36 **Abstract.** Drought and heat events are becoming more frequent in Europe due to human-induced climate change, affecting  
37 many aspects of human well-being and ecosystem functioning. However, the intensity of these drought and heat events is not  
38 spatially and temporally uniform. Understanding the spatial variability of drought impacts is important information for decision  
39 makers, supporting both planning and preparations to cope with the changing climatic conditions. Currently, data relating to  
40 the damage caused by extended drought episodes is scattered across languages and sources such as scientific publications,  
41 governmental reports and the media. In this review paper, we gathered data of damage caused by drought and high temperatures  
42 from 2018 until 2022 in forest ecosystems and combined our data with Europe-wide data sets such as (1) crown defoliation,  
43 (2) damaged wood by insects, (3) burnt forest areas, and (4) tree cover loss. We partitioned the data stemming from 16  
44 European countries into four regions: Northern, Central, Alpine, and Southern.

45 During the 2018-2022 period, forests across all four zones exhibited diminished vitality due to drought and elevated  
46 temperatures, albeit with varying severity. We identify several trends affecting more than one climate zone: (1) Conifers have  
47 no significantly higher defoliation rates within the Northern zone or individual countries within it, but higher rates are observed  
48 in the Central and Southern zones. Broadleaves exhibit significantly higher defoliation rates across the three zones,  
49 (2) There is a significant increase in general tree cover loss in the Northern, Central, and Southern zone. Although in several  
50 regions 2021 was an average year high levels of damages were still observed indicating strong legacy effects from the events  
51 in 2018- 2020, (3) The Northern and the Alpine zones showed comparatively lesser impacts, and (4) Central Europe and  
52 Sweden experienced notable damage to wood from bark beetles. Notable zone-specific trends were: (1) The Central zone  
53 experienced notable challenges exacerbated by bark beetle infestations, (2) While wildfires pose a colossal challenge for  
54 Southern Europe, their impact during this specific timeframe is not pronounced and (3) while some adaptive responses to heat  
55 and drought were discernible in the Southern zone. Overall, given the projected increase in future occurrences of drought and  
56 heat, these results emphasise the critical necessity for implementing tailored strategies to alleviate the detrimental impacts of  
57 climate change on European forests.

58

## 60 **1 Introduction**

### 61 **1.1 General introduction**

62 The global temperature rise, due to the accumulation of anthropogenic greenhouse gases in the atmosphere, causes extreme  
63 drought and heat events to become more likely and more extreme (Seneviratne et al., 2021). Even if we manage to stay below  
64 the 2°C global warming threshold by the end of the 21st century (relative to pre-industrial levels), in Europe one out of every  
65 two summer months is projected to be as warm or warmer than the summer of 2010, which was one of the warmest across  
66 Europe to date (Suarez-Gutierrez et al., 2018). Furthermore, the likelihood of such extremely warm summers co-occurring  
67 with extreme drought conditions over Europe is increasing rapidly (Suarez-Gutierrez et al., 2023). When extreme heat occurs  
68 jointly with severe drought conditions, it can lead to devastating ecological and socio-economic impacts (Feller et al., 2017;  
69 Zscheischler et al., 2020; Bastos et al., 2021), such as economic losses (García-León et al., 2021), increased risk of wildfires  
70 (Ruffault et al., 2020), increased risk of crop loss (Toreti et al., 2019, Brás et al., 2021; Bento et al., 2021), and unprecedented  
71 forest mortality events (Schuldt et al., 2020). Extreme drought is often closely linked with extreme heat, which in turn increases  
72 heat-related mortality and morbidity (Watts et al., 2020). Vicedo-Cabrera et al., (2021) found that up to 30% of heat-related  
73 deaths globally in the last 30 years can be attributed to anthropogenic climate change. Mitchell et al., (2016) found the risk of  
74 heat-related mortality during the intense 2003 summer heat wave increased in Central Paris by ~70% and by ~20% in London,  
75 both attributable to human factors having exacerbated the likelihood for such heat episodes. As such, the recent period of  
76 drought and heat between 2018-2022 is especially concerning as the possible beginning of a new climatic era in Europe.

77 The recent hot and dry extremes are part of a long-term trend being observed in Europe over the last 42 years, making it a hot  
78 spot for heatwaves in comparison to other regions of the northern hemisphere midlatitudes (Rousi et al., 2022). Central and  
79 Southern Europe are affected by a longer-term drying trend, in line with expectations from theory and climate model  
80 simulations (Ionita et al., 2022). This trend includes also consecutive multi-year meteorological summer droughts, such as  
81 those of 2018 to 2022 in Central and Western Europe, which are characterised by two or more summers of lower than normal  
82 precipitation and higher than normal evaporative demand, resulting in a larger reduction of soil moisture content in the second  
83 year of the drought, and therefore to potentially more extreme drought impacts (Van Der Wiel et al., 2022). Worryingly,  
84 climate models project a strong increase of dry spells (Rousi et al., 2021) and multi-year droughts in Western Europe in  
85 response to further global warming (Van Der Wiel et al., 2022; Suarez-Gutierrez et al., 2023).

### 86 **1.2. Scope, aims and research approach**

87 In this review we present the impacts documented in European forests during the years 2018-2022, some of the warmest and  
88 driest on record over Europe. We focus on forest ecosystems because they are not irrigated and thus the effects of climate  
89 extremes are clearer, and we avoid a potential bias in the interpretation of results due to variation in irrigation levels. Forests

90 play a fundamental role in our livelihoods and supply wood, a renewable raw-material and other essential ecosystem services.  
91 For example, forests contribute significantly to maintaining biodiversity, sequestering carbon, mitigating climate change,  
92 preventing land degradation, and offering recreational value (Jenkins and Schaap, 2018).

93 We partitioned the forest environment of Europe into four main geographical zones with distinct climatic and environmental  
94 conditions: (1) Northern Europe, (2) Central Europe, (3) Alpine zone, and (4) Southern Europe. The four geographical zones  
95 do not overlap in all cases with the international borders. Thus, since some of the information sources (e.g. government reports)  
96 used for this review refer to political boundaries (at country-level), we assigned those sources to whichever geographical zone  
97 was the most appropriate. An exception was that four countries were assigned to two zones because they are partly in the  
98 Alpine zone.

99 The evaluation of the extraordinarily intense compound drought and heat event between 2018 and 2022, along with its impacts  
100 were derived using an interdisciplinary study integrating different information sources that allow for the assessment of  
101 temporal and spatial heterogeneity impacts. We start with the description of the climatic conditions in 2018-2022, with a focus  
102 on drought and high temperatures. We describe droughts in the years before 2018 where it is needed to provide a better context  
103 for our focal period of 2018-2022. Following this, we focus on the drought and heat impacts on forests. We collected the  
104 different estimates of damages from research papers, reports, and even media coverage when no better source was available.  
105 We focus our review on damage caused by drought and heat that induced (i) physiological stress, (ii) insect pests, and (iii) fire  
106 events, as the three impacts most well-documented in our sources.

107 The data source often posed issues and challenges. Concerning fire events, we focus on forest fires, which are defined as  
108 uncontrolled fires in at least partly forested areas. However, for some countries only statistics on wildfires (all uncontrolled  
109 vegetation fires) were available. Also, the online available data on number and burnt areas from the European Forest Fire  
110 Information System (EFFIS) shows number of wildfires and total affected vegetation area. To resolve these issues, we used  
111 data about forest fires where available and pointed out when we present information about wildfires. This study examines  
112 forest damage spanning 2018-2022, only the exceptional forest fire damage in 2017 in Southern Europe is included, as it  
113 provides context for subsequent damage. Post-2017, significant management measures were implemented in Southern Europe  
114 to mitigate forest fires, affecting subsequent damage trends. Forest damage of other zones is not discussed for 2017 as it was  
115 comparatively minimal.

116 In order to evaluate and attribute the impacts of heat and drought during the years 2018 to 2022 in Europe, we considered the  
117 years 2010-2014 as a reference period. We note that the year 2015 was characterised as an extraordinary drought period in  
118 Europe (e.g. Hoy et al., 2017, Laaha et al., 2017) and therefore we did not include 2015 in our reference period. Compared to  
119 other periods in the new millennium, the period 2010 to 2014 was characterised by fewer climate extremes, such as intense  
120 heat waves, widespread droughts or severe floods, e.g. the water balance levels in Germany show only small deviations from  
121 the climatological mean during that pperiod (*cf.* DWD Dokumentation SPEI). The period of 2010-2014 had below-average to  
122 average annual mean temperatures (relative to the 1991-2020 average) across Europe, in particular during 2010, 2012, 2013.  
123 Moreover, damage data availability was sufficiently available for the period 2010-2014.

124 In the following sections, we take a closer look at the climatic situation during those five critical years in four European zones  
125 (Northern, Central, Alpine, and Southern). Table 1 lists the countries and regions present in this review. Countries were selected  
126 based on exposure to heat and drought during 2018-2022, but also based on data availability and language barriers. Out of the  
127 44 European countries (UN 2024) 28 countries were not included (i.e. Albania, Andorra, Belarus, Bosnia and Herzegovina,  
128 Cyprus, Denmark, Estonia, Georgia, Greece, Hungary, Iceland, Latvia, Liechtenstein, Lithuania, Luxembourg, Malta,  
129 Moldova, Monaco, Montenegro, North Macedonia, Romania, Russia, San Marino, Serbia, Slovakia, Slovenia, Turkey,  
130 Ukraine, and Vatican City). Data collection was conducted as broadly as possible across Europe over months of work by a  
131 working-group in the ClimXtreme project (<https://www.climxtreme.net/index.php/en/>) with additional experts beyond the  
132 project contributing their expertise.

133  
134 **Table 1:** Four climate zones and the associated 16 countries in total, the countries of the Alpine zone are also assigned to other  
135 zones.

---

Zone	Countries
Northern	Finland (FIN), Sweden (SWE), Norway (NOR), United Kingdom (UK), Ireland (IRL)
Central	Poland (POL), Czech Republic (CZE), Switzerland (CHE), Austria (AUT), Germany (GER), Netherlands (NLD), Belgium (BEL), France (FRA)
Alpine	Switzerland, Austria, Italy (ITA), France
Southern	Italy, Spain (ESP), Portugal (POR)

---

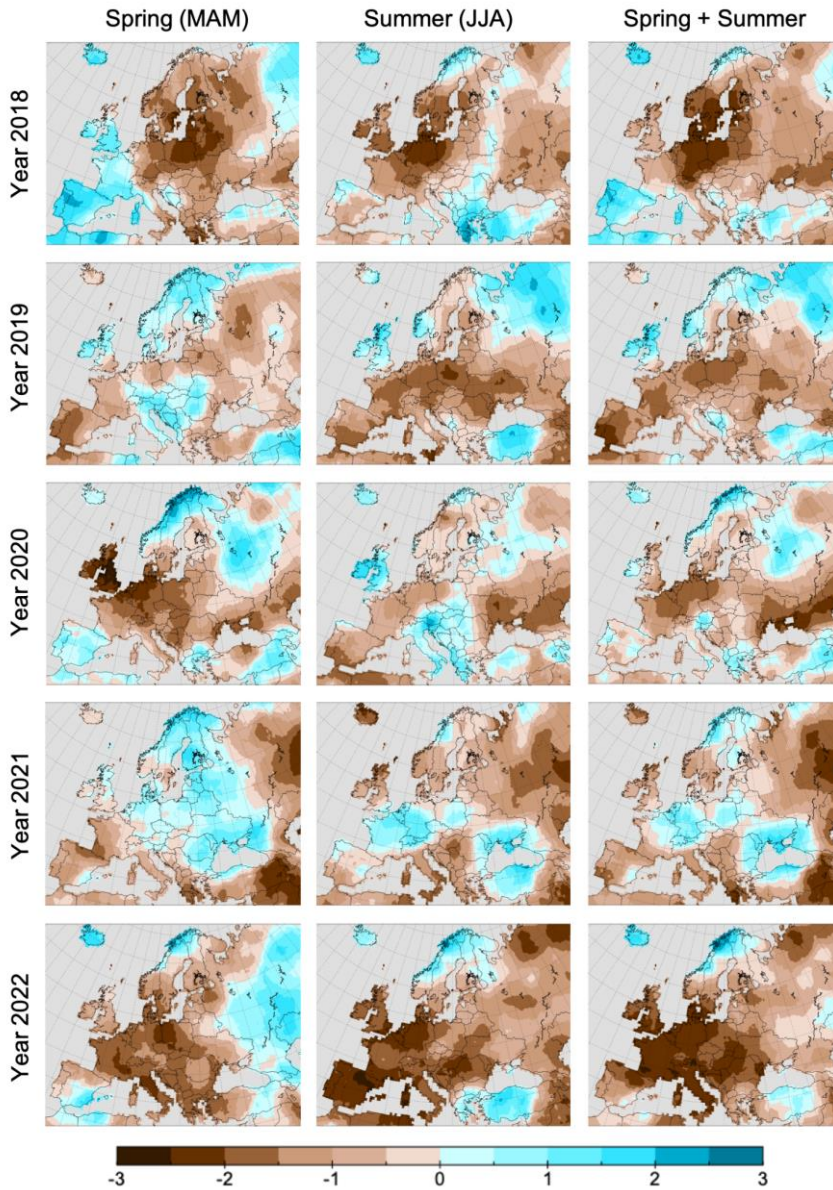

136

## 137 **2. Meteorological conditions**

### 138 **2.1. Occurrence of drought and heat in Europe during 2018-2022**

139 Persistent above average temperatures and extreme deficits in precipitation characterised the summers during 2018-2022 (Fig  
140 1) across Europe, one of the worst consecutive drought periods that occurred in the continent. The extreme climatic conditions  
141 were linked to strong atmospheric blocking conditions over Europe, characterised by persistent high-pressure anticyclonic  
142 systems, especially in late spring and summer 2018. It was found that a persistent positive North Atlantic Oscillation, a pattern  
143 defined by higher-than-average atmospheric pressure over the subtropical North Atlantic and lower-than-average pressure over  
144 the North Atlantic (Drouard et al., 2019; Li et al., 2020), combined with a double jet stream configuration, with two instead of  
145 one single current of high-speeds winds in the upper atmosphere affecting the intensity and persistence of atmospheric patterns  
146 in the inter-jet region, were present before the initiation of the heatwave (Rousi et al., 2023). Furthermore, sea surface  
147 temperature anomalies exhibited a tripolar pattern in the North Atlantic which has previously been identified as a precursor  
148 for European heatwaves (Beobide-Arsuaga et al., 2023), such as the one of 2015 (Duchez et al., 2016), as well as a precursor

149 for increased drought risk in Central Europe via changes in the large-scale atmospheric circulation (Haarsma et al., 2015; Rousi  
150 et al., 2021; Ionita et al., 2022).

