derive crop relevant results, all indices
228 were evaluated for the most vulnerable stages of phenological crop development according to the specific region using the
229 German Weather Service (DWD) phenological data set (Kaspar et al., 2015). A spatially explicit linear regression between

230 yield anomaly and stress indices was computed for time series covering the past three decades and the coefficient of
231 determination (R^2) was calculated to express the proportion of yield anomaly that can be explained by heat, drought or
232 compound stress.

233 **2.7 Loss and damage of compound vs. non-compound wind extreme events of the winter 2018**

234 The precipitation-wind storyline starts with a description of the synoptic situation during the winter season 2018. The cyclone
235 track analysis in this section is based on the cyclone tracking methodology of Murray and Simmonds (1991) and Pinto et al.
236 (2005) applied to ERA5 data (Hersbach et al., 2020).

237 Loss and damage in this section is defined according to the UN Framework Convention on Climate Change (UNFCCC) as the
238 harm caused by anthropogenic (human-generated) climate change (UNFCCC, 2021; OECD, 2021 and references therein). For
239 the quantitative assessment of the impact of CEs in terms of loss and damage, a compound wind and precipitation extreme is
240 defined when both variables exceed their local 98th percentile (Martius et al., 2016). For winter events, these percentiles are
241 calculated using data from the December to February season. Co-occurrence is defined when wind gusts and precipitation both
242 exceed their respective 98th percentile at a specific grid box, with precipitation exceedance occurring on the same day, the day
243 before, or the day after, within a 50 km radius around the grid box centre.

244 The daily loss data for residential buildings accumulated over Germany provided by the German Insurance Association (GDV)
245 are categorised by days on which a CE occurred and days on which it did not. This results in two separate loss distributions
246 for compound and non-compound events.

247

248 **2.8 Concurrent heavy rain and storm extremes – estimation of probability of event occurrence**

249 The estimation of the probability of occurrence of compound heavy rain and wind is carried out on precipitation and wind time
250 series from DWD weather stations. Multivariate distributions in the form of copulas are used to determine the probability of
251 occurrence of combined events. Copulas make it possible to model the dependency structure of the variables under
252 consideration independently of their marginal distributions (e.g. Manning et al., 2024 and references therein). This allows for
253 the use of any distribution function for the marginal distributions.

254 We carried out fitting tests for both the marginal distributions and the copulas. However, Archimedean copulas are generally
255 preferred when dealing with hydrological parameters (Bender, 2015; Jane et al., 2020). In this particular case, the Frank copula
256 (Frank, 1979) was chosen as the most appropriate option. The Frank copula is a one-parametric copula in which the copula
257 parameter θ can be determined from the correlation between random variables. The approach treats the extremes of the
258 two variables (rain and wind) separately. The annual maximum values (AMAX) are extracted from the time series and tested
259 for statistically significant trends using the Mann-Kendall test at a 5% significance level. Stationary methods of extreme value
260 statistics are applied, requiring the assumption of independence and identical distribution of all time series. Consequently,
261 series with significant trends are homogenised using linear regression. The distribution parameters of the strong wind and
262 precipitation data sets are then determined using maximum likelihood. In addition, the correlation between heavy rain and

263 storm is calculated using the Kendall rank correlation. For each AMAX wind value, the concurrent precipitation value is
264 selected and vice versa. To ensure the independence of precipitation events, wet episodes are separated by a dry period of at
265 least as long as the accumulation period. Due to this restriction, not all AMAX wind events can be paired with a precipitation
266 episode, even when precipitation is present, e.g., for longer precipitation durations (>1day) and considering a ± 2 -day window,
267 no AMAX wind and precipitation episode pairs exist. Subsequently, these pairs of values are applied to adjust the marginal
268 distributions and copulas, thereby determining the combined probabilities of occurrence.

269 **2.9 Rockfall events**

270 Rockfall is an impact that can be triggered by extreme precipitation (e.g., Nissen et al., 2022). Favourable preconditions, such
271 as previous freeze-thaw cycles and enhanced sub-surface moisture, increase the susceptibility for such events. A logistic
272 regression model, describing the probability of rockfall in the Central European low mountain ranges as a function of
273 meteorological (pre-) conditions, was fitted using the Rupp and Damm (2020) database of rockfall events. To find the optimal
274 statistical model, a large number of models including different atmospheric predictors and interaction terms between the
275 predictors were compared. The best model was selected based on the logarithmic skill score determined during cross validation.
276 The best-performing model includes across-site percentile of a fissure water proxy D (precipitation minus potential evaporation
277 determined for the last 5 days), the local percentile of daily precipitation and the binary information if a freeze-thaw cycle has
278 occurred within the last 9 days. It also considers the interaction between daily precipitation and D. By including several
279 meteorological parameters the statistical model describes the multivariate compounding nature of rockfall initialization. By
280 taking preconditions into account the preconditioned compounding component is addressed. Using the statistical model, a
281 probability for a rockfall event can be determined for each day from the meteorological conditions of the previous 9 days and
282 the day itself. Details of the statistical model can be found in Nissen et al. (2022).

283 **2.10 Convective cluster events of the summer 2018**

284 Convective cluster events (CCEs) are spatially connected areas of intense lightning activity that occur simultaneously in the
285 same geographic region. CCEs can be detected using the Spatial-Temporal Density-Based Spatial Clustering of Applications
286 with Noise (ST-DBSCAN) algorithm (Ester et al., 1996; Birant and Kut, 2007). The data used are cloud-to-ground lightning
287 strokes from the European Cooperation for Lightning Detection (EUCLID) network (Schultz et al., 2016). ST-DBSCAN is
288 further developed and specifically adapted for the detection of spatio-temporal clustering of lightning strokes (Augenstein et
289 al., 2023). The algorithm identifies arbitrarily shaped clusters in a set of given points, which in this case are spatio-temporally
290 close lightning strokes. For the identification of CCEs, thresholds from sensitivity studies have been used, i.e., if at least 40
291 lightning strokes occur within 20 minutes and 50 km, single lightning strikes are marked belonging to a CCE. These thresholds
292 have proven to be an “optimal” balance to distinguish between lightning clusters and noise.

293 **2.11 Occurrence of extreme compound events from recent to near-term future climate conditions**

294 The estimation of the projected changes in the frequency of CEs from recent to near-term future climate conditions is based
295 on the 30-member CMIP6 MPI-GE (Olonscheck et al., 2023). The historical and SSP5-8.5 (Riahi et al., 2017) simulations for
296 the periods 1975-2025 and 2025-2075 are used, representing climate conditions that for the CMIP6 MPI-GE range from about
297 1 to 3 °C increase in global mean surface temperature since pre-industrial times (Olonscheck et al., 2023). The projections
298 cover Germany and more specifically the region defined by the 4°-16° E and 45°-55° N latitude-longitude domain. The
299 compound heat and drought years are defined by the cumulative precipitation from May to October and the mean daily
300 maximum temperature from June to August, spatially averaged over Germany. Extreme compound hot and dry years exceed
301 the 20-year return levels for both precipitation deficit and maximum temperature individually, defined as the 5th and 95th
302 percentiles, respectively, for the period 1975-2025. The compound precipitation-wind years are defined on the winter
303 (December to February) daily mean precipitation and daily maximum surface wind. The selection of events is based on the
304 exceedance of the 98th percentile for wind and precipitation during the period from 1975 to 2025. For each grid cell, wind and
305 precipitation events are identified when they exceed this threshold on the same day, while for precipitation alone, the
306 exceedance can occur either on the same day or the day after. The cumulative effect for the whole season is the sum of all
307 daily occurrences over all winter days and each grid cell. Extreme compound wind and precipitation years exceed the 20-year
308 return levels for precipitation and wind individually, defined as the 95th percentile of each variable for the period 1975-2025.

309 **2.12 Representation of moisture availability of 2018 in model simulations**

310 The performance of model simulations in realistically representing drought conditions like those of 2018 and the 2018-2020
311 three-year drought cluster of events is assessed based on the estimated trend of the warm season (March to August) moisture
312 availability in Germany. Drought conditions are described with the SPEI index (Vicente-Serrano et al., 2010) for observations,
313 using ERA5 data (Hersbach et al., 2020) for the period 1979-2019, and for bilinearly interpolated (regular 0.5° lon-lat grid)
314 and extended to 2021 ensemble simulations of CMIP5 (Taylor et al., 2012; Aalbers et al., 2023) global circulation models and
315 of EURO-CORDEX 0.11° (Giorgi et al., 2009) regional multi-model ensemble for the historical (1950-2005) and the near-to-
316 mid-term future (2006-2070) periods under RCP8.5. The linear trend of the 3-year running mean for the March to August
317 intervals is calculated over the periods 1975-2021 for the simulations (1979-2019 for ERA5) and 2022-2070 in order to account
318 for the transition from dimming to brightening regime in the 1970s (Wild, 2009, 2016).