151  
152 **Figure 1.** SPEI (Standard Precipitation Evaporation Index) for spring (March to May), summer (June to August) and the entire  
153 growing season (March to August) during the 2018 (top row) to 2022 period (bottom row). SPEI results are shown in units of  
154 standard deviation from the long-term mean of the standardised distribution. SPEI includes precipitation, effects of temperature  
155 and hence evapotranspiration. SPEI uses a climatic water balance D obtained at various time scales (i.e. over three and six  
156 months). E.g. for a 6-month SPEI, first a time series is constructed by the sum of D values from five months before to the  
157 current month. For a SPEI series comparable in space and time, the D series is transformed using equal probability to a normal

158 distribution with a mean of zero and standard deviation of one. This way the SPEI values are in standard deviations without  
159 seasonal effects (Vicente-Serrano et al., 2012, 2013, Beguería et al., 2013). Data was derived from the Global Drought Monitor,  
160 which offers near real-time information about drought conditions at a global scale. (Vicente-Serrano, Sergio M. & National  
161 Center for Atmospheric Research Staff (Eds). Last modified 2023-09-04 "The Climate Data Guide: Standardised Precipitation  
162 Evapotranspiration Index (SPEI)".

163  
164 Using pattern climatology data for Europe and linking it with observations over the last 120 years, Hari et al., (2020) claim  
165 that alone the consecutive 2018-2019 drought was unprecedented during the last 250 years. Including also 2020 in their  
166 analysis, Rakovec et al., (2020) found that the 2018-2020 drought was not only unprecedented in intensity, but what made it  
167 truly exceptional was its average near-surface air temperature anomaly of +2.8°C above the pre-industrial period. From a  
168 spatial perspective, the authors found that approximately 35% of Europe was affected during the first two most severe years  
169 of the drought. Following the 2018-2020 extreme drought, 2021 marked a rather normal to wet year. However, persistent hot  
170 and dry conditions returned in spring and summer 2022, leading to similarly depleted soil water levels as in 2018 and regionally  
171 critical drought conditions (Fig 1). Throughout the summer of 2022, heat waves and exceptionally low rainfall led to very dry  
172 conditions in Central Europe. Observed runoff anomalies highlighted the 2022 European drought as potentially the worst in  
173 500 years (Schumacher et al., 2022). Many areas in Europe were subject to the strongest 500 hPa geopotential height anomalies  
174 since 1950 between May and July 2022 (Toreti et al., 2022a).

175

## 176 **2.2. Drought and heat in the Northern zone 2018-2022**

177 **Finland** had a warm and dry year in 2018. The summer was long with many days over 30°C temperatures and rainfall levels  
178 were at a record low in some areas. In Central Finland, the all-time lowest groundwater table levels were measured in small  
179 and shallow aquifers (Veijalainen et al., 2019). Furthermore, the summer of 2018 saw uncommonly large algal blooms and the  
180 death of fish and mussels and a 20% reduction in crop yields (Winland-project Policy Brief VII 2019). Summer 2019 was not  
181 as severe as 2018, but with significant impacts, for example, on the ground water levels, which were very low already from  
182 the previous year. Summertime temperatures were about 1°C higher than normal in Southern and Western Finland, but slightly  
183 lower in eastern and northern parts. Summer 2019 was drier than normally, especially in Central and Eastern Finland, where  
184 such dryness was last experienced in 1955 (Ilmastokatsaus, 2019). The year 2020 was a record breaking warm-year in Southern  
185 and Central Finland. Summer and autumn were exceptionally warm, but also many rainfall records were broken  
186 (Ilmastokatsaus, 2020). Year 2021 was not overall exceptional, but June and July were warmer than normally. June  
187 temperatures were in many parts of the country higher than ever recorded before. Summer was also unusually dry, although  
188 only in June and July (Ilmastokatsaus, 2021). The year 2022 was warmer than normal and summertime temperatures were  
189 almost 2°C higher than normal. Southern and Western Finland experienced less rainfall than normally, whereas Central and  
190 Northern Finland experienced more rain (Ilmastokatsaus, 2022).

191 **Sweden** experienced prior to 2018 two rather dry years in 2016 and 2017. Especially in Southern Sweden, streamflow was  
192 28% below normal and many regions issued local water use restrictions (Geological Survey of Sweden, 2017). This drought  
193 continued and culminated in 2018 (Swedish Board of Agriculture, 2019), which ultimately led to the most serious wildfires in  
194 modern times in Sweden (Teutschbein et al., 2022). Fires like those in 2018 were made approximately 10% more likely in  
195 Sweden under current climate conditions compared to pre-industrial climate (Krikken et al., 2021). Drought conditions eased  
196 in the following years, with the return of slightly drier conditions in 2022.

197 **Norway** also experienced periods of drought in the years 2018-2022. In the spring and summer of 2018 temperatures were up  
198 to 4.7 °C above normal levels. Precipitation between May and September 2018 was only between 18-46% of the average  
199 precipitation level for the years 1991-2020 (Norwegian Center for Climate Services, 2023). The summer of 2018 had the  
200 longest consecutive drought period in the past five years, but 2021 and 2022 were also dry with 83 and 84% of average annual  
201 precipitation, the driest month for the country being August 2021 (Norwegian Center for climate services, 2023). This led to  
202 a reduction in groundwater levels down to 75% of the average levels in most of South-eastern Norway below the treeline in  
203 August 2018 and August 2022, causing problems for agricultural production in the region (NVE, 2023). As predicted by  
204 climate models (projection for 2031-2060, RPC 4.5. Reference period 1971-2000), precipitation is becoming more  
205 concentrated, leading to periods of floods (during early spring and on certain days in summer) followed by periods of drought  
206 (late spring to summer) (Hanssen-Bauer et al., 2017).

207 In 2018, most parts of the **United Kingdom (UK)** suffered a combined heatwave and drought (Holman et al., 2021). In some  
208 parts of the UK a protracted dry spell extended into late 2018 and 2019 (Turner et al., 2021). Nonetheless, humid weather  
209 conditions in the period from June 2019 to February 2020 led to harmful flood events (Sefton et al., 2021). The year 2020 was  
210 hot with a dry spring but a wet summer (Kendon et al., 2021) and the year 2021 continued this trend with temperature and  
211 rainfall reaching slightly below the long-term average (Met Office 2021). The year 2022 was the first with an annual average  
212 temperature across the UK exceeding 10°C for the first time, while the UK's total rainfall accumulation has remained  
213 persistently below average (Met Office 2022, Royal Meteorological Society 2023). At Coningsby, Lincolnshire, a temperature  
214 above 40°C was recorded for the first time in the weather record history of the UK (Met Office 2022).

215

### 216 **2.3 Drought and heat in the Central zone 2018-2022**

217 Due to its geographical location and unfavourable hydrological conditions, **Poland** has few water resources relative to Europe  
218 (Ministry of Climate and Environment, 2023, SUSZA 2023). The relative scarcity of water resources is illustrated by the fact  
219 that almost 40% of arable and forested land in Poland is permanently threatened by drought (Polish Supreme Chamber of  
220 Control, 2021). Drought in Polish agriculture typically occurs every five years, and recently it has covered significant areas of  
221 the country almost every year - in 2015, 2016, 2018, 2019, and 2020. In 2018, the soil drought was severe with regions having  
222 more than 50 days of no plant-available water (Wielkopolska and Kujawy Region; Wawrzoniak et al., 2019). In recent years,  
223 soil droughts have been observed also in large parts of forested areas (Lech et al., 2021).

224 The severe drought event of 2018 was centred over southwest **Germany**, Benelux and northeast **France**, the centre of the  
225 2019 drought was further east, with Eastern Germany and neighbouring countries most affected. The severity of the 2019  
226 summer drought was not exceptional in itself, but the fact that it was a second consecutive drought year led to a worse water  
227 deficit than 2015 in many parts of Germany and France (as 2015 was the worst drought until 2018). Also, the spatial extent of  
228 the 2019 drought exceeded that of previous years. Using GRACE data, Boergens et al., (2020) found drought conditions were  
229 most severe in the western part of Germany in autumn 2018, while drought conditions were most severe in Eastern Germany  
230 and Poland in summer 2019. Germany and France (with exception of Southern Germany) experienced continued drought  
231 conditions till late summer 2020. Summer 2021 brought a relief in terms of precipitation, leading to severe flooding in Central  
232 Europe (Mohr et al., 2023). The summer of 2022 saw a return to extreme drought conditions in Germany and France. These  
233 dry conditions were related to persistent lack of precipitation combined with early heatwaves in May and June. Overall, the  
234 extent of drought affected areas in Germany reached almost 40% of the country in 2022, followed by 2019 (30%), 2018 (19%)  
235 and 2020 (16%).

#### 236 **2.4 Drought and heat in the Alpine zone 2018-2022**

237 In **Switzerland**, 2018 included the fourth warmest spring (March, April, May) and the third warmest summer (June, July,  
238 August) since the start of instrumental measurements in 1864 (Bader et al., 2019). While summer 2018 received only 70% of  
239 the long-term mean precipitation (1981–2010), winter rainfall (including snowfall) was above normal, which helped alleviate  
240 the worst impacts of the summer. Between 2019 and 2021, frequent heat episodes occurred during the summer seasons, but  
241 mean precipitation during winter was about normal. This changed in winter 2021/2022, when anomalously warm and dry  
242 conditions persisted especially in Southern Switzerland and Northern Italy. Summer 2022 saw record-breaking temperatures.  
243 July 2022 was one of the hottest since measurements began in 1864, beating some of the records set only four years earlier.  
244 The heat was accompanied by low rainfall, which led to record low levels for many lakes in Eastern and Central Switzerland.  
245 **Austria** with its Alpine topography is generally considered as a water-rich country with freshwater resources that exceed  
246 demand even in relatively dry years. However, Austria did experience exceptional heat and drought episodes in recent years,  
247 particularly in 2018 and 2022, raising concerns about water availability (Stelzl et al., 2021). One factor is a significant decline  
248 in observed snow depth in the wider Alpine region, which is required to balance the increased evaporative demand in summer  
249 (Matiu et al., 2021). While the summer of 2019 was less dry in Austria, it tied for the warmest summer on record with 2003  
250 (since at least 250 years). Summer 2022 was the 4<sup>th</sup> warmest in recorded history, taking place right after a rather dry and mild  
251 winter, and while several heavy rainfall events occurred, they barely alleviated the drought conditions due to the high runoff.  
252

#### 253 **2.5 Drought and heat in the Southern zone 2018-2022**

254 **Italy** was affected by the 2018 drought to a lesser extent compared to Central and Northern European countries. For instance,  
255 there were no significant soil moisture anomalies and forest disturbance during 2018 in Italy (see Fig. 1 in Senf and Seidl,

256 2021a). Drought conditions persisted during the 2021 and 2022 summer (Toreti et al., 2022a). The rainfall deficit during winter  
257 2021 to 2022 exacerbated drought conditions across the peninsula (Toreti et al., 2022b; Bonaldo et al., 2023). The winter of  
258 2022/2023 continued to be rather dry (Toreti et al., 2023).

259 In **Spain**, in the 2020/2021 water year precipitation was 5% below the normal value. Between the start of the next hydrological  
260 year on 1 October 2021 to the next reporting date on 8 March 2022, the national average value of accumulated rainfall was  
261 38.2% below the normal value (BOE, 2022). As of 8 March 2022, the peninsular water reserve stood at 40.5%, significantly  
262 lower than the average for the last 5 years (52.5%) and the average for the last 10 years (60.8%). The water reservoir network  
263 in Spain was conceived to sustain demand during dry years using the reserves from prior wet years. The succession of years  
264 with below average precipitation experienced in the region since the 2012/2013 water year, with the sole exception of  
265 2017/2018, led to low to depleted water reserves compounding the extremely persistent hydrological and meteorological  
266 drought conditions in the years 2012-2022 (BOE, 2022). The hydrological year 2021/2022 ended as one of the three driest  
267 years on record, with 25% less precipitation than average and water reservoirs levels at around 35%, the lowest in 27 years  
268 (Greenpeace, 2022).

269 The last 20 years have been particularly dry in mainland **Portugal**, with 6 of the 10 driest years occurring after 2000, including  
270 2017-2018, 2019 and 2021/2022. The average value of the amount of precipitation in the hydrological year 2021/2022 (488.3  
271 mm), shows a precipitation deficit of -393.8 mm, compared to the normal accumulated precipitation for 1971-2000. Compared  
272 to previous years of drought, 2021/2022 it is the 3rd driest hydrological year after 2004/05 and 1944/1945, presenting a sharp  
273 deficit in relation to the average value throughout the year (APA, 2023).

274 For the period 2018 to 2020, Portugal was affected by drought to a lesser extent, and mostly in the southern part of the country  
275 (Figure 1). The drought conditions impacted water storage, with monthly storage deviations from the average in the last  
276 hydrological years, showing that in 2019/2020 the hydrological drought was more severe with five of the eleven hydrographic  
277 basins in Portugal maintaining negative deviations throughout the year. The 2020/21 hydrological year ended with only four  
278 watersheds with below-average storage levels (APA, 2023).

## 279 **2.6 Drought attribution**

280 As discussed earlier in the general introduction, a long-term drying trend has been observed in Central and Southern Europe  
281 in recent years and climate--simulations project these trends to continue (Stagge et al., 2017, Ukkola et al., 2020, Bakke et al.,  
282 2023). There is high confidence that both temperature increase, and precipitation decrease has already led to increased aridity  
283 in the Mediterranean region (IPCC, 2021a). According to the last IPCC report (IPCC, 2021b), the combined warming and  
284 drying trend is already attributable to human causes. This trend is less clear in Western and Central Europe (Germany, Northern  
285 France, Southern UK), which is not surprising given the fact that there is high confidence of decreased aridity in response to a  
286 mean precipitation increase in Northern Europe (Scandinavia, Scotland, Ireland) in a warmer climate (IPCC, 2021a).  
287 Nonetheless, using summer SPEI trends between 1950-2018, Christidis and Stott (2021) found that there is an increased  
288 drought risk also in France and Germany, both in observations and in CMIP6 model simulations. South-eastern Europe is also

289 affected based on rainfall and precipitation minus evaporation reanalysis data (1950-2018; Christidis and Stott, 2021). A  
290 similar result is found when analysing longer-term SPEI trends (1902-2020), where hotspots in terms of drying were found in  
291 Spain, Portugal, Southern France, Italy, Eastern Germany, the Czech Republic, Poland, Hungary, Slovenia, and Croatia, with  
292 the opposite trend in Norway (Ionita et al., 2021a). The same authors hypothesise that those observations might be linked to  
293 changes in large-scale atmospheric circulation in the North Atlantic region (Ionita et al., 2022). Others have highlighted that  
294 the changes in the North Atlantic circulation may in turn be linked to the slowdown of the Atlantic Meridional Overturning  
295 Circulation (AMOC; Caesar et al., 2018). Hence, the question remains to what extent the observed trends are directly  
296 (thermodynamically) or indirectly (dynamically) attributable to anthropogenic factors. There are two ways to address this  
297 question more broadly: (1) The paleo-climatic perspective based on proxy data (climate indicators like pollen, tree rings, etc)  
298 and (2) longer-term climate model projections.

299 (1) Looking at climate reconstructions based on proxy data that are typical for summer conditions over the Czech Republic  
300 and neighbouring regions in Poland, Germany, Austria, Hungary, and Slovakia, Büntgen et al., (2021) found that the most  
301 recent drought extremes between 2015 and 2018 are not only unprecedented during the period of proxy-target overlap, but  
302 also in the context of the past approximately 2,000 years. In other words, the most recent drought episode is beyond the  
303 variability seen in proxy data from paleoclimatic records that reach as far back as two millennia. These results are in contrast  
304 to findings by Ionita et al., (2021b), who claim that mega-droughts during the 15<sup>th</sup> and late 18<sup>th</sup>/early 19<sup>th</sup> century were longer  
305 and more severe compared to recent drought events. It is noteworthy, that both studies used summer scPDSI (self-calibrated  
306 Palmer-Drought Severity Index) data which are not entirely comparable with SPEI, but they should at least be consistent  
307 against one-another. We can thus only conclude that neither the location (central part of Europe in case of Ionita et al., (2021b)),  
308 the method (the latter based on the Old World Drought Atlas; Cook et al., 2015), nor the spatial extent considered may be  
309 different. What the results do highlight though is that it remains difficult to draw definite conclusions as far as current drought  
310 intensity in a historic or paleo-climatic context is concerned.

311 (2) Climate model projections based on the latest CMIP6 assessment broadly confirm the historical trends deduced from  
312 observations. As shown in ICCP (2021b), the rainfall deficit is projected to be most pronounced during the summer season  
313 (end of 21<sup>st</sup> century vs current conditions). While increased winter and spring precipitation may balance some of the summerly  
314 water deficit, this is unlikely to be the case in France and Germany (and certainly not in the Mediterranean region). Given that  
315 trends in evapotranspiration are already negative with regard to the annual mean, the negative trend is only going to intensify  
316 in summer for the time being. In this context, it is important to note that annual mean rainfall changes are not informative when  
317 it comes to drought attribution. In fact, drought and heavy precipitation is often occurring in the same season, leading to adverse  
318 conditions for the agricultural and forest sector despite a climatologically balanced mean rainfall amount. In tandem with the  
319 rainfall deficit, it is very likely that meteorological drought conditions will occur much more often than under recent climate  
320 conditions (e.g. Mömken et al., 2022 for the Iberian Peninsula). It is highly unlikely that the current string of extreme drought  
321 years is an exception, rather it is a harbinger of what will soon be the new normal in large parts of Europe. That said, these  
322 projections are valid only for transient warming conditions. If we stop emitting carbon to the atmosphere, the planet will slowly

323 transition from its current transient warming state and enter the equilibrium warming phase following an e-folding trajectory.  
324 Thermodynamically, the transient warming state is characterised by a maximised temperature contrast between land and ocean  
325 (land masses warming much faster than ocean waters), causing the water deficit over land to increase even more than it would  
326 under (hypothetical) uniform land and ocean warming conditions. Given that the water vapour supply from oceans is limited  
327 due to relatively cooler ocean SSTs, the relative humidity over many land areas decreases (Byrne and O’Gorman, 2013). While  
328 not relevant for the near future, it should be kept in mind that the current drying trend is unlikely to continue if the climate  
329 system is allowed to return to a new equilibrium state, which has recently been highlighted by Dittus et al., (2024) as well.  
330 How do these two lines of evidence compare with actual attribution studies of individual extreme drought events? While it is  
331 generally straight-forward to attribute heat waves to anthropogenic climate change (e.g. Vogel et al., 2019; IPCC, 2021a), the  
332 fact that the signal-to-noise ratio for drought events is still low despite attributable global warming of 1.2-1.3°C, which leaves  
333 the attribution community in a limbo as far as robust results are concerned. For example, Van der Wiel et al., (2022) concludes  
334 that drought events like 2018-2020 are part of the realm of possibilities in the present-day climate, that is, a comparable event  
335 was expected to occur based on the average frequency or return period as eventually the signal will emerge from natural  
336 variability with the detrimental effects for biodiversity and human health in general.  
337 As it is difficult to reconcile the existing lines of evidence, only a few drought attribution studies have tried to quantify the role  
338 of humans thus far. A prominent rapid event attribution of the intense 2022 drought in Central and Western Europe showed  
339 that human-induced climate change made the root zone soil moisture drought about 3-4 times more likely, and the surface soil  
340 moisture drought about 5-6 times more likely (Schumacher et al., 2022). The authors concluded that while the magnitude of  
341 historical trends vary between different observation-based soil moisture products, they all agree that the dry conditions  
342 observed in 2022 would have been less likely to occur at the beginning of the 20th century. One study on the 2015 European  
343 summer drought concluded that the attribution results depend on the methodology used (Hauser et al., 2015). Only when using  
344 the largest possible forcing difference in CMIP5 models, were they able to detect a human influence for an increased likelihood  
345 of Central European droughts. García-Herrera et al., (2019) analysed the drought that affected France and western Germany  
346 from July 2016 to June 2017, stating that recent trends, including those in human-induced higher temperature, have exacerbated  
347 the severity of the drought event. Finally, Philipp et al., (2020) investigated the hydrological drought of 2018, stating that the  
348 trend is driven by strong trends in temperature and global radiation rather than a trend in precipitation, resulting in an overall  
349 trend in potential evapotranspiration. Given that these trends match results from climate model simulations, the authors  
350 conclude that the observed trend in agricultural drought can at least in part be attributed to human-induced climate change.

### 351 **3. Damages to forests**

352 Drought and heat are environmental factors that can have harmful impacts on forest ecosystems. Drought events compounded  
353 by heat waves can fundamentally transform the composition, structure, and biogeography of forested ecosystems (Allen et al.,  
354 2010, 2015). Overall, the consequences on forests can be summarised in three major impact categories: (i) physiological stress,

355 (ii) insect outbreaks, and (iii) forest fires (e.g. Brodribb et al., 2020, Seidl et al., 2020, Mezei et al., 2022, Salomon et al., 2022).  
356 From 1950 to 2019, observations of natural disturbances in European forests have increased, with wind being the most  
357 important factor (46% of total damage), followed by fire (24%) and bark beetles (17%), although the latter's contribution to  
358 total damage has doubled in the last 20 years (Patacca et al., 2023).

359 One of the primary impacts of heat and drought on forests is increased tree mortality (Allen et al., 2010, Anderegg et al., 2013,  
360 George et al., 2022). Trees can be highly sensitive to drought stress, and prolonged periods of high temperatures and low  
361 precipitation can cause trees to experience water deficits, leading to physiological stress and ultimately death. In general, trees  
362 under drought and heat stress may experience carbon starvation and face greater risks of embolism, which can cause a failure  
363 in water transport (Allen et al., 2015, Schuldt et al., 2016). Such physiological stress can lead to mortality but also to milder  
364 consequences such as crown defoliation, early leaf shedding or death of branches that reduces the vitality and growth of the  
365 trees (Schuldt et al., 2016). Soil drying may lead to water repellency (soil hydrophobicity), which slows down the infiltration  
366 of rainwater following the end of the drought and produces a heterogeneous soil wetting front (Grünzweig et al., 2022). Soil  
367 hydrophobicity has been observed in various temperate forests and diverse soil types in Europe, which may increase drought  
368 stress and tree die-off (Gazol et al., 2018, Gimbel et al., 2016, Hewelke et al., 2018, Seaton et al., 2019). The reduced water  
369 availability can also strongly affect the carbon cycle by limiting photosynthesis and nutrient uptake and lead to decreased  
370 growth rates and reduced carbon storage in forests. Heat and drought can also disrupt forest ecosystem dynamics and alter  
371 community composition (Hicks et al., 2018), as tree species differ in their vulnerability to drought stress, leading to shifts in  
372 species abundance and distribution (Morin et al., 2018). These changes can also have cascading effects on other organisms  
373 that depend on forest ecosystems, such as mammals, birds, reptiles, amphibians or invertebrates such as insects and  
374 microorganisms (Liebhold et al., 2017).

375 At the same time, other processes like outbreaks of forest pests can co-occur and follow droughts. In the resistance of  
376 coniferous trees against bark beetles, the release of resin plays a pivotal role (Morcillo et al., 2019). Yet, resin is highly costly  
377 in available resources to produce and strongly linked to tree vigour as well as water availability (Zas et al., 2020). However,  
378 not only drought-induced host-weakening determines beetle outbreaks. Dry and warm conditions generally also increase the  
379 vitality and reproduction of poikilotherm insects with consequent shorter generation times, higher fecundity and survival rates  
380 (Jactel et al., 2019, Pettit et al., 2020). It should be noted that heat waves can also negatively affect some insect pest species or  
381 pathogens because of their response to the heat stress (Sire et al., 2022).

382 Heat and dry conditions can create favourable conditions for wildfires to start and spread (Kirchmeier-Young et al., 2019), and  
383 drought-stressed trees are more susceptible to ignition and can burn more readily. Although wildfires have decreased on a  
384 global scale, and across Europe over the last decade 2010-2020, there have been years with the highest level of fire damage  
385 ever recorded in Europe in the past decade (Grünig et al., 2023; Patacca et al., 2023). Several regions (inter alia Central Europe)  
386 are likely to face larger and more frequent wildfires in the future (Feurdean et al., 2020, Milanovic et al., 2020). A study

387 investigating storm and fire disturbances in Europe from 1986 to 2016 identifies storms and fires as the most important abiotic  
388 disturbances in the recent past, with wind (i.e. storms) mainly dominating in Central and Western Europe and fire in the  
389 southern part of the continent (Senf and Seidl 2021b). While in 2018 fire was likely only responsible for about 3 % of area  
390 disturbed in Northern and Central Europe (Senf and Seidl, 2021a), there is strong evidence that wildfires will increase in a  
391 warmer and drier environment (Seidl et al., 2017). This increase can facilitate deforestation, loss of habitat, soil erosion, and  
392 long-term changes in forest structure and composition that can have severe environmental, economic and social consequences  
393 (Leverkus et al., 2019). Wildfires commonly lead to hydrophobic soils (Davies et al., 2013, Mao et al., 2019), thus reducing  
394 water infiltration and causing further damages to trees (Grünzweig et al., 2022).