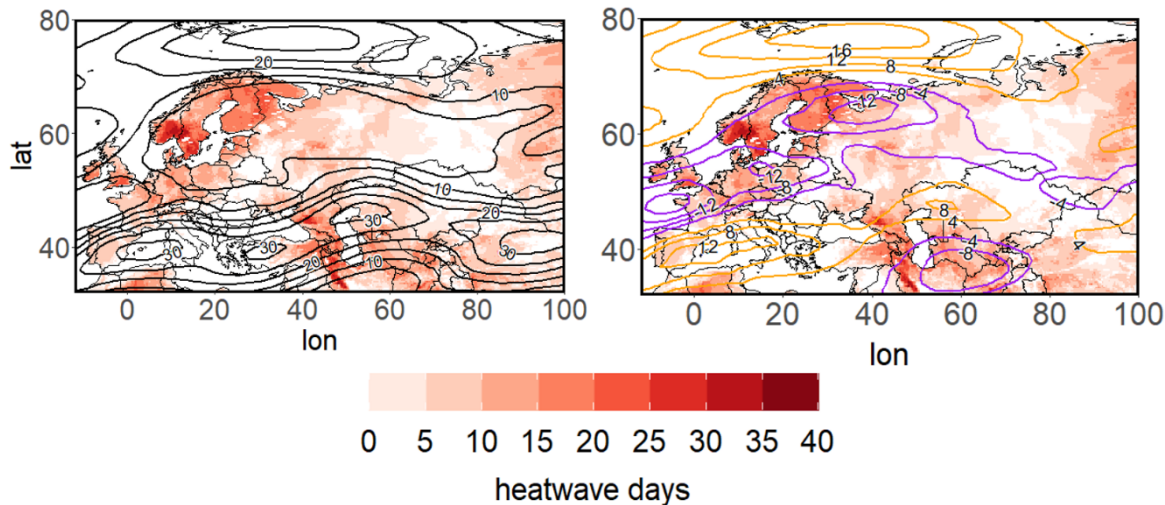

319 **3 Compound events in the year 2018**

320 **3.1 Temperature-precipitation compound events during 2018**

321 The exceptionally hot and dry conditions in 2018 extended over larger areas including central and northern Europe and were
322 associated with impacts on various economic sectors (e.g. Toreti et al., 2019a; Zscheischler and Fischer, 2020; Bastos et al.,
323 2023; Conradt et al., 2023; Shyrokaya et al., 2024).

324 **3.1.1 Drivers of the hot summer of 2018**

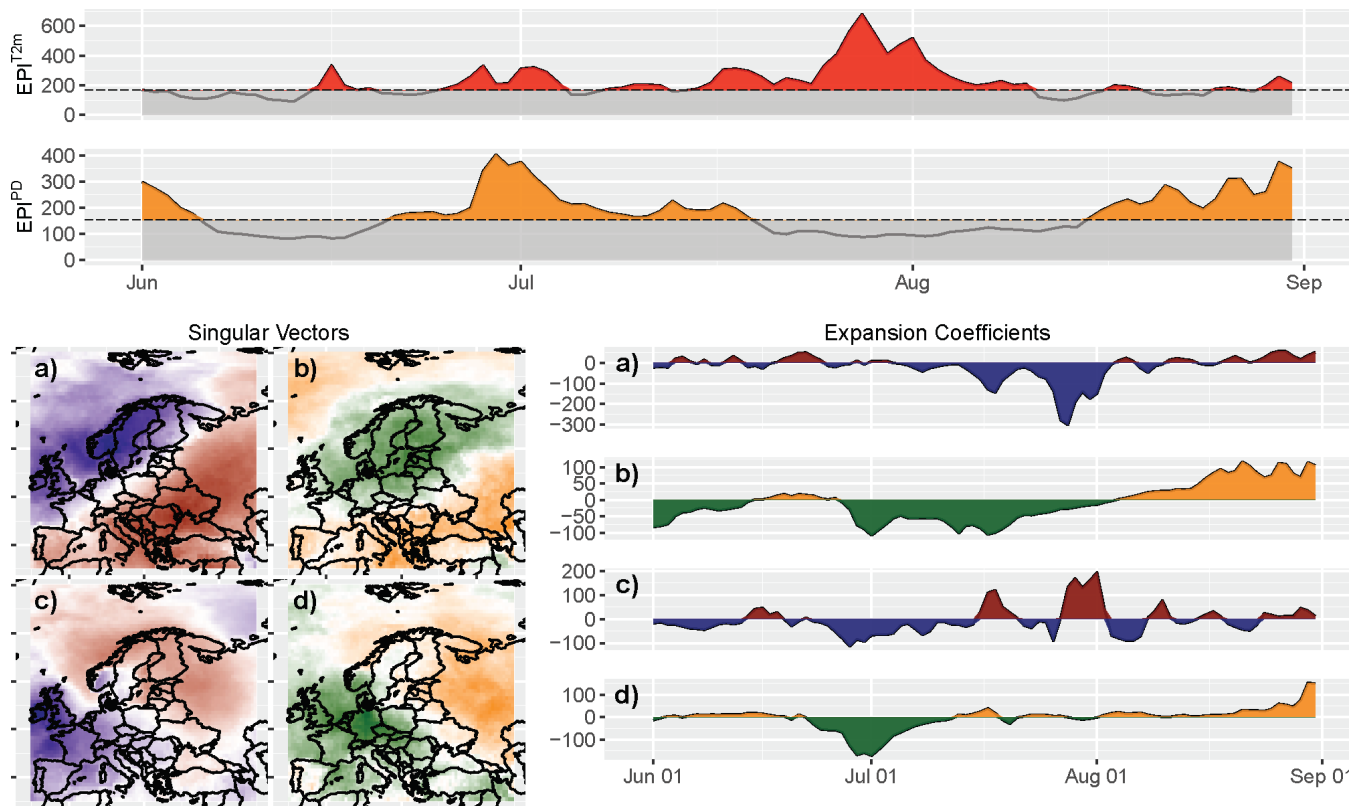

325 The 2018 heatwave was a spatially CE featuring concurrent heatwaves in Scandinavia and central Europe (Spensberger et al.,
326 2020; Rousi et al., 2023). Prior to the 2018 heatwave, a striped high-pressure system formed over northern Europe in late June,
327 during a combination of the positive phase of the North Atlantic Oscillation and the Rossby Wave 7 pattern (Drouard et al.,
328 2019; Kornhuber et al., 2019). Figure 1 presents the jet stream state during the 2018 summer and the heatwave day frequency
329 for each grid point over the Eurasian sector. During the intense European summer heatwave, a large blocking system at 500
330 hPa, and a double jet stream configuration is visible in the 250 hPa zonal wind field (Kornhuber et al., 2019; 2020; Rousi et
331 al., 2023, see Methods section 2.1). Heatwave hot spots over Europe coincide with areas of weak winds between the polar and
332 subtropical jets. Such large-scale atmospheric conditions are conducive to the occurrence of extreme events over Europe, in
333 particular to heatwaves near the centre of the blocking system (see Kautz et al., 2022 for a review). In particular, the hot
334 summer of 2003 (western/central Europe, Luterbacher et al., 2004; Fink et al., 2004; Fischer et al., 2007; García-Herrera et
335 al., 2010) and 2010 (heatwave over western Russia, Barriopedro et al., 2011; Di Capua et al., 2021; Rousi et al., 2022) were
336 characterised by similar large-scale conditions.

337
338 **Figure 1: Jet stream state (contour lines) and heatwave days in summer 2018 (shading). Left: zonal wind at 250 hPa (black contours**
339 **from 5 m/s to 30 m/s every 5 m/s); Right: zonal wind anomalies at 250 hPa (anomalies based on 1979-2020 July climatology and**
340 **plotted with contours from -16 m/s to 16 m/s every 4 m/s, negative anomalies are shown in purple contours and positive in orange**
341 **for the period 4-25 July 2018, the longest period of consecutive double jet states. All fields stem from ERA5 reanalysis data (Hersbach**
342 **et al., 2020).**

3.1.2 Detection of spatial patterns of extreme events

During the summer 2018, large-scale temperature (T2m) and precipitation deficit (PD) patterns characterize the exceptional conditions. Figure 2 shows the analysis of typical pattern of common extremes and their expression during the 2018 heatwaves at the European scale based on cross-TPDM and EPI (see Methods section 2.2). In July-August 2018 the pronounced heatwave is accompanied by extreme EPI^{PD} preceding the heatwave for several days. This heatwave is considered the most prominent event in the period under consideration (see also Liu et al., 2020). The negative eigenvector anomalies of the second mode (Fig. 2a,b bottom left) mostly cover the regions identified as heatwave spots in Figure 1. Thus, the anomalies in the second mode expansion coefficients (Fig. 2a,b bottom right) indicate the beginning of the heatwave, which initially affected northern Europe (i.e., Finland, Norway, and northwestern Russia). From mid of June onwards, there were extremes in PD, particularly in Central Europe, as indicated by the third mode of the expansion coefficient (Fig. 2c,d bottom right). By the end of July 2018, the heatwave extended to Central Europe as evidenced from the abrupt change of sign in the third mode expansion coefficient (Fig. 2c,d bottom right).

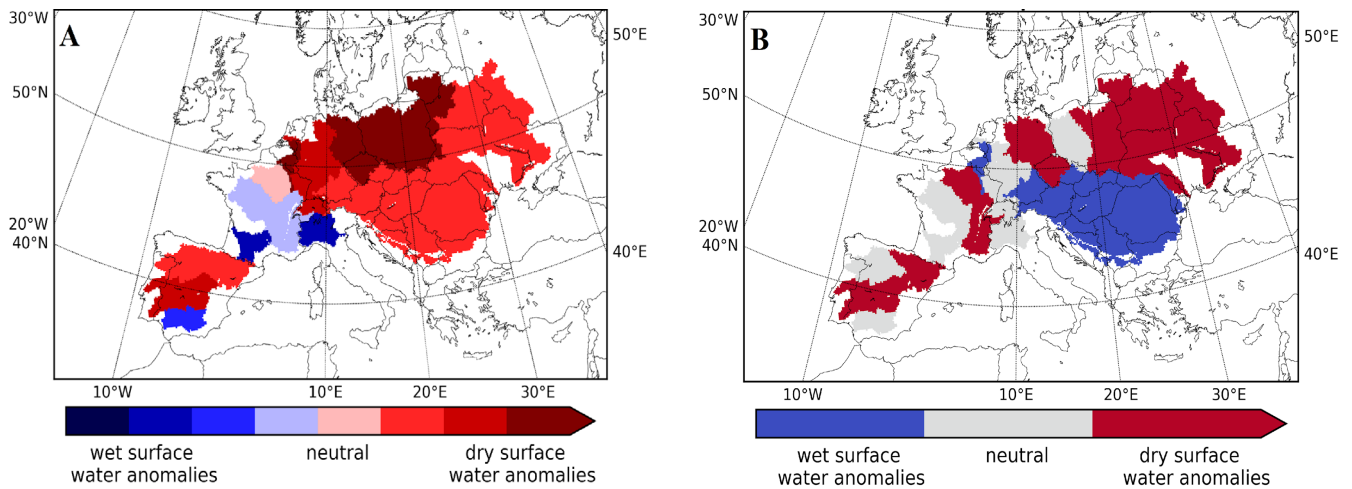

355
356 **Figure 2: Top: Extreme Pattern Index (EPI) for T2m surface temperature (EPI^{T2m}, red) and precipitation deficit (EPI^{PD}, orange)**
357 **for northern Hemisphere 2018 summer months. Values exceeding the 80th percentile are considered to identify extreme events in**
358 **PD and T2m from EPI and are highlighted in red/orange, respectively; Bottom left: second (a, b) and third (c, d) singular vectors**
359 **(CVs) associated with large-scale temperature (blue/red) and precipitation deficit (green/orange) pattern; Bottom right: second (a,**

360 **b) and third (c, d) expansion coefficient for northern hemisphere 2018 summer months. Positive values are plotted in red/orange**
361 **and negative values in blue/green.**

362 **3.1.3 Surface water storage of the dry summer of 2018**

363 The high temperature in 2018 was mainly due to increases in the amount of net surface radiation caused by the clear skies
364 associated with reduced precipitation (Liu et al., 2020). Germany experienced a strong increase of net radiation of
365 approximately +31%. Liu et al. (2020) report that land cover played a critical role in determining the occurrence and strength
366 of soil moisture-temperature coupling, i.e. cropland/grassland depletes soil moisture more readily than forests, thereby
367 triggering a more rapid release of sensible fluxes a major feature observed during the 2018 heatwave. During the 2018
368 heatwave, because of different soil moisture conditions, latent flux in Germany decreased by 12% and sensible flux
369 significantly increased by 122% (Liu et al. 2020). Further, Bastos et al. (2020) used 11 vegetation models and showed that
370 spring conditions promoted increased vegetation growth, which, in turn, contributed to fast soil moisture depletion, amplifying
371 the summer drought. Figure 3 presents the groundwater memory in the summer 2019 of the ensuing hydrological year
372 2018/2019 for each of the 20 European river basins on the following year's summer surface water storage (S_u). The ensemble
373 simulations indicate that following the 2018 drought the conditional probability that the autumn of the hydrological year
374 2018/2019 (August to November 2018) is anomalously dry $p(S_{u,d})$ is 95.5% with a $100 \pm 0.0\%$ confidence with respect to the
375 climatological variability. In the following seasons, $p(S_{u,d})$ and the associated confidence decrease due to the increasing
376 influence of the uncertainty in the atmospheric conditions. Specifically, for winter $p(S_{u,d})$ is 81.8% with a confidence of 99.5
377 $\pm 0.3\%$, for spring (March to May 2019) 63.6% with a confidence of $80.2 \pm 6.0\%$ and for summer (June to August 2019) of
378 the hydrological year 2019/2020 $p(S_{u,d})$ is 68.2% with a confidence of $90.1 \pm 3.7\%$ with respect to the climatological variability.
379 Without considering the groundwater storage memory effect, a probability of a dry surface water anomaly $p(S_{u,d})$ of $\sim 50\%$
380 would be expected due to the atmospheric uncertainty accounted for in the ensemble of realisations at the interannual time
381 scale. Taking drought as a precondition for S_u on this scale, the analysis shows that even one year later a $p(S_{u,d})$ of 68% is still
382 well above 50% at a confidence level of $90 \pm 4\%$. Thus, statistically, groundwater storage takes longer than a year to fully
383 recover from a drought influencing surface water storage, independent of the ambient atmospheric conditions (Lorenz et al.,
384 2010; Orth and Seneviratne, 2012; Song et al., 2019). Recent evidence points to the fact that the impact of global warming on
385 soil moisture drought severity in west-central Europe such as the case in 2018 is increased. The drought risk is strongly
386 enhanced by the drought intensification and increase in frequency, yielding shorter recovery time between events for nature
387 and society (Aalbers et al., 2023).

388

389

390

391

406

To address sectoral impacts (e.g. Conradt et al., 2023), we focus on the effects of the 2018 drought on agriculture and forestry in Germany. For this purpose, the temporal evolution of soil moisture deficits at different depths from the ERA5 dataset and agricultural data from German national institutes such as the Statistisches Bundesamt (Destatis) are analysed. Focusing on the temporal evolution of soil moisture, a deficit developed during the spring and early summer of 2018 (Rousi et al., 2023), which also reached the lowest soil layer with a temporal delay of about three months, as shown in Fig. 4. The dryness in 2018 was more intense than the usual soil moisture variability in the period 1991-2020, as shown by the soil moisture dropping below the range of ± 1 standard deviation of the 1991-2020 mean soil moisture (shaded area). While the moisture in the three upper soil layers mostly recovered during the following winter 2018/2019, the moisture did not percolate down to the lowest soil layer, which remained in a dry anomaly. The recurrent drying of the upper layers in spring and summer 2019 inhibited considerable infiltration, so that the moisture deficit of the lower soil layer persisted until winter 2019/20, when the relatively wet climatic conditions allowed a recharge of the lower soil layer moisture reservoir (Brakkee et al., 2022) and thus probably also of the groundwater (e.g., Brauns et al., 2020). Hence, the lack of soil moisture reached the entire soil column and thus the entire root zone of the vegetation during the summers of 2018 and 2019, placing the vegetation under soil moisture stress (Tijdeman and Menzel, 2021).