395 The forest damage caused by drought lead to significant socioeconomic consequences in European forest ecosystems (Lindner  
396 et al., 2010) as forest owners, logging companies, and other stakeholders in the forestry sector experience significant losses  
397 due to a reduction in volume and quality of timber (e.g. Brecka et al., 2018, Davies et al., 2020, Knoke et al., 2021). Further  
398 impacts to local economies and communities can occur, since the forestry sector is an important employer in many rural areas  
399 of Europe, employing about 3.6 million people (EU-27, Eurostat 2023). Furthermore, the value of forest areas is likely to  
400 decrease, if economically valuable tree species decline (Hanewinkel et al., 2012), and the cultural and recreational qualities of  
401 forests can suffer (Winkel et al., 2022). Finally, drought can have consequences particularly for biodiversity, since forests  
402 provide habitat for a wide range of plant and animal species, and drought can disrupt these ecosystems (Krumm et al., 2020,  
403 Vicente-Serrano et al., 2020).

404 The projected increase in frequency and intensity of heat and drought events (Spinoni et al., 2018) will likely increase forest  
405 damage. The drought of 2018 alone was probably the largest source of severe forest disturbances in Europe in over 170 years  
406 (Senf and Seidl, 2021a). Forest disturbances during 2018 have increased 5-fold in large parts of Europe when compared with  
407 the average levels over the past three decades, and disturbances remained above average also in 2019 and 2020 (Senf et al.,  
408 2021). However, there are opportunities to better understand the damage, offering opportunities to mitigate future harm.

### 409 **3.1. Europe-wide damages to forests 2018-2022**

410 To comprehensively assess the diverse effects of drought and higher temperatures on forests, we gathered Europe-wide data  
411 where applicable (Table 2). This multifaceted approach allowed for a comprehensive view of the multifarious impacts of  
412 drought and temperature elevation on forest ecosystems. Our objective was to elucidate the impacts by comparing the  
413 consequences of the drought period spanning 2018-2022 with a reference period from 2010-2014. Physiological stress  
414 indicators, specifically crown defoliation data segregated into conifers and broadleaves, were sourced from ICP Technical  
415 reports (<http://icp-forests.net/page/icp-forests-technical-report>). Information regarding insect pests was obtained by analysing  
416 the extent of wood damage caused by insects, drawing from various reliable sources. Forest fire data were derived from the  
417 JRC Technical reports (<https://forest-fire.emergency.copernicus.eu/reports-and-publications/annual-fire-reports>). To broaden  
418 our understanding, we incorporated tree cover loss data from Global Forest Watch (<https://www.globalforestwatch.org/>).

419 Significant differences between the study period (2018-2022) and the reference period (2010-2014) were discerned utilising a  
 420 t-test conducted with RStudio 2022.12.0.

421

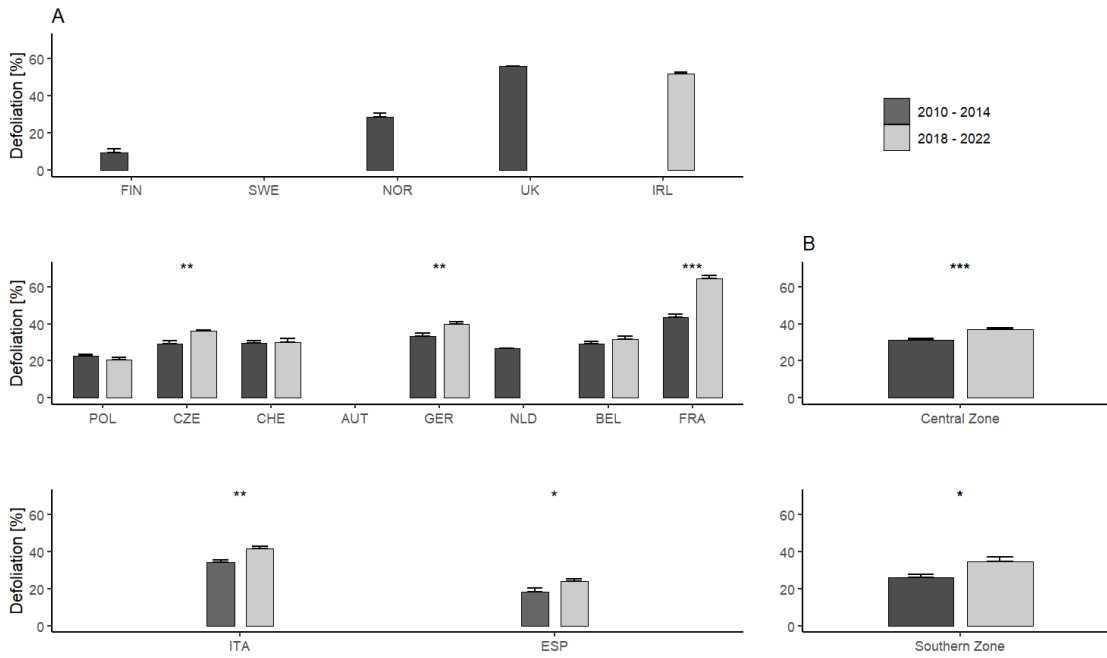

422 **Table 2:** Differences between the study period 2018-2022 (18-22) to reference period 2010-2014 (10-14), where available.  
 423 Denoted next to the higher average value ( $\bar{x}$ ) in each cell are the results of the statistical tests: n.a. (not applicable), n.s. (not  
 424 significant), \* significant ( $p < 0.05$ ), \*\* highly significant ( $p < 0.01$ ), \*\*\* very highly significant ( $p < 0.001$ ).

Zone	Crown defoliation [%]		Damaged wood by insects [1000m <sup>3</sup> ]	Burnt forest area [ha]	Tree cover loss [%]

425

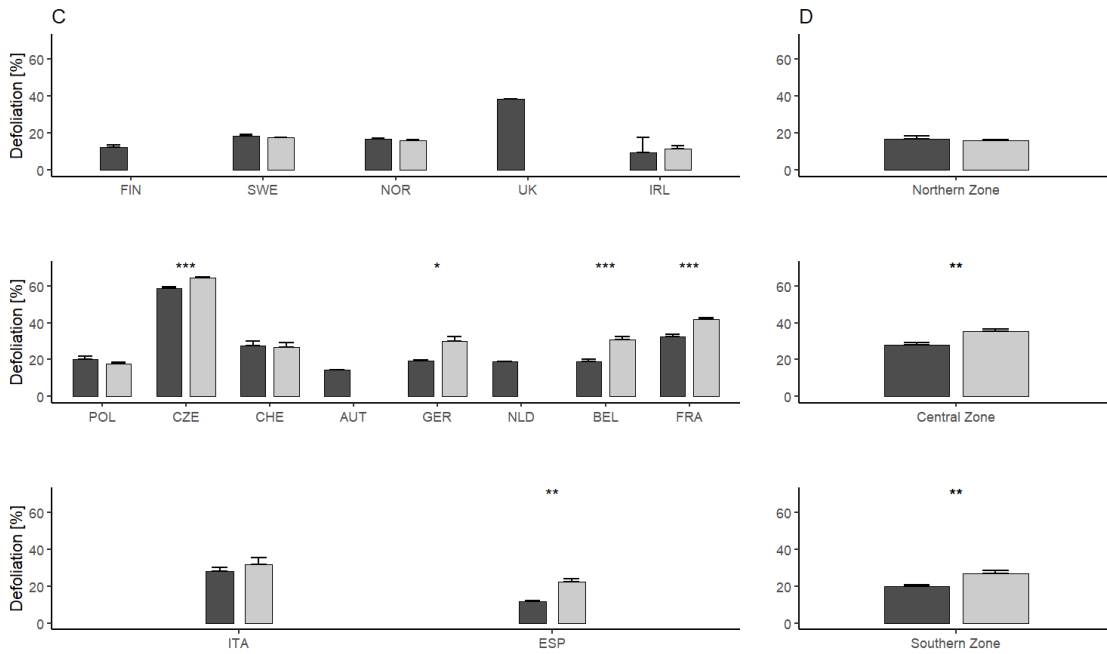

426 A pairwise t-test comparing the averages presented in Table 2 examined whether the observed changes (difference in means)  
 427 between the two periods (2010-2014 and 2018-2022) are statistically significant. The test results indicate that the difference  
 428 between the two periods was not statistically significant ( $p = 0.06$ ) for defoliation of both conifers and broadleaves, with a  
 429 mean difference of 9.4%. The t-test results for forest fire occurrence clearly showed no significant difference ( $p = 0.34$ , mean  
 430 difference: 3400.9 ha). However, for tree cover loss, the mean difference of 0.34% was highly significant ( $p = 0.004$ ). A similar  
 431 statistical test for damaged wood by insects was not feasible due to insufficient data availability.

### Broadleaves

432

### Conifers

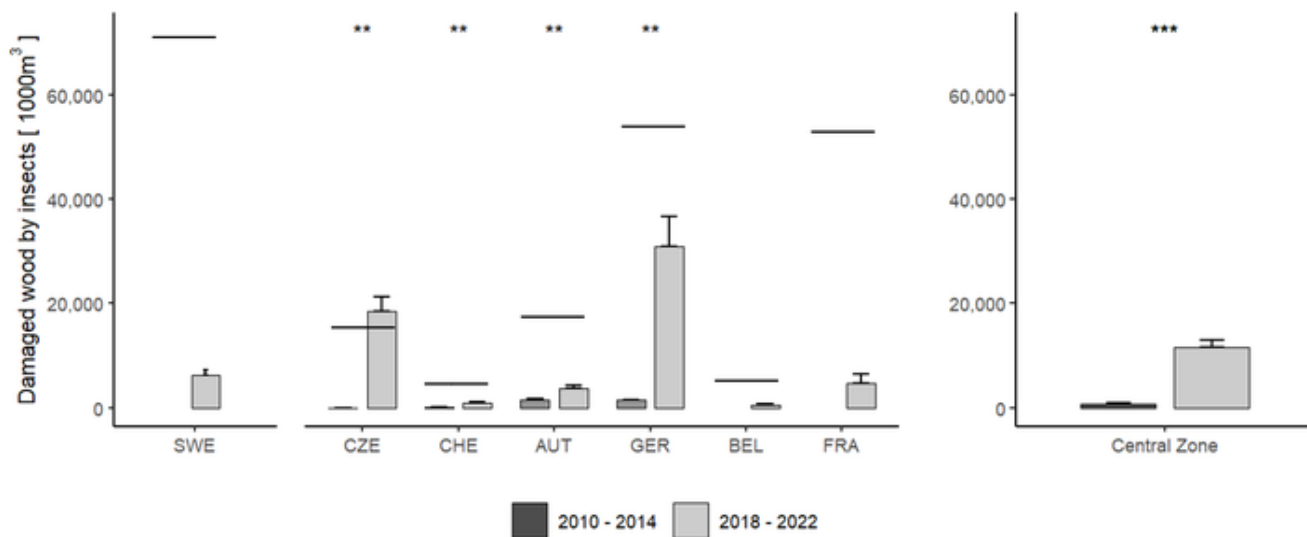

433

434 **Figure 2.** Relative crown defoliation of broadleaves (A, B) and conifers (C, D) during the dry period 2018-2022 and the  
 435 reference period 2010-2014 (> 25% needle/leaf loss, i.e. moderate to severe defoliation); data from ICP-forests (2022). For  
 436 Broadleaves in the Northern zone data was not sufficiently available.