421

422

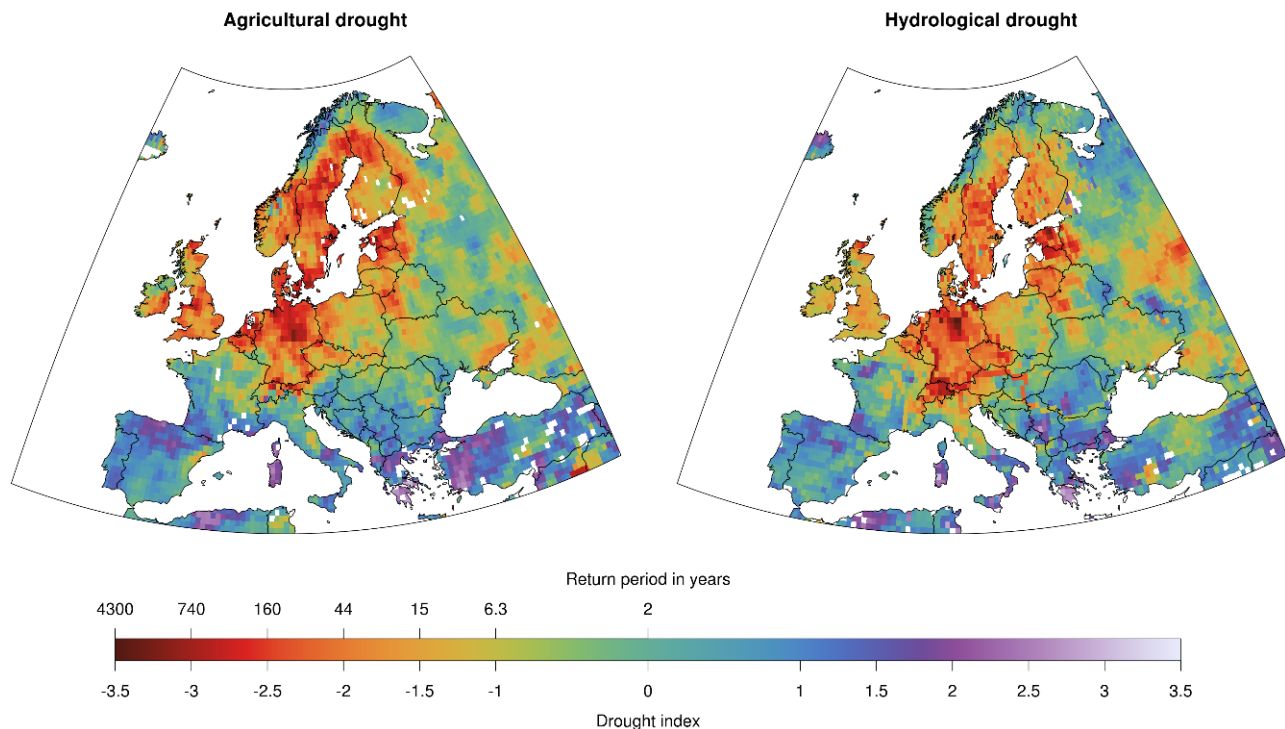

423

424

425

The anomalous soil moisture conditions are reflected in an anomalous low ET/PET ratio over the summer months (June, July, August), indicating a severe agricultural drought (Fig. 5, left). In almost the entire northern part of Germany, the agricultural drought index exceeds -2.5, which is equivalent to a return period of more than 160 years, an estimate associated with uncertainties. However, the agricultural drought is not limited to northern Germany but comprises large parts of central, northern, and northeastern Europe. The low soil moisture conditions also lead to a hydrological drought (low river flow) over the summer months (Fig. 5, right). However, the severity and spatial pattern of hydrological drought differs from the pattern of agricultural drought because propagation from soil moisture drought to hydrological drought takes time and typically leads to a lagged occurrence (Van Loon and Van Lanen, 2012) and a longer persistence (see section 3.1.3 on Surface water storage). Another reason is that hydrological drought can spread along the river network affecting regions unaffected by low soil moisture (e.g., along the Danube river in eastern Europe). Nevertheless, in many parts of Germany and northern Europe, agricultural and hydrological drought coincided in the summer of 2018 (Blauhut et al., 2022), affecting the possibility to

426 irrigate as a means to alleviate the agricultural drought. This provides an example of how co-occurring impacts (droughts) can
427 amplify each other to cause even greater secondary impacts (agricultural yields, see section 3.1.6 on Impact on the agricultural
428 production) in a similar way as co-occurring meteorological conditions trigger CEs.

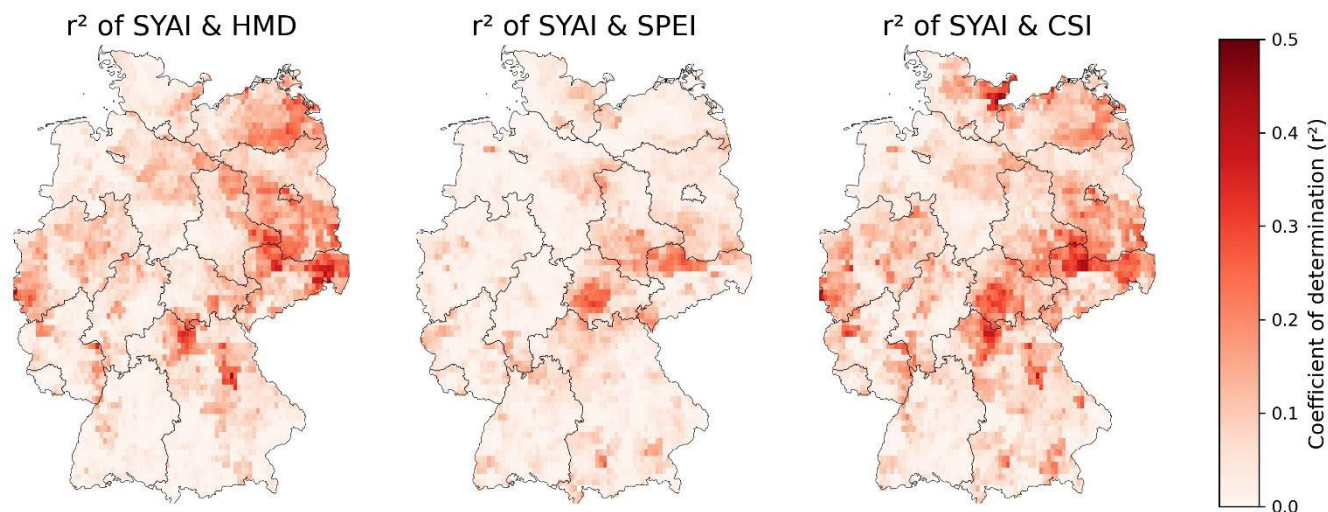

429
430 **Figure 5: Drought severity and return period of agricultural and hydrological drought during summer 2018. Note that drought**
431 **severity (as expressed by the drought index) and return period are closely related (see Methods section 2.5).**

432 433 3.1.6 Impact on the agricultural production of 2018

434 In Germany, the hot and dry spring and summer of 2018 had an unprecedented impact on crop yields. Extremely low crop
435 yields (Toreti et al., 2019a; Bellouin et al., 2020; Conradt et al., 2023 for northeastern Germany) led to large insurance claims
436 over agricultural losses and financial support requests by farmers from governments in Germany (EUR 340 million), Sweden
437 (EUR 116 million) and Poland (EUR 116 million) (D'Agostino, 2018; Munich Re 2019). Winter wheat yields were more than
438 10% below the 30-year average and 13% below the previous three years. In some counties, yields were more than 40% lower
439 than in previous years. Regionally, winter wheat was particularly hard hit in eastern and northeastern Germany, with an average
440 loss of 22% compared to the last three decades. The HMD index and the SPEI indicate a severe heatwave and drought
441 respectively, which was most pronounced in central and northeastern Germany. Figure 6 shows the explained variance of yield
442 anomalies and the stress indices HMD, SPEI and CSI (see Methods section 2.6) revealing a strong connection between these

443 components. However, not all regions experienced such severe yield losses; winter wheat yield in southwest Germany was
444 hardly affected, with losses of only 1.2% compared to the last three-decade average. A hydrological see-saw with rather wet
445 conditions in southern Europe and the resulting yield increases characterise the unique combination of climatic anomalies in
446 Europe in 2018 (Toreti et al., 2019a). Winter wheat productivity was even positively affected in some regions.

447
448 **Figure 6: Coefficient of determination of Standardized Yield Anomaly Index (SYAI) and stress indices Heat Magnitude Day (HMD),**
449 **Standardized Precipitation Evapotranspiration Index (SPEI) and Combined Stress Index (CSI) demonstrate the impact of heat,**
450 **drought and compound stress over the last three decades on winter wheat in Germany.**

451

452 3.1.7 Impact on the forests in 2018

453 The drought of 2018 was likely the largest source for severe forest disturbance in Europe for more than 170 years (Senf and
454 Seidl, 2021), especially in central and northern Europe (Buras et al., 2020). Consequently, in the summer of 2018, about 11%
455 of the central European forest area experienced early wilting (Brun et al., 2020), resulting in a large reduction in greenness
456 (Schuldt et al., 2020; the three aforementioned studies are based on NDVI data). The 2018 drought continued into 2019, making
457 the consecutive European droughts of 2018 and 2019 unprecedented in the last 250 years (Hari et al., 2020). The low soil
458 moisture content in 2018 and an increased water-vapour pressure deficit in the following two years were the main drivers for
459 the forest disturbances of about 4.74×10^6 ha in Central Europe (Senf and Seidl, 2021). The likely cause for these forest
460 damages was that trees under drought and heat stress experience carbon starvation (Bastos et al., 2020) and have risk for
461 embolism, which causes failures in water transport (Allen et al., 2015; Schuldt et al., 2016). The drought and heatwave in that
462 period facilitated outbreaks of bark beetle, enhancing the damage levels to forests. As such, insect outbreaks in Central Europe
463 had a 2-3-fold increase in annual losses between 2017 and 2018 (Hlásny et al., 2019) and extraordinary mortality and damage
464 occurred during 2018 in Sweden due to rapid beetle population growth (Öhrn et al., 2021). Although wildfires have decreased

465 on a global scale recently, Central Europe is likely to face larger and more frequent forest fires (Feurdean et al. 2020, Milanovic
466 et al. 2020; Carnicer et al., 2022), which can have severe environmental, economic and social consequences (Lidskog et al.
467 2019).

468 **3.2 Precipitation-wind compound events during 2018**

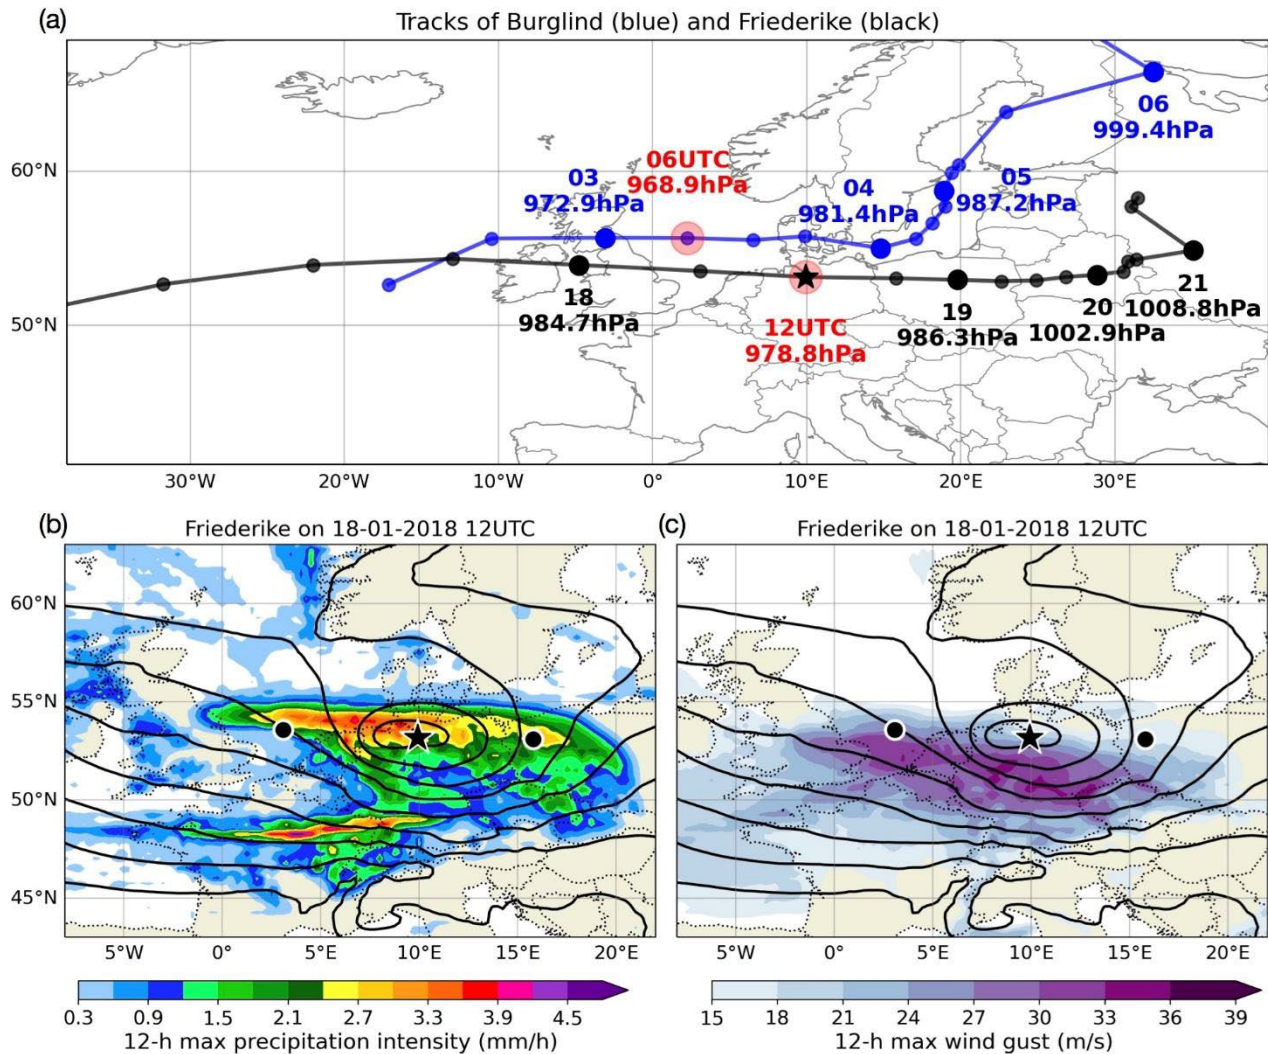

469 In this section, CEs that involve heavy precipitation and strong winds are described. Examples include two January windstorms
470 (Friederike and Burglind) and several weeks of convective activity in May and June of 2018.

471 **3.2.1 Loss and damage of compound vs. non-compound wind extreme events of the winter 2018**

472 On January 16, windstorm Friederike formed as a low-pressure system near Newfoundland. Within the next two days,
473 Friederike intensified and quickly travelled across the Atlantic (Fig. 7), losing its closed structure at 1800 UTC on 17 January.
474 Friederike re-intensified over the British Isles on 18 January while crossing the jet streak towards the northern jet exit region,
475 a behaviour favourable for intense windstorm development (e.g., Pinto et al., 2009). The storm moved eastward over the North
476 Sea, Germany and Poland, and weakened after 19 January over eastern Europe (Fig. 7a). Analysing the compound character
477 of Friederike around peak intensity using the hourly ERA5 reanalysis data (Fig. 7b,c), the typical near-surface wind and
478 precipitation structure of intense extratropical cyclones is found (e.g., Dacre et al., 2012). Strong 10 m wind gusts (maximum
479 values of 34 m/s relative to the Earth's surface) were present behind and to the right of the eastward moving cyclone centre.
480 Heavy precipitation occurred at both the warm front to the northeast of the centre, wrapping around as the cyclone approached
481 its mature stage, and along the east-southwest stretching cold front (Fig. S1a). During the 12 h period when Friederike passed
482 through Germany from 0600 UTC to 1800 UTC on 18 January, the persistently active warm front left a widespread footprint
483 near the northern edge of the cyclone centre (Fig. 7b) with ERA5 accumulated precipitation exceeding 17 mm. Meanwhile,
484 the cold front contributed to a high precipitation rate (> 4 mm/h based on ERA5) along a narrow west-east oriented band across
485 northern France and southern Germany (Fig. 7c). The co-occurrence of strong winds and heavy snowfall gave to this storm
486 the risk and damage characteristics of a CE (Fig. 7b,c). The highest damages were reported in Ireland, Great Britain, northern
487 France, Belgium, the Netherlands, Germany, Czech Republic and Poland, where gust measurements suggested wind speeds of
488 the order of 100 – 150 km/h. At higher altitudes the observed wind gusts reached 173 km/h at the Sněžka in Czech Republic
489 and 203 km/h at Brocken in Germany (Haeseler et al., 2018). Wind and snowfall associated with Friederike caused further
490 traffic disruption, power outages, property damage including falling trees, and several deaths. Friederike was the strongest
491 storm affecting central Germany since windstorm Kyrill in 2007.