437  
 438 In the examination of conifer defoliation patterns across European regions, no significant differences in defoliation were  
 439 discernible in the Northern zone or within individual countries situated in it (Figure 2). However, within the Central zone, a  
 440 substantial and statistically significant discrepancy in defoliation levels was evident between the periods of 2018-2022 and  
 441 2010-2014, with the former exhibiting markedly higher rates. This disparity was particularly pronounced in the Czech  
 442 Republic, Belgium, and France, where the differences were highly significant. Additionally, significant differences in  
 443 defoliation were noted in Germany. The Southern zone displayed notable deviations during the dry period 2018-2022  
 444 compared to the reference period, with Spain also registering significant differences.  
 445 Notably, data for the Northern zone were not applicable for broadleaves. In the Central zone, a significantly higher defoliation  
 446 level was evident in the dry period (2018-2022) than in the reference period (2010-2014). This discrepancy was particularly  
 447 pronounced in France. Similar significant differences in defoliation were observed also in the Czech Republic and Germany.  
 448 In the Southern zone, similar significant differences were detected between the two investigated periods in Italy and Spain.  
 449

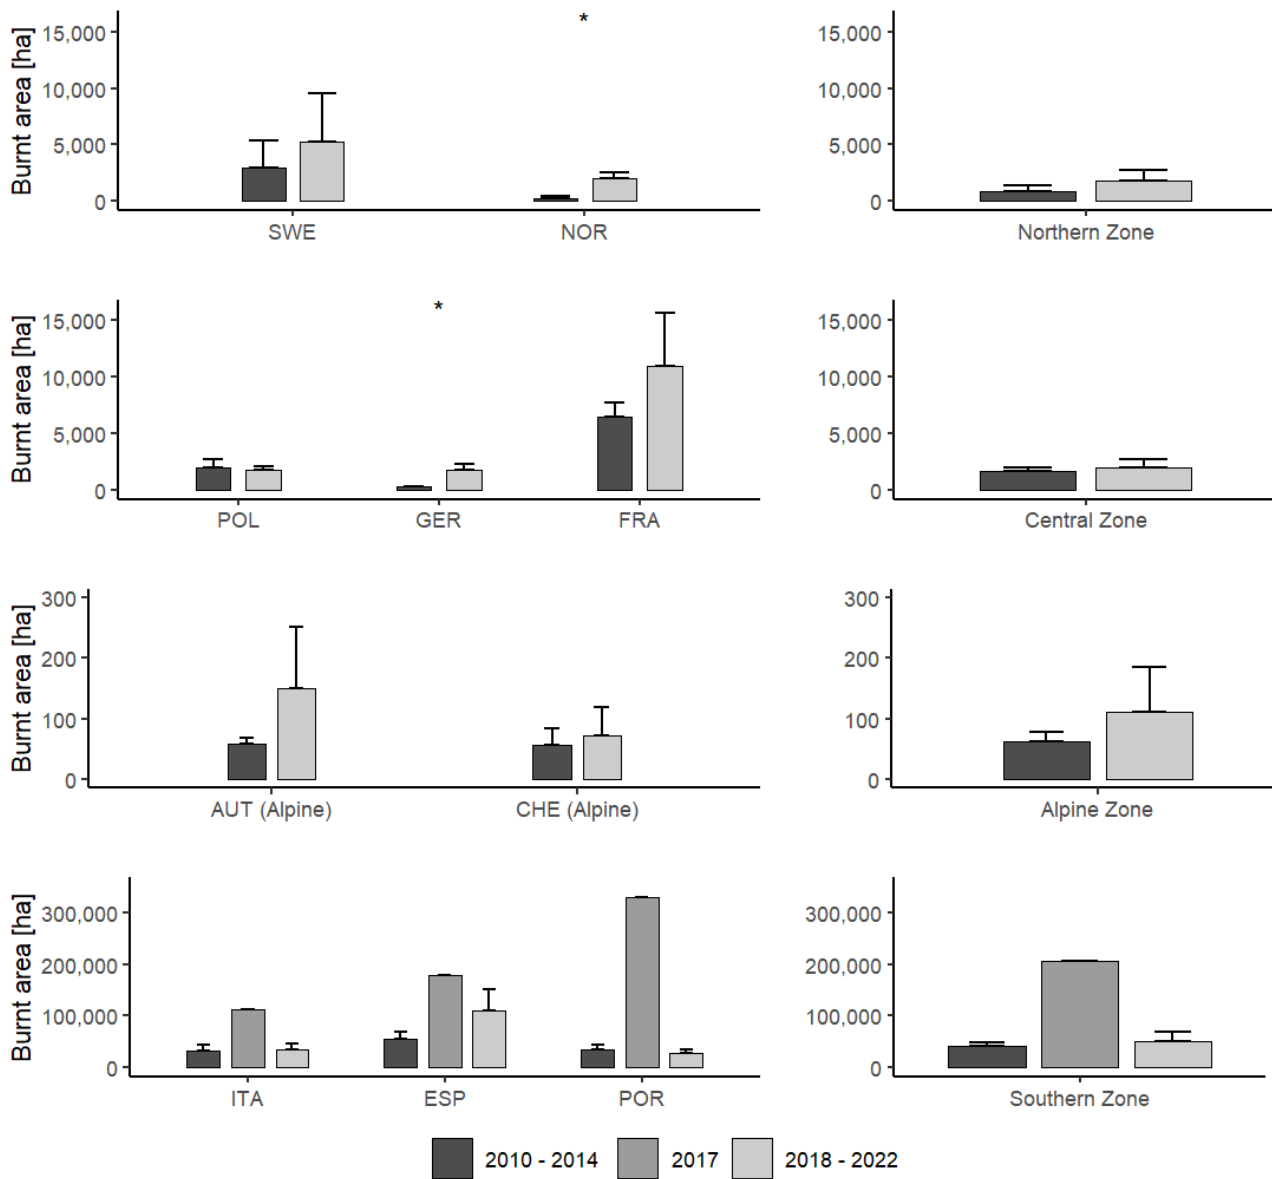

450  
 451 **Figure 3.** Damaged roundwood (1000 m³) by insect pests in Europe in the period 2018-2022, partly in comparison with the  
 452 reference period 2010-2014. The black lines show the Total roundwood production average per year 2010-2014. Wood data  
 453 derived from different sources (EUROSTAT 2016, Wulff and Roberge 2020, Öhrn et al., 2021, EUWID 2022, ICP 2022,

454 DESTATIS 2020, DESTATIS 2023, Waldschutz 2023, WSL 2023, BFW 2020, 2023, Czech Statistical Office). For the other  
455 countries data was not available.

456

457 Damaged wood caused by insect infestation was significantly higher across Central Europe in the study period of 2018-2022  
458 than the reference period (2010-2014), being particularly evident in countries such as the Czech Republic, Switzerland, Austria,  
459 and Germany (Figure 3). Notable is the situation in the Czech Republic, where instances of insect-induced wood damage even  
460 surpassed the mean annual roundwood production (2010-2014). Sweden also experienced a degree of roundwood damage  
461 attributable to insects during the assessed drought period. While data on damaged roundwood by insects was accessible for  
462 select countries, it was not uniformly available across all regions. Notably, acquiring such data was comparatively easier during  
463 the more recent period, indicative of heightened pressures exerted by insect pests within forest ecosystems and a greater interest  
464 in monitoring forest damage.

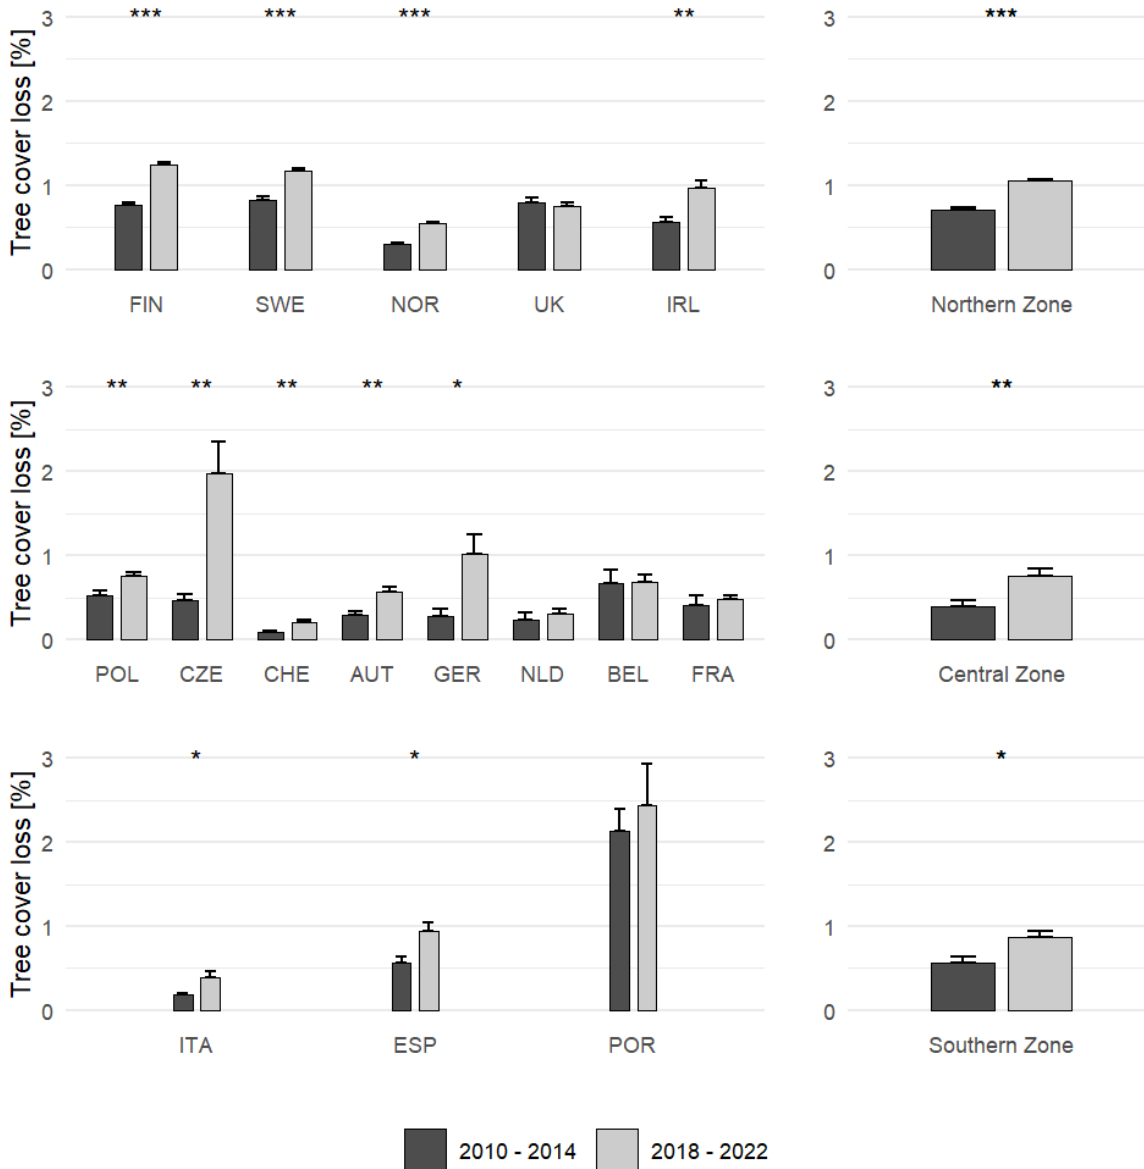

465

466

467 **Figure 4.** Burnt forested area (mean for the two periods under consideration) in selected European countries. Italy and Portugal  
 468 had large fires in 2017 (accordingly, value for 2017 is given for the Southern zone). All data from JRC Technical Reports of  
 469 the years Forest Fires in Europe, Middle East and North Africa of the years 2010 to 2022 (<https://forest-fire.emergency.copernicus.eu/reports-and-publications/annual-fire-reports>). The data utilised here stems from the JRC national  
 470 reports of the years 2010 until 2022, where areas are designated as forested regions. Absolute values were employed instead  
 471 of relative values due to inconsistent forest area data across all countries within the dataset. Please note the different scales.  
 472

473 In our analysis of forest fire occurrences, we did not find significant differences between the dry period of 2018-2022 and the  
 474 reference period of 2010-2014, except for Norway and Germany (Figure 4). This lack of significance was consistent across  
 475 the Northern, Central, Alpine, and Southern zones. Generally, countries in the Southern zone experienced severe impacts from  
 476 forest fires. For example, the damage in Sweden and France, who had the highest values of burned area in their climatic zone  
 477 (5,000 and 10,000 hectares, respectively), during the period of 2018-2022 was only a fraction of that observed in Portugal  
 478 during 2017.

479  
 480  
 481

**Figure 5.** Relative tree cover loss (mean for the two periods under consideration); data from GlobalForestWatch.

482 The loss of tree cover can stem from various human and natural factors, such as forestry activities (e.g., logging or  
483 deforestation), natural occurrences (e.g., diseases or storms), and fire incidents (Figure 5). Notably, very highly significant  
484 disparities between the dry period (2018-2022) and the reference period (2010-2014) were observed in the Northern zone.  
485 Specifically, Finland, Sweden, and Norway exhibited very highly significant differences, while Ireland showed highly  
486 significant variations. Within the Central Zone, significant differences were detected between the two study periods, with  
487 Poland, the Czech Republic, Switzerland, and Austria all displaying such disparities. Additionally, significant differences were  
488 noted for Germany. Turning to the Southern zone, significant differences were evident, with Italy and Spain also showing  
489 significant differences.

### 490 **3.2 Damages to forests in the Northern zone 2018-2022**

491 The total forested area of **Finland** is 26 million ha (EFFIS: 24.1 million ha), of which 20 million ha is suitable for forest  
492 production. Forest damage in Finland directly coming from the drought were highest in 2018 (21,700 ha) and have been  
493 decreasing since then, followed by an increase in 2022 (damage levels over 2019: 15,800 Ha, 2020: 14,000 ha, 2021: 12,000  
494 ha and 2022: 19,100 ha; Nuorteva, 2019; Nuorteva et al., 2022a, 2022b; Melin et al., 2022, Terhonen et al., 2023). These  
495 numbers are high for Finland, because the accumulated forest drought damage previously for years 2009-2015 were 8,700 ha  
496 (Nevalainen and Pouttu, 2017).