492 Another CE affecting Germany in the same month was the windstorm Burglind, which formed on the 2nd January 2018. The
493 depression intensified rapidly as it moved eastwards towards the British Isles (Fig. 7a). It reached a peak intensity of 968.9
494 hPa at 0600 UTC on 3 January 2018 over the North Sea, followed by a weakening over the Baltic Sea. The long active cold
495 front affected a large area of western Europe (Fig. S1b). Heavy precipitation with daily values > 30 mm led to rapid snowmelt
496 and massive flooding in many regions. Around the time of the peak cyclone intensity, widespread areas were simultaneously

497 affected by high precipitation intensities ($> 4 \text{ mm/h}$) and high wind gust ($\sim 100 \text{ km/h}$) (Fig. S1c,d). Further detailed information
 498 on Burglind can be found in Eisenstein et al. (2022, see their section 5). Compared to storm Friederike, the compound features
 499 of Burglind were more strongly shaped by orography.

500

501 **Figure 7: (a) Cyclone tracks of windstorms Friederike (black) and Burglind (blue) in January 2018. Big circles show locations at**
 502 **0000 UTC on the day as indicated, with the central pressure noted below. Red circles indicate their lifetime peak intensity based on**
 503 **the minimum pressure. (b) Mean sea level pressure (thick contours; increasing from 960 hPa with 5 hPa intervals) at 1200 UTC on**
 504 **18 January 2018 (location of Friederike shown by the star) and maximum precipitation intensity (shaded) during the period 6 h**
 505 **before and after (locations shown by black circles). (c) Same as b, but for the wind gust at 10 m height (shaded). All fields are derived**
 506 **from the ERA5 reanalysis (Hersbach et al., 2018).**

507

508 Although the co-occurrence of extreme wind and precipitation is discussed in previous studies for specific events (e.g. Fink et
 509 al., 2009 for storm Kyrill) or globally (Martius et al., 2016; Messmer and Simmonds, 2021), there are no studies so far
 510 quantitatively evaluating the effect in terms of loss damage. To distinguish between single extreme wind speed events and
 511 compound extreme wind speed and precipitation events, we follow the definition of Martius et al. (2016), where both variables
 512 are considered simultaneously (see the Methods section 2.7). The loss damage distribution for compound and non-compound
 513 events determined from loss data of the GDV is depicted in Fig. 8. For Friederike, there are three days where a co-occurrence
 514 of wind and precipitation extremes can be identified over Germany, i.e. 17, 18, and 19 January 2018. The loss ratio for these
 515 three days is marked with blue dots in the right column of Fig. 8. The GDV Naturgefahrenreport (2019) reports 900 Million €
 516 loss damage for Germany with respect to Friederike. To this date, it was the most damaging winter storm of the last ten years.

517
 518 **Figure 8: Loss ratio of residential buildings [per thousand] accumulated over Germany for winter events from 1997-2016. Each dot**
 519 **represents one day. Left (non cooc events) bar shows all days which cannot be linked to co-occurrence (cooc) of both extreme wind**
 520 **and precipitation, i.e. single extreme events. Middle bar (cooc events) shows all days which can be linked to co-occurrence of extreme**
 521 **wind and precipitation. Right bar shows the three days for the co-occurrence during windstorm Friederike. The loss ratio is defined**
 522 **by loss normalized with the local sum of insured values.**

523

524 3.2.2 Concurrent heavy rain and storm extremes – estimation of probability of event occurrence

525 In a detailed analysis of the probability of co-occurrence of extremes, based on copulas (see Methods section 2.8), the annual
526 maximum values of hourly precipitation and wind speed data at the station Münster/Osnabrück Airport of DWD that are
527 available since 1996 were analysed. The records show an increase in the intensity and frequency of the variables but lack a
528 statistically significant trend. The occurrence probabilities for concurrent precipitation and wind extreme events are shown by
529 the black isolines in Fig. 9. The grey dots are pseudo-observations (artificial precipitation and wind combinations generated
530 using the copula function), while the black, red and green dots mark the observed CEs at the station for each year and the green
531 dot represents Friederike. The distribution of the dots illustrates that - depending on the precipitation duration – wind or
532 precipitation, individually, may not be extreme. A counterexample is the year 2020 windstorm Sabine (red dot; internationally
533 known as Ciara) for which the simultaneous wind and hourly precipitation values both correspond to the respective annual
534 maximum event of that year. The location of the dots relative to the isolines define the return period of the event, where the
535 return period of windstorm Friederike at the station Münster/Osnabrück exceeded 5 years and the one of windstorm Sabine
536 100 years.

537
538 **Figure 9: Multivariate analyses for the temporal compound event heavy precipitation and strong wind determined with Copula**
539 **functions: quantile isolines (lines of equal probabilities), observed event combinations (black dots) and the pseudo-observations (grey**
540 **dots). Green dot represents storm Friederike (2018) and red dot storm Sabine (2020).**

541

542 3.2.3 Rockfall events

543 Another hazard with CE triggers observed in connection with Friederike was a rockfall event. Although wind is normally not
544 considered as one of the triggering factors (D'Amato et al., 2016), such events may also occur as the consequence of the
545 precipitation associated with the windstorm. It is well known that heavy precipitation can initiate landslides and rockfall events
546 (e.g. Nissen et. al., 2022). Slope susceptibility is influenced by pore water/fissure water preconditions, rendering them events
547 with multivariate and temporally compounding triggers. With respect to rockfall, another potentially triggering factor are
548 freeze-thaw cycles prior to the event. In terms of reported hill slope failures, storm Burglind was more effective than storm
549 Friederike. For storm Friederike, only one rockfall event is registered in the landslide database for Germany. The event
550 occurred near Göttingen in Lower Saxony. Figure 10 shows the relationship between the predictors (across-site percentile of
551 a fissure water proxy D -precipitation minus potential evaporation determined for the last 5 days-, the local percentile of daily
552 precipitation and the binary information if a freeze-thaw cycle occurred within the last 9 days) and the rockfall probability
553 expressed as percentage change with respect to the climatological probability. The red dot indicates the conditions on the 18th
554 January 2018 in the area of the event associated with Friederike. The soil at the location was still wet after storm Burglind at
555 the beginning of month and the fissure water (proxy D) at its 83rd percentile. The daily precipitation on the day of the event
556 was 4.5 mm (REGNIE data, Rauthe et al., 2013), which corresponds to the 77th percentile for the given location, assuming
557 immediate melting of the reported snow due to the above freezing air temperature at the event location. The probability of a
558 rockfall event was further increased by pre-event thawing conditions. The logistic regression model suggests that the
559 probability of rockfall on that day was increased by almost 250% (3.5 times more likely) compared to the long-term
560 climatology.