497 The areas influenced by drought and bark beetles were localised and, on an annual scale, quite small when compared to, for  
498 example, snow and moose-based damage (Nuorteva, 2019; Nuorteva et al., 2022a, 2022b; Melin et al., 2022, Terhonen et al.,  
499 2023). In Finland, the bark beetle population slightly grew between 2018-2020 and the damages increased from 12,600 ha to  
500 21,400 ha, but slightly declined in 2021 to 20,800 ha and in 2022 to 18,000 ha. In 2021, the bark beetle damages were slightly  
501 lower than in 2020, but in 2022 the Finnish Forest Centre received reports of more damages than usual from more northern  
502 areas (South Karelia and North Savo). The reported salvage logging due to insect outbreaks was 3,400 ha by November 2022,  
503 which is three times more than in 2021 (Metsäkeskus, 2022). Overall, beetle damage in Finland has been increasing during the  
504 last decade, and in the future, the risk of more intense damages is rising (Neuvonen, 2020). It should be mentioned that the  
505 storm damages to forest in Finland have also increased from 2018 to 2022: from 249,000 ha to 276,300 ha (being highest in  
506 2021: 307,100 ha) and forest damage could be influenced by the overall well-being of the trees. Additionally, the efficiency  
507 of collecting the fallen trees influences the bark beetle spread and outbreaks since they provide prime habitat for the beetle  
508 population to grow (Hroššo et al., 2020).

509 The number of forest fires in Finland in 2018 was the second highest recorded, but approximately only 1,200 ha of forest was  
510 damaged (Lehtonen and Venäläinen, 2020). In 2019 the area in Finland damaged by forest fires was roughly 500 ha, in  
511 2020/2021 slightly over 1,000 ha burned and in 2022 only a bit over 265 ha of forest was burned (Aalto and Venäläinen, 2021;  
512 Melin et al., 2022, Terhonen et al., 2023). Kosenius et al., (2014) estimated the financial losses of forest fires in Northern  
513 Karelia and the Republic of Karelia for the years 2009 to 2012. They considered the direct and indirect costs when preparing  
514 estimates for the total costs. Venäläinen et al., (2016) used the estimates made by Kosenius et al., (2014) to derive a median

515 estimate for forest fire costs in Finland: 6660 €/ha (estimate ranged from 5381 €/ha in 2009 to 8810 €/ha in 2012). Using the  
516 Swedish forest fire costs estimates of Venäläinen et al., (2016) for Finland, between 2018-2021 these caused roughly 25 million  
517 € of total damages.

518

519 In **Sweden**, about 90 million m<sup>3</sup> are felled every year (UNECE 2022) and the total forested area is 30 million ha (EFFIS 2023).  
520 Physiological damage expressed as crown defoliation was between 17.1 and 17.8% in conifers in the years 2018-2021 (data  
521 for the year 2022 and for broadleaved trees was not applicable; Michel et al., 2022). In Sweden during 2018, bark beetles  
522 damaged 3–4 million m<sup>3</sup> spruce, 7 million m<sup>3</sup> in 2019, and 8 million m<sup>3</sup> in 2020 and 2021, thus over 20 folds more than in the  
523 average of the previous years (Wulff and Roberge 2020, Öhrn et al., 2021, UNECE, 2022). This increase in mortality and  
524 damage was initiated by the heat and drought of 2018, enabling a rapid beetle population growth (Öhrn et al., 2021). In Sweden,  
525 the dry and warm period of summer 2018 led to a severe outbreak of forest fires, with estimates reaching roughly 25,000 ha  
526 (the total forested area in Sweden is 28 million ha) and 3 million m<sup>3</sup> of wood damaged (Forestry 2018). Using the estimate of  
527 Venäläinen et al., (2016) the costs for the year 2018 are over 166 million € in Sweden. This is a similar estimate as if the 2014  
528 forest fires in Sweden (14,000 ha, costs 1 billion Swedish Krona) would be upscaled to 2018: 160-200 million €.

529

530 In **Norway**, the total forested area is over 12 million ha from which 8.6 million ha is suitable for forest production (SSB, 2022).  
531 On the national level, drought did not yield severe consequences for Norwegian forestry. In 2017, there was a total of 965  
532 million m<sup>3</sup> of standing forest, and in 2020 this increased to 987 million m<sup>3</sup> (SSB, 2022). Physiological damage expressed as  
533 moderate to severe crown defoliation was between 14.9 and 17.2% in conifers in the years 2018-2021 (data for the year 2022  
534 and for broadleaved trees was not applicable; Michel et al., 2022).

535 Norway's annual roundwood production is about 11 million m<sup>3</sup> (ICP 2022). Numbers from NIBIO's forest portal *Kilden*  
536 (NIBIO, 2023) show an increase in bark beetles in the region, from 8,540 per trap in 2017, to 20,600 in 2021, and while  
537 concerning, these levels remain below outbreak levels.

538 The forest area influenced by fires in Norway was over 2,000 ha in 2018 and reduced to less than 1,000 ha in 2019 and 2020  
539 (NIBIO, 2023). During 2018, between January and August occurred 1906 forest fires, a new record. Wells and drinking water  
540 resources were almost emptied, low water levels in rivers led to fish dying and electricity production was down 20% compared  
541 to normal production levels (-23 TWh) at times, which led to higher electricity costs (MET Norway, 2019). Favourable wind  
542 conditions meant that the total affected area was relatively small (2000 ha affected by forest fires), so the consequences were  
543 more related to costs and social uncertainty. The Norwegian Directorate for Civil Protection - DSB (2019) estimates that about  
544 8.4 billion € (100 million NOK) were spent on fighting the forest fires, while indirect costs are unknown, but expected to be  
545 high (loss of infrastructure, houses and cabins). Reports from the county governor of Vestfold and Telemark (Statsforvalteren,  
546 2020; 2021) show some of the consequences for the forests in the region. Vestfold and Telemark County has 6.5 million ha of  
547 productive forest, and annual growth of 2.75 million m<sup>3</sup> in timber volume. Damage from forest fires led to an increase in tree  
548 felling in both 2018, with felling of 1.1 million m<sup>3</sup>, 2019, with 1.23 million m<sup>3</sup> and 2020, with 1.1 million m<sup>3</sup> despite low prices

549 on timber especially in 2020. In comparison, the average felling in the 2010-2014 reference period was 896.000m<sup>3</sup>/annum. To  
550 mitigate the consequences of the 2018 fires, 296,599 saplings were planted in 2019 and a further 250,000 in 2020, compared  
551 to an average planting of 131.000 in the reference period. While there were some short-term consequences, there have not  
552 been lasting negative effects of the drought in Norway so far.

553

554 In the **United Kingdom (UK)**, the area of woodland is estimated to be 3.24 million ha, with 1.65 million ha (51%) conifers  
555 and 1.59 million ha (49%) broadleaves (Forest Research 2022a). In 2018, early leaf senescence due to drought was observed  
556 across much of the Southern UK (Michel et al., 2019). In 2019, trees were not strongly affected by drought, since it was both  
557 warmer and wetter than average (Michel et al., 2020). Merely 3% of UK native woodlands are in unfavourable condition due  
558 to pests and diseases, but problems with oak health have been identified in the South and West of the UK (Quine et al., 2019,  
559 Michel et al., 2020). In 2020, a year of weather extremes (wet and hot), ash dieback (*Hymenoscyphus fraxineus*) continues to  
560 spread across the UK. Accordingly, it is expected that the majority of ash trees will subsequently die from or be significantly  
561 affected by the disease in the coming years (Michel et al., 2021). The fungus-like pathogen *Phytophthora pluvialis* was  
562 discovered in climatically average year 2021, where it was found to be affecting mature western hemlock and Douglas-fir trees  
563 (Michel et al., 2022; Forest Research 2023c). In the very hot and dry year 2022, the trees lost their leaves in August over a  
564 large area due to the drought (e.g. Cheshire 2021). A comparison between 2015 and 2020 surveys reveal that 79% of woodland  
565 owners in UK observed an increase in pathogen in the last five years (Hemery et al., 2020). To counteract the damages  
566 associated with drought about 14,000 ha of new woodland were generated in the UK in 2020-2021, and there was a 4% increase  
567 in new planting and a 9% increase in restocking in the UK in 2021-2022 (Forest Research 2022b). In UK, there were large  
568 wildfires in the years 2018 (17,689 ha burned area), 2019 (28,754 ha), 2020 (13,793 ha) and 2022 (20,362 ha), while over  
569 2021 there were only 6,236 ha burned (EFFIS Annual Statistics for UK, 2023). The mean burnt area from 2011 to 2022 was  
570 10,000 ha.

571 The area of woodland in **England** is estimated to be 1,323 million ha, with 343,000 (26%) ha Conifers and 980,000 ha (74%)  
572 broadleaves (Forest Research 2022a). In England, just over 79,000 ha land burnt throughout the twelve-year period 2009-10  
573 to 2020-21 (2017-18: 2,352ha, 2018-19: 26,047, and 2019-20: 3,686ha, 2020-21: 6,251, 2022 was not applicable, data from  
574 Forestry Commission 2023). In 2018, England witnessed the worst wildfires in recent history (Turner et al., 2021). In the two  
575 major fires in the Greater Manchester region, an area of 3,600 ha burned, which could only be extinguished after more than a  
576 month: In Saddleworth Moor, seven square miles (i.e. 1,800 ha) of moorland burned (telegraph 2018), in Winter Hill also  
577 1,800 ha (BBC 2018). Surprisingly, the overwhelming majority of wildfires have been in broadleaved woodland (10.4%) and  
578 not conifer woodland (1.8%). The rest of the wildfires took place across all other land covers including built-up areas, gardens,  
579 and grassland. According to the BBC (2022), fire services in England dealt with almost 25,000 wildfires during the summer  
580 2022, with more than 800 recorded wildfires on one single day (19.7.2022).

581 The area of woodland in **Wales** is estimated to be 310,000 ha, with 152,000 ha (49%) Conifers and 152,000 ha (51%)  
582 broadleaves (Forest Research 2022a). South Wales suffers from about 3,000 blazes a year and there is a strong possibility that  
583 this will continue to increase (e.g. BBC 2021a, BBC 2021b). Fires in spring 2020 in the sections of the Afan Valley and Seven  
584 Sisters forests have caused damage of more than €115,000 (£100,000), destroyed almost 140 ha of Natural Resources Wales  
585 (NRW) managed forestry including 80,000 newly planted trees (NRW 2020).

586 In **Scotland**, Forests and woodlands cover about 1,486 million ha, with 1.092 million ha (74%) Conifers and 395,000 ha (26%)  
587 broadleaves (Scottish Government 2019, Forest Research 2022a). Sitka spruce (*Picea sitchensis*) dominated major plantations  
588 along the east coast as well as Scottish rainforests along the west coast are particularly at risk, since both are vulnerable to  
589 aridity (Kirkpatrick et al., 2021). At a clear-cut area in Harwood Forest, Northumberland, the 2018 drought prevented the  
590 development of a Sitka spruce orchard that would have formed from a clear-cut area in the second year after replanting  
591 (Xenakis et al. 2020). In Scotland, wildfires are generally more likely to spread through grassland or peatland, however  
592 Scotland's forests - which are among the most productive in Europe - provide an abundance of flammable biomass (Forestry  
593 and Land Scotland 2023). Several wildfires were reported in April 2018 in the north of Scotland (Copernicus 2023). Wildfire  
594 severely affected 11,700 ha in 2019 (The Herald 2021). Statistics from the Scottish Fire and Rescue Service (SFRS) show that  
595 during March and April 2022, 95 wildfire incidents (involving an area of more than 1,000 m<sup>2</sup>) were recorded across Scotland  
596 (Highland Council 2023). Several Scottish key industries are dependent on water supplies, which can be disrupted by droughts:  
597 e.g. whisky production (valued with £5.5 billion) and forestry (valued with £1 billion) GVA per year respectively (Kirkpatrick  
598 et al. 2021).

599 In **Northern Ireland**, the area of woodland is estimated to be 118,000 ha, with 64,000 ha (54%) Conifers and 54,000 ha (46%)  
600 broadleaves (Forest Research 2022a). In spring 2022, wildfires caused damage to an estimated 720 ha of land (DAERA, 2022).

601 **Ireland** has a forest area of 551,110 (EFFIS 2023) or 770,020 ha (Forest Statistics Ireland 2020) with three quarters conifers  
602 (51% Sitka spruce alone) and one quarter broadleaves. Physiological damage expressed as moderate to severe crown  
603 defoliation was only applicable for 2020 and 2021, where it was very low for conifers (9.8 and 13.0%), but surprisingly high  
604 for broadleaves (53.4 and 52.0%; Michel et al., 2022). Furthermore, national reports about forest conditions state for Ireland  
605 that forest health remains good in 2019 and 2020 (Michel et al., 2020, 2021). Regarding tree pests, Ireland is generally known  
606 to have a good plant health status due to its island status and high plant protection regulations (O'Hanlon et al., 2021), which  
607 provides protection from pest such as the eight-toothed spruce bark beetle (*Ips typographus*), which is absent from Ireland  
608 (Forest Health 2021). Around 3,000 ha of forest burned in each of the years 2018-2022 (see Table Fire). Compared to the  
609 record years 2011 (16724 ha) or 2017 (7219 ha), this is a moderate level of damage (EFFIS Annual Statistics for Ireland,  
610 2023).

611

### 612 3.3 Damages to forests in the Central zone 2018-2022

613 **Poland** has a forest area of 9,242,000 ha (Central Statistical Office, 2017). In 2018, the drought significantly weakened the  
614 condition of the forests in an area of 43.500 ha. The same year forest damage was observed in 29,400 ha (Jabłoński et al.,  
615 2019a; Jabłoński et al., 2019b). In 2019, the order of species from healthiest to most damaged was determined based on an  
616 analysis of three parameters: average defoliation, the proportion of healthy trees (up to 10% defoliation), and the proportion  
617 of damaged trees (above 25% defoliation), is as follows: *Fagus sylvatica*, *Alnus spec.* < *Abies* < other deciduous, other  
618 coniferous < *Pinus sylvestris* < *Betula spec.* < *Picea abies* < *Quercus spec.* (Wawrzoniak, 2019). In 2020, symptoms of  
619 weakened or damaged forest stands caused by disruption of water relations, mainly by drought, were reported in 253 of 430  
620 (i.e. 59%) of all forest districts (Lech, 2021).

621 Pests, which until a few years ago were considered of little concern in Polish forests, today cause the death of many hectares  
622 (Perlińska, 2019). As a result of the drought in the years 2015-2019, secondary factors leading to the death of pine stands  
623 (which represent 58,2 % of the Polish forests), have become more active (Perlińska, 2019). The key role played the following  
624 pests: The bark beetle (*Ips acuminatus*), mistletoe (*Viscum spec.*), Sphaeropsis blight (*Sphaeropsis sapinea*), *Phaenops cyanea*,  
625 Heterobasidion root disease, and *Armillaria spec.* (Sierota & Grodzki, 2020). Observations in Poland indicate a significant  
626 correlation between drought and engraver beetle (*Ips acuminatus*) outbreaks (Jabłoński et al., 2019a; Jabłoński et al., 2019b;  
627 Plewa & Mokrzycki, 2022), a species that until not long ago was not considered a significant forest pest (Głowacka, 2013).  
628 Underestimated was also the occurrence of mistletoe (*Viscum spec.*). After prolonged drought periods, the area of the  
629 coniferous (mostly pine) forests heavily infested by mistletoe has drastically increased from 1,400 ha in 2017 to almost 23,000  
630 ha in 2018 (Jabłoński et al., 2019a). The mistletoe was found on 14 species of forest trees: most severely infested by mistletoe  
631 were fir and pine trees and to a lesser extent birch, and a mixture of deciduous species and spruce (Lech et al., 2019). Also,  
632 well-known forest pests such as European spruce bark beetle (*Ips typographus*) continue to pose a huge threat to the Polish  
633 Forests. The dieback of Norway spruce stands increased already through the 1970s and 1980s in Central and Eastern Europe  
634 (Sierota et al., 2019). After the drought of 2015 the Norway spruce decline continues with new bark beetle outbreaks, affecting  
635 stands in the Western Carpathian and Sudetes mountains. The ongoing climatic conditions, combined with high bark beetle  
636 populations, make the risk of a further outbreak extremely high (Grodzki, 2010).

637 Surface losses occurred in recent years on State Forest land in Poland (source: DGLP, Dyrekcja Generalna Lasów  
638 Państwowych) in terms of drought (2018: 40,852 ha, 2019: 60,356 ha, 2020: 58,056 ha, 2021: 34,673 ha, and 2022: 20,258  
639 ha). Surface losses in terms of high temperatures were relatively small (burns, wilt and dieback) were (2018: 80 ha, 2019: 340  
640 ha, 2020: 2574 ha, 2021: 197 ha, and 2022: 244 ha). Recent years have seen significant surface losses on Poland's State Forest  
641 land due to drought and high temperatures (Source: DGLP, Dyrekcja Generalna Lasów Państwowych): Drought-related losses  
642 were specified with 40,852 ha (2018), 60,356 ha (2019), 58,056 ha (2020), 34,673 ha (2021), and 20,258 ha (2022). High  
643 temperature losses (burns, wilt, dieback) were reported with 80 ha (2018), 340 ha (2019), 2,574 ha (2020), 197 ha (2021), and  
644 244 ha (2022). Long-lasting drought in Poland has also led to a lowering of the surface and groundwater table, and a decrease

645 in the growth of trees, the vitality of stands, and their resistance to pathogens and pests (Kwiatkowski et al., 2020). Among the  
646 species affected by this process are oak trees, where the impact of declining groundwater has been observed since the late  
647 1980s (Przybył, 1989). Current groundwater fluctuations are further weakening the oak trees and accelerating their decline  
648 (Jakoniuk, 2022), e.g. on the Krotoszyn Plateau (Danielewicz, 2016).

649 Furthermore, the prolonged drought increases the fire hazard in forests. Although the number of fires is high, the situation in  
650 Poland is relatively good. As the average forest fire in the state forests is only 0.25 ha, indicating a high efficiency of fire  
651 protection systems. According to official statistics, almost 25,000 fires with a total area of 6,049 hectares occurred in areas  
652 managed by the State Forests between 2011 and 2020, causing a loss of approximately PLN 39 million. However, the year  
653 2020 was marked by an extremely large fire (6,000 hectares) in the Biebrza National Park in Northeastern Poland (see Figure  
654 3).

655

656 In the **Czech Republic**, forest disturbances, mainly by pests, were triggered by drought and higher temperatures: Near Kostelec  
657 nad Černými Lesy, studies found that bark beetle outbreaks were related to the duration of April's solar radiation in the previous  
658 year and the current year's average annual air temperature (Pirtskhalava-Karpova et al., 2024). In the Bohemian forest, it was  
659 observed that the surface temperature in stands subsequently attacked was higher in the year preceding pest colonisation when  
660 compared to intact stands (Kozhoridze et al., 2023). At the beginning of the massive bark beetle attacks, spruce accounted for  
661 50.5% of stands, and pine for 16.4% respectively (Zahradník & Zahradníková 2019). This abundance of trees sensitive for the  
662 bark beetle led to the suggestion that the Czech Republic may have been the epicentre of bark beetle outbreaks in Europe  
663 (Hlásny et al., 2021), since more than 50% of Czech forests were seriously threatened by this pest, leading to high ecological  
664 and economic losses (Fernandez-Carrillo et al., 2020). Common harvested volume per year is about 15 million m<sup>3</sup> and around  
665 1 million m<sup>3</sup> of wood infected by insects (WII). In 2018, 25.6 million m<sup>3</sup> were harvested, 13 million m<sup>3</sup> WII; in 2019—32.5  
666 million m<sup>3</sup> were harvested with 22.8 million m<sup>3</sup> of WII, and for the year 2020, the estimate is ranking between 40 and 60  
667 million m<sup>3</sup> of WII (Fernandez-Carrillo et al., 2020). The timber damage was almost exclusively caused by infestations with  
668 European spruce bark beetle (*Ips typographus* L.). The largest forest fire in Czech history broke out in Bohemian Switzerland  
669 in the Northern Czech Republic and spilled over into Germany. The fire affected an area of about 1,060 ha, over 1,000  
670 firefighters, 5 helicopters and two firefighting aircraft were needed to get the fire under control (Worlds Aid 2022). On the  
671 German side of the border, an area of about 150 ha in the Saxon Switzerland National Park was affected (DAV 2022). During  
672 the decade 2010 - 2020, in the Czech Republic almost 100 mio. m<sup>3</sup> of solid timber has been harvested linked to bark beetle  
673 attacks, which leads to financial losses in the Czech forestry sector of ca. 1.12 billion Euro (Toth et al., 2020). More than half  
674 of this volume has been mined since 2017. In the Czech Republic this amount of unplanned salvage logging represents an  
675 increase of about 3-folds from 2017 to 2018 (Moravec et al., 2021). There are also clear signs of loss of vitality during the dry  
676 period in the Czech Republic (in this study 2015-2019), where growth reductions in five major species due to drought  
677 conditions were observed when compared to the reference period of 2005–2009 (Jiang et al., 2024).

678

679 In the **German** forest sector, the years 2018 until 2020 and 2022 are considered dry years (e.g. DFWR, 2021, Toreti et al.,  
680 2022). Monthly data from the Earth observation satellites Sentinel-2 and Landsat-8 shows dramatic canopy losses in Germany,  
681 in which coniferous forests in the middle of the country were particularly affected: from Saxon-Switzerland in the east, through  
682 Thuringia to the Harz Mountains, to the Sauerland region and finally to the Eifel in the west (Thonfeld et al., 2022). From  
683 January 2018 up to and including April 2021, tree losses were recorded on around 501,000 ha in Germany, which corresponds  
684 to 5% of its total forest area. The results of the German Forest Condition Survey show that in 2018 29% of the investigated  
685 trees showed moderate to severe crown defoliation ( $\geq 25\%$ ), which is the highest value since records began in 1984, when it  
686 was 23% (BMEL 2023a). In the years that followed, this value increased to about 26-37% during the years 2019-2022. Also  
687 on a regional scale, results show the same, e.g. the forest condition survey in the German federal state Lower Saxony shows  
688 that the defoliation values are at the highest level in the time series since 1984 (NWFVA 2022). High water availability enabled  
689 trees to maintain growth in a floodplain forest in Germany during summer 2018, but the consecutive drought in 2019 caused  
690 strong reductions to tree growth, even in a forest ecosystem with comparably high levels of water supply demonstrating the  
691 accumulating effect of consecutive drought years (Schnabel et al., 2021). Even if deciduous forests in Germany are not dying  
692 off to the same extent as coniferous stands, they are also strongly affected by climate change. In the forest condition survey  
693 (BMEL 2020), more dead trees were recorded than ever before, across all tree species examined. Only about 20% of the trees  
694 did not show any crown thinning, for European beech it is only 11%, older beeches (>60 years) and trees at drier sites show  
695 especially a reduced growth and increased mortality (BMEL 2020, Leuschner 2020). Even tree species that are considered to  
696 be relatively drought-resistant, such as Scots pine (*Pinus sylvestris*) experienced massive mortality since 2018 in Germany  
697 (e.g. Kunert 2019). In this case in addition to the hot and dry summers, the fungus *Spaeropsis sapinea* (or *Diplodia pinea*)  
698 causes pine dieback (Mette and Kölling 2020).

699 In Germany, outbreaks of European spruce bark beetle (*Ips typographus*) have inflicted widespread damage on forests,  
700 particularly during episodes of heat and drought. In many cases, the harvest was lost and there was a need for emergency  
701 felling and even deforestation to prevent the pest from spreading (e.g. HessenForst 2022; Thonfeld et al., 2022). In the German  
702 federal state Thuringia almost 21 million m<sup>3</sup> in the period 2018 until 30.9.2022 deciduous (mainly beech) and coniferous  
703 (mainly spruce) dead wood incurred, of which around 65% due to insect infestation fall and 35% due to drought and storms  
704 (TMIL 2022). In 2022 around 344,000 m<sup>3</sup> of damaged wood (202,000 m<sup>3</sup> of hardwood and 142,000 m<sup>3</sup> of coniferous) registered  
705 by drought alone, without the primary pests being involved. In the period 2018-2022 4.9 million m<sup>3</sup> of damaged wood resulted  
706 from heat and drought (TMIL 2022). The estimates are that about 500,000 ha (4.4% of the German forest area) forest damaged  
707 by drought and bark beetles and need to be afforested in order to offset the damages from the drought years 2018-2022 (BMEL  
708 2023c). For the approx. 13.3 million m<sup>3</sup> of damaged wood by bark beetles, 95.6% goes back to activities of the European  
709 spruce bark beetle and 2.76% to the Spruce wood engraver (*Pityogenes chalcographus*). Although the latter still plays a  
710 subordinate role, this could gain increasing importance since the engraver specialised on weaker dimensions, which is a large-  
711 scale threat in the future regarding reforestation means or rejuvenation with conifers (TMIL 2022). 2018, 2019, and 2022 were  
712 above average years for forest fires in Germany.

713 The burnt area of 2022 is more than five times the annual average (since 1991) of almost 776 ha, the pure wood damage and  
714 was estimated at 30 to 40 million € (Feuerwehrverband 2022). In Germany, during 2018 – 2019 damages due to natural  
715 disturbances were estimated at 2.5 billion EUR (DW 2020). It is difficult to disentangle the exact costs of a big disturbance in  
716 a field like the German forestry sector, which generates about €170 billion annually and employs directly and indirectly more  
717 than 1.1 million people (Popkin 2021). Möhring et al., (2021) estimated the economic damage caused by the extreme weather  
718 events of 2018 to 2020 in forestry with an amount of more than 12.7 billion Euro – this corresponds to ten times the annual  
719 net profit of the entire forest economy in Germany.