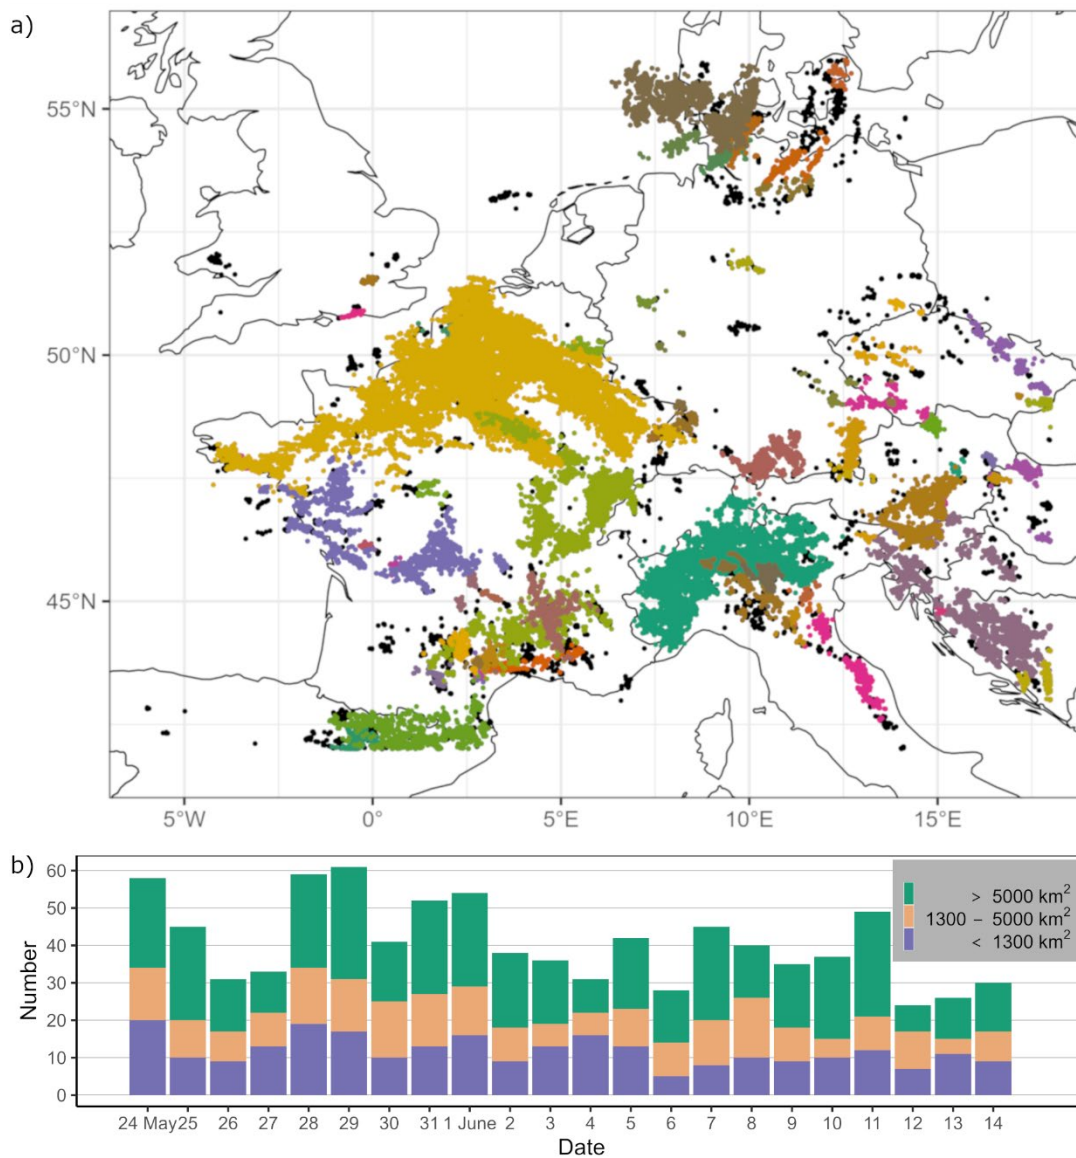

561

562 **Figure 10: Rockfall probability expressed as percentage change with respect to the climatological probability (isolines) as a function**
 563 **of moisture preconditions (D), daily precipitation and preceding freeze-thaw cycles. The red dot marks the conditions in the vicinity**
 564 **of Göttingen (Lower Saxony) on 18th January 2018.**

565 **3.2.4 Convective cluster events of the summer 2018**

566 The spatially as well as temporally compounding nature of severe convective storms (SCSs) can be demonstrated on the
 567 example of a three-week series of SCSs in western and central Europe from 22 May to 12 June 2018 leading to the unusual
 568 high temporal accumulation of CCEs lasting several days (Fig. 11). During this period, an exceptional persistence of reduced
 569 stability combined with sufficient moist air masses caused high thunderstorm activity daily in France, Belgium, Netherlands,
 570 Luxembourg, Germany, Switzerland, and/or Austria, associated with precipitation accumulations of up to 80 mm/h within 1
 571 hour and several flash floods (Mohr et al., 2020). The temporal compounding nature of the serial clustering of SCSs over
 572 several days to weeks over the same geographic region may increase the probability of flooding and damage. Figure 11b shows
 573 a large amount of identified CCEs, especially those with large spatial extent (> 5000 km²), during a three-week period over
 574 western and central Europe indicating high thunderstorm activity whose accumulation was unusual (Piper et al., 2016; Mohr
 575 et al., 2020). The repeating occurrence is caused by persistent synoptic conditions that favour thunderstorm development over
 576 several days to weeks. The presence of atmospheric blocking has been found to be highly conducive to such prolonged
 577 thunderstorm episodes, which typically occur on its western and /or eastern flanks (Piper et al., 2016; Mohr et al., 2020; Kautz
 578 et al., 2022). Based on statistical analyses, Mohr et al. (2019) found that a block over Scandinavia or over the Baltic Sea

579 favoured the occurrence of thunderstorms in western and central Europe along the western flank of the blocking system due
 580 to of southwesterly advection of warm, moist, and unstable air masses. It is expected that low-frequency modes of climate
 581 variability like North Atlantic Oscillation (NAO) or East Atlantic Pattern (EA) could also have an impact on clustered
 582 thunderstorm activity over several days (Piper et al., 2019), as these patterns are connected with atmospheric blocking.

583
 584 **Figure 11: (a) Lightning strokes on the 28 May 2018 in western and central Germany. Each colour represents a convective cluster**
 585 **event (CCE) resulting from the ST-DBSCAN method (see Methods section); black dots represent lightning strokes identified as**
 586 **noise. (b) Daily number of CCEs between the thunderstorm episode from 22 May to 12 June 2018. The colours represent CCEs of**
 587 **different sizes. Note: clusters that overlap are separated in time.**

588 **4 Compound events under climate change**

589 In this paper, we have analysed in detail several extreme events that have affected Europe within the calendar year of 2018,
590 starting with the windstorm series in January, followed by a period of heavy thunderstorms in May/June and extended heatwave
591 in July and August which affected various parts of Europe, and the associated drought effects extended well into the autumn
592 season. Our analysis clearly revealed the multivariate and complex characteristics of the events, and thus they can undoubtedly
593 be classified as CEs. The analysis of compound variables was used as a tool to investigate the impacts of man-made climate
594 change. For the two overarching compound types collected in this contribution (hot and dry; wet and windy) we now analyse
595 possible changes of their frequency of occurrence under future climate conditions. Recent studies have provided evidence that
596 regionally extreme hot and dry conditions such as the summer 2018 are expected to become more frequent in the future (e.g.,
597 Toreti et al. 2019a; Zscheischler and Fischer, 2020; Aalbers et al., 2023; van der Wiel et al., 2021; Bevacqua et al., 2023).
598 Figure 12 shows a comparison of the occurrence of CEs under recent (1975-2025) climate conditions, with a global mean
599 surface temperature of 1 °C above pre-industrial levels, and under future (2025-2075) conditions of 3 °C above pre-industrial
600 levels, based on the 30-member CMIP6 MPI-GE under SSP5-8.5 (see Methods section 2.11). For drought and heat events, our
601 analysis reveals a clear increase in both the frequency and intensity of extreme compound heat and drought years (Fig. 12,
602 left). Over the past 50 years, extreme compound heat-drought events have occurred with a probability of 1.5%, or about 1-2
603 times per century. Over the next 50 years, such extreme CEs are projected to become almost 10 times more frequent, occurring
604 more than once every 10 years, and reaching much higher temperatures and precipitation deficits.

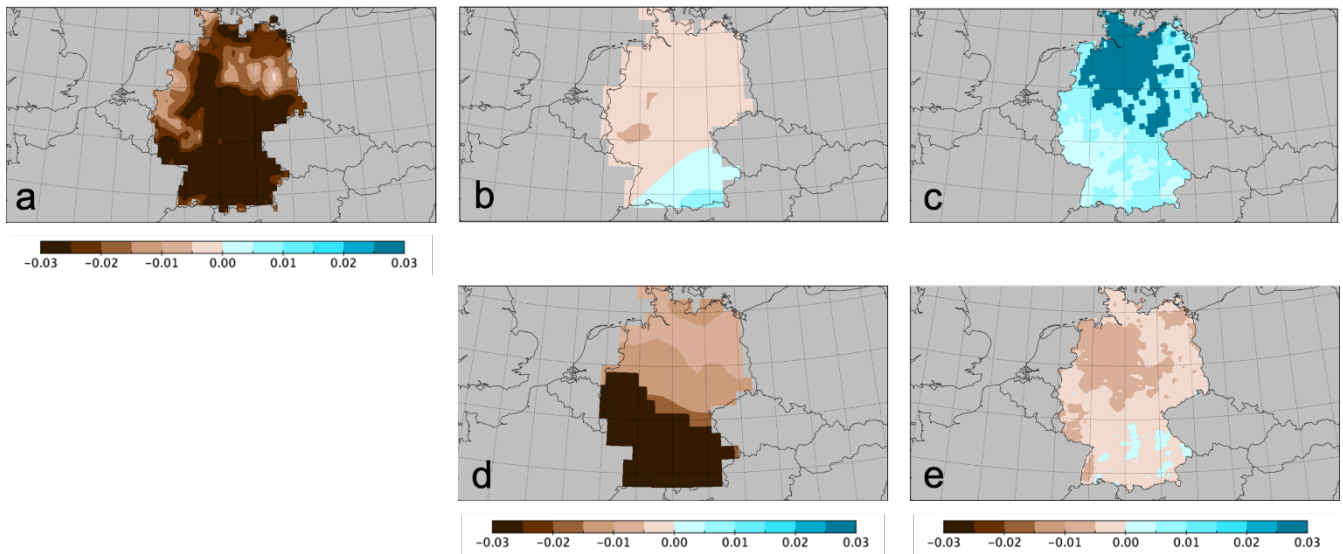

605
606 **Figure 12: Changes of temperature-precipitation (heat-drought, left) and precipitation-wind (wet-windy, right) compound years**
607 **occurrence in terms of frequency and intensity, at 1 °C (1975-2025) and 3 °C (2025-2075) above the pre-industrial levels based on**
608 **the 30-member CMIP6 MPI-GE under SSP5-8.5 (Olonscheck et al., 2023) over Germany.**

609

610 The likelihood of winters with extreme compound precipitation-strong wind events does not change significantly with global
611 warming in the CMIP6 MPI-GE projections (Fig. 12, right). Such wet and windy winters, where both precipitation and wind
612 are extreme, are projected to occur about once every 50 years. However, although the number of projected events remains
613 roughly the same, the intensity of the actual wind and precipitation levels reached during the most extreme compound wet-
614 windy events increases substantially in the near future. .

615 A factor that strongly modulates the occurrence of extremes in Europe is the soil moisture availability, as decreasing soil
616 moisture availability initiates a suite of processes feeding back into an intensification of both heat waves and droughts (Miralles
617 et al., 2019). Figure 13 presents a comparison between the observed (ERA5), simulated (extended historical) and projected
618 (RCP8.5) drought conditions via the SPEI moisture availability index (see Methods section 2.12). For the historical period
619 1979-2019, the reanalysis shows trends in the 3-year running mean SPEI, with a clear drying tendency in central and southern
620 Germany during the warm season, with lower values elsewhere in Germany (Fig. 13a). Part of this trend may be related to the
621 multi-year drought of 2018-2020 at the end of the time series. The CMIP5 multi-model ensemble under observed (extended
622 historical) greenhouse gas concentrations (Fig. 13b) fails however at depicting the trends for the past decades, while Euro-
623 CORDEX (Fig. 13c) simulates an increased water availability across Germany. The future projections following the RCP8.5
624 scenario are roughly consistent between CMIP5 (Fig. 13d) and EURO-CORDEX (Fig. 13e). Both ensembles predict a
625 considerable trend towards more impactful multi-year drought conditions under RCP8.5. Differences between the various
626 sources of data may be related to specific characteristics and settings of the climate models, such as the treatment of
627 anthropogenic aerosols, the inherited uncertainty and bias of climate models to replicate the precipitation variability at the
628 regional and local scale, the differences of the convective precipitation during the warm part of the year (Dyrrdal et al., 2017),
629 but also the use of multi-model ensembles that may mask the individual model skill (Ridder et al., 2022). These examples
630 demonstrate the need for further model development to improve their ability to accurately reproduce observed CEs and their
631 characteristics, thus reducing the uncertainty of future projections and contributing to improved prevention, risk management
632 and future preparedness.

633

634

639
 640 **5 Conclusions – Lessons learned and future steps**

641 Compound climate events had severe impacts across Europe in 2018, as combinations of extreme weather events unfolded
 642 simultaneously or in succession, resulting in extensive socio-economic, environmental, and infrastructural damage. The study
 643 highlights two primary types of CEs: hot-dry and wet-windy, each amplifying the effects of individual weather extremes. A
 644 variety of statistical approaches and datasets have been explored and implemented, spanning different types of events and
 645 disciplines.

646 The summer of 2018 was marked by prolonged heatwaves and drought conditions across Europe, driven largely by persistent
 647 large-scale atmospheric blocking. Soil moisture declined sharply from spring through summer, imposing widespread stress on
 648 agriculture, forests, and water resources. These conditions led to significant agricultural losses, particularly in winter wheat
 649 yields, and imposed severe stress on European forests, resulting in large-scale forest fires and insect outbreaks.

650 The winter of 2018 saw a sequence of intense storms, including Friederike and Burglind, which brought strong winds and
 651 heavy precipitation, causing widespread flooding, property damage, and economic losses in multiple countries. The
 652 combination of sustained high winds and heavy precipitation further increased the risk of landslides and rockfalls, particularly
 653 in regions with saturated and thawing soils.

654 Projections indicate that, under progressing climate change, hot-dry events will increase in frequency and severity, while wet-
 655 windy events may retain similar frequencies but with greater intensity. Current adaptation and risk management strategies may

656 be insufficient, as they often focus on single-event risks and may underestimate the compound hazards posed by concurrent
657 extremes.

658 This study encourages further research on compound events to improve predictive capabilities and inform adaptation strategies.
659 Integrated climate models that better represent the complex interactions of multiple extremes are crucial. Next steps involve
660 validating the physical relationships between predictors and CEs to identify the underlying mechanisms that drive or modify
661 these events, which could lead to more accurate analyses and predictions of CEs. Furthermore, given the complexity of CEs
662 and their direct impacts, a redefinition of events based primarily on their relevant impacts, rather than purely statistical
663 characteristics, is necessary to effectively assess and manage these risks.

664 These findings underscore the need for comprehensive climate adaptation approaches that address the interconnected nature
665 of compound events, ensuring more effective preparedness for the compounded risks of future climate extremes.

670

671 **Data availability**

672 The ERA5 (<https://doi.org/10.1002/qj.3803>, Hersbach et al., 2020) reanalysis data are publicly available via the Copernicus
673 Climate Change Service (<https://doi.org/10.24381/cds.adbb2d47>, Hersbach et al., 2023). The gridded observational datasets
674 E-OBS (<https://doi.org/10.1029/2017JD028200>, Cornes et al., 2018) are publicly available on the European Climate
675 Assessment & Dataset website (<https://www.ecad.eu/download/ensembles/download.php>, ECA&D, 2023). The observational
676 datasets (<https://doi.org/10.5194/asr-10-99-2013>, Kaspar et al., 2013) and the phenological data from the German Weather
677 Service (DWD; <https://doi.org/10.5194/asr-11-93-2014>, Kaspar et al., 2015) are publicly available on the DWD website under
678 their Open Data Portal (<https://opendata.dwd.de/>, DWD, 2023). The yield productivity data (<http://dx.doi.org/10.22029/jlupub-7177>, Ellsäßer and Xoplaki, 2022a), the yield anomaly catalogue (<http://dx.doi.org/10.22029/jlupub-7176>, Ellsäßer and
679 Xoplaki, 2022b) and supplementary data (<http://dx.doi.org/10.22029/jlupub-7203>, Ellsäßer and Xoplaki, 2022c) are publicly
680 available at the JLUpub research data repository. Historic climate data from the GSWP-W5E5 dataset used for LPJmL5
681 simulations are available from <https://doi.org/10.48364/ISIMIP.982724> (Lange et al., 2022). The historical data of atmospheric
682 N deposition and atmospheric CO₂ concentrations can be obtained from <https://doi.org/10.48364/ISIMIP.600567> (Yang and
683 Tian, 2020) and <https://doi.org/10.48364/ISIMIP.664235.2> (Büchner and Reyer, 2022), respectively. All input data, model
684 code, model outputs, and post-processing scripts that have been used to produce the LPJmL-related results in this paper are
685 archived at the Potsdam Institute for Climate Impact Research and are available upon request.

689 review process was guided by an independent editor, and the authors also have no other competing interests to declare.

690

691 **Author Contribution**

692 EX and FE coordinated the interdisciplinary task force on compound events within climXtreme and this collaborative paper,
693 conducted the agriculture case study analysis with Figure 6, prepared the first and final drafts of the paper based on the
694 contribution of the co-authors; ER contributed the drivers of the hot summer of 2018 case study with Figure 1; SS contributed
695 the detection of spatial patterns of extreme events and Figure 2; LG and SK contributed with the surface water storage case
696 study analysis and Figure 3; LJ contributed the soil moisture case study and Figure 4; JH contributed with the analysis of the
697 agricultural and hydrological droughts and Figure 5; DG and FK contributed with the forestry case study; JGP and T-CC
698 contributed the windstorms description and prepared Figure 7 and S1; JGP contributed to the compound events under climate
699 change section; JG conducted the loss analysis for windstorms with Figure 8 and contributed to the methods section; FS
700 conducted the copula analysis and prepared Figure 9; KNM contributed the rockfall events case study analysis with Figure 10,
701 drafted the section on precipitation-wind compound events and contributed to the compound events under climate change
702 section; SM and MA analysed convective storms and provided Figure 11; LSG did the CMIP6 MPI-GE projection study and
703 prepared Figure 12; KH contributed the analysis of soil moisture representation and trend in model simulations with Figure
704 13. NL and OV contributed to the temperature-precipitation compound events section; JL contributed drafting different
705 sections and versions of the paper and all authors followed the analysis from the beginning, provided text and
706 edited/commented the final version of the manuscript.