720

721 In the **Netherlands**, there are clear signs trees suffered from the drought and heat in 2018, where especially deciduous tree  
722 species had stunted or no growth (measurements by dendrometers, see Lerink et al., 2019). On a national level, the average  
723 volume of living and dead wood continued to increase for the period 2017-2021 although at a slower rate due to the dry  
724 summers in 2018-2020 (the seventh systematic national forest inventory; NBI-7, 2022). There are several indications of tree  
725 mortality: the volume of standing dead wood compared to the NBI-6 (2012-2013) shows an increase from 6.1 to 10.0 m<sup>3</sup> ha<sup>-1</sup>  
726 from 2012-2013 (NBI-6) to 2017-2021 (NBI-7), respectively, and lying dead wood increased from 6.6 to 9.2 m<sup>3</sup> ha<sup>-1</sup> for the  
727 same periods. However, there is no information about crown defoliation. The next systematic monitoring of forests in the  
728 Netherlands has started in 2022 and will be completed in 2026.

729

730 In the northern part of **Belgium** (Flanders), new forest plantations have suffered from the droughts, especially on sandy soils,  
731 of which several have died in 2018, without further quantification available (CIW, 2019). In 2019, besides young trees,  
732 widespread dying of mature deciduous trees was also observed, and also Norway spruce and larch trees. Oak and beech trees  
733 exhibited dead tops or crowns, and dying juvenile trees of chestnut, sycamore, and silver birch were observed (CIW, 2020).  
734 Also, in 2020 it is reported that several trees exhibited needle and leaf loss, and especially Norway spruce trees had died (CIW,  
735 2021). The annual forest vitality inventory for Flanders (Sioen et al., 2022) provides information on the state of the forests for  
736 each year by monitoring trees in about 70 locations with a radius of about 18 metres. The annual inventories (Sioen et al.,  
737 2019; 2020; 2021; 2022) provide an indication of trends in vitality (e.g. loss of leaves and needles), but do not provide an  
738 overall estimate of the total damage to the complete stock of forests and wood in Flanders. Despite the effects of drought in  
739 the years 2019-2020, the year 2021 demonstrated some recovery, with a significant reduction in the loss of leaves and needles.  
740 Information for 2022 is not yet published. The inventories also show that the number of damaged trees in the samples increased  
741 since 2008 (Figure 16 in Sioen et al., 2022), with a recent peak in 2020 (30% damaged broad-leaved trees; 20% damage  
742 deciduous trees), and a decline in 2021.

743 In Wallonia, the southern part of Belgium, nearly one third of the 550,000 ha forest is covered with spruce. Accordingly,  
744 mortality has been high throughout Wallonia since the beginning of the drought years in 2018. In 2018, 500,000 m<sup>3</sup> of spruce  
745 were infested by bark beetles, compared to 5-10,000 m<sup>3</sup> in normal years. This number increased to approximately 1 million  
746 m<sup>3</sup> in the years 2019 and 2020 (Saintonge et al., 2021). During the colder and wetter year 2021, the newly infested timber

747 volume has dropped again to about 500,000 m<sup>3</sup> (Saintonge et al., 2021). Wildfires occur in Belgium, but not excessively and  
748 were highest in 2021 with 659 ha burned (EFFIS 2023).  
749

750 In **France**, from 2018 to 2020 300,000 ha were affected by forest dieback in public forests alone (ONF 2020). The northeast  
751 is particularly affected by bark beetles. In the two most affected regions, Grand Est and Bourgogne-Franche-Comté, 170,000  
752 ha of forest, equivalent to 58 million m<sup>3</sup> of wood, are covered with spruce at elevations below 800 m before the 2018-2022  
753 drought event (Saintonge et al., 2021). The 2018-2019 drought and associated bark beetle damage was the main reason for the  
754 dieback (ONF 2020). Salvage logging of the damaged public forests led to the harvest of 6.5 million m<sup>3</sup> of low value wood in  
755 the period 2019-2020 compared to less than 1 million on average in a normal year, which represents 26% of the total harvest  
756 in public forest (ONF 2021). If the share of affected spruce stands is extrapolated to private forests, 19 million m<sup>3</sup> of spruce  
757 can be considered as killed by bark beetles in the two most affected regions in the period 2018-2021 (Saintonge et al., 2021).  
758 Interestingly, the damage increases from year to year, reaching a temporary peak of 9 million m<sup>3</sup> in 2021 (Saintonge et al.,  
759 2021), although this year was the only one in the period 2018-2022 that was not particularly hot and dry. The French  
760 government has allocated 150 million for the period 2021-2022 to regenerate and adapt the impacted surfaces (Gouvernement  
761 Français 2020).

762 Another indicator to measure the impact of drought is the share of wood declared as accidental or sanitary products. This  
763 indicator only refers to commercially used timber, which could explain the lower numbers compared to the numbers on killed  
764 forest areas, which are often based on remote sensing data. The accidental products are often related to storm damage, while  
765 the sanitary products, which are responsible for the bulk of the total damage, relate to drought damage or to pest infestation  
766 and thus indirectly mostly to drought as well (MAA 2021a). The share of harvested wood of all tree species declared as  
767 accidental and sanitary products in metropolitan France increased from 0.8% in 2017 to 1,5% in 2018 (MAA 2019a) to 5.5%  
768 in 2019 (Beaufils 2022, MAA 2021a), to 10.6% or 3.8 million m<sup>3</sup> in 2020 (MAA 2022a) and 4.1 million in 2021 (MAA 2023).  
769 Spruce is particularly impacted with more than 2 million m<sup>3</sup> in 2020 (MAA 2022a).

770 In addition, higher defoliation rates have been observed since 2015, which is probably largely due to the droughts and heat  
771 waves and a resulting increase of pests. While in 1997 only 2.2% of the deciduous trees and 1.8% of the conifers were affected,  
772 in 2019 it is already 9.6% and 4.3%. In addition to Scots pine (*Pinus sylvestris*) and Norway spruce (*Picea abies*), European  
773 beech (*Fagus sylvatica*) is particularly affected (Piton et al., 2020).

774 In terms of wildfires, the situation in France in the period 2018-2022 is also exceptional. During this period, the 3 years (namely  
775 2019, 2021 and 2022) with the largest cumulative wildfire burnt area since the start of systematic Copernicus observations in  
776 2006 have been observed. In 2022, the largest cumulative burnt wildfire area so far was measured, with 66,393 ha, it was more  
777 than 13 times higher than the 2006-2017 average (EFFIS 2023).

### 778 3.4 Damages to forests in the Alpine zone 2018-2022

779 In **Austria**, the centres of drought and heat are in the lowlands, especially in the east (Vienna, Lower Austria, Burgenland),  
780 but also in the southeast (Styria) and in the northern foothills of the Alps (Upper Austria, Northern Salzburg). Austria was hit  
781 hard by bark beetle attacks between 2018 and 2022. In particular, in 2018 (5,210,000m<sup>3</sup>), 2019 (4,690,000m<sup>3</sup>), and 2022  
782 (3,750,000m<sup>3</sup>, see Figure 3) the wood losses were large. Overall, forest damage in Austria 2022, which is primarily caused by  
783 climate change, is estimated at around 28 million euros (Bundesforste 2023). Around 940,000 m<sup>3</sup> wood was damaged in 2022,  
784 which corresponds to around 59% of the total amount of wood harvested in 2021. The main reason for this is an increase in  
785 bark beetle damage. Due to climate change, Austria's largest forest pest has already spread to the tree line at around 2,000  
786 meters above sea level (Bundesforste 2023). In March 2022, a huge wildfire raged in Allentsteig in Lower Austria. With a  
787 burnt area of about 800 ha, of which 400 hectares were forested, it was one of the largest forest fires that have ever occurred  
788 in Austria (Müller 2022).

789 In the Alps, due to rainfall in the summer months, it is usually less hot and dry than in lower areas (climate monitoring of  
790 GeoSphere Austria). A study based on NDVI data confirms that drought impacts decrease with elevation: especially at above  
791 1,500m (Rita et al., 2019). Damage caused by forest insects could only be detected sporadically, as during 2022 in East Tyrol  
792 (cipra 2022). In Tyrol, there was a bigger fire in the Alps in March 2022, directly across the border to Germany around 35 ha  
793 of mountain forest burned down in Pinswang in Tyrol (SZ 2022, Merkur 2022). An EUSALP study, initiated by the Austrian  
794 ministry, highlighted that the total direct costs for firefighting and for necessary measures on burnt areas (without preventive  
795 measures) in connection with forest fires are currently estimated at around 75 million € per year in the Alpine region. (Müller  
796 et al., 2020).

797  
798 In **Switzerland**, during both 2018 and 2022, the canopies of numerous beech trees had already changed colour by the end of  
799 July, with extensive areas of the forest in the Mendrisiotto region appearing brown by August (WSL 2022a). The volume of  
800 spruce wood damaged by bark beetle calamities amounts to approximately 800,000 m<sup>3</sup> in 2018, twice as high as in 2017. In  
801 2019 the volume increases further to 1.5 million m<sup>3</sup> before decreasing in 2020 (Dubach et al., 2021) and 2021 down to 1.2  
802 million and 600,000 m<sup>3</sup> respectively because of colder and wetter spring and summer (Saintonge et al., 2021). A Study based  
803 on Swiss NFI data (5092 NFI plots) until 2017 showed, that only 14% were classified as ‘naturally disturbed’, most of them  
804 (59%) by wind, but only 16% by insects (predominantly bark beetle), 1.2% by fire and 1.6% by drought (Scherrer et al., 2022).  
805 The interim results of the fifth state forest inventory (NFI5) over the survey years 2018 to 2022 clearly show that there is an  
806 increase in dead and damaged trees (WSL 2023b); Spruce has declined in the Jura, the Mittelland and the foothills of the Alps,  
807 and the sweet chestnut on the southern side of the Alps. The decline of ash trees, attributed to ash dieback caused by the fungus  
808 *Hymenoscyphus fraxineus*, spread rapidly and reached the inner Alpine valleys within a few years, with East Tyrol being  
809 affected in 2010 at the latest (Heinze 2017). The annually growing amount of wood is lower than five years ago. In addition,  
810 fewer young trees are growing in a quarter of all forests throughout Switzerland. The Alps and especially the southern side of

811 the Alps are particularly affected. Besides the interim results of NFI5, only a few reports could be found at high altitudes in  
812 Switzerland, for example about a regional increase in bark beetles in the Alps in 2020 (e.g. Schreiner Zeitung, 2020).

813

814 In **Italy**, after the Vaia windstorm in 2018, the number of pests was rather moderate, but at the beginning of June 2021, there  
815 was a pronounced heat wave, which triggered a massive swarming of the spruce bark beetle (Agrar-&Forstbericht Südtirol,  
816 2021). In 2022, around 5,000 ha of the 350,000 ha of forest in South Tyrol were infested with the bark beetle (Tagesschau  
817 2022). From mid-May 2022, the bark beetle then spread rapidly in Tyrol (cipra 2022). In 2021 around 105,000 m<sup>3</sup> of wood  
818 were affected, while in 2022 around one million m<sup>3</sup> were affected. The amount of damaged wood in the years 2018-2022  
819 corresponds to around 15 times the amount of normal use in a year (Dolomitenstadt 2023). In 2017, a long-term drought during  
820 growing season led to the largest fire outbreak regarding simultaneous fires of the last 30 years in the Alpine region: in autumn  
821 2017, there were 11 simultaneous large fires in the Piemonte Region, Italy, that burned almost 10,000 ha in a week, consuming  
822 mainly broadleaved forests (Müller et al., 2020). In October 2018, one of the largest forest fires ever with 632 ha occurred in  
823 Monte San Lucano, in the Veneto region in Italy (Müller et al., 2020).

### 824 **3.5 Forest damages in the Southern zone 2018-2022**

825 **Italy** was not under extreme drought conditions in spring and summer 2018 (Senf and Seidl, 2021; Rousi et al., 2023), but it  
826 suffered from extended forest damage caused by the extra-tropical windstorm Vaia over North-eastern Italy in autumn 2018  
827 (Motta et al., 2018). Vaia damages accounted for more than 70% of the total roundwood removed in Italy in the year 2018  
828 (Pilli et al., 2021). Although there was no extreme drought in Northern Italy in 2018, the precipitation was below normal for  
829 the months April, June, and September (Desiato et al., 2018), which might have contributed to the forests being drier than  
830 normal and thus more vulnerable to the storm Vaia in October 2018. Italy did suffer from an extreme heatwave and drought  
831 in 2017, which contributed to significant wildfire activity and subsequent burned forest of a total of 161,987 ha, the highest  
832 annual total since 2007 (European Commission, 2018; RAF Italia 2017-2018, 2019).

833 More generally, for the period 1998-2021 there was an increase in defoliation, forest mortality and leaf discoloration in Italian  
834 forests, especially in montane conifer forests, with the peaks reached in 2021 (Bussotti et al., 2022), and leaf discoloration  
835 mainly occurring in deciduous and evergreen oak forests. These high damage levels in 2021 are a result of a combination of  
836 increased summer drought and the lagged effect of the storm Vaia of 2018 that compromised the stability of the trees and  
837 increased the probability of insect attacks due to the large accumulation of dead wood in the forests (Bussotti et al., 2022).

838 The summer of 2022 Italy was affected by severe-to-extreme meteorological drought (Toreti et al., 2022a). Northern Italy was  
839 strongly affected, facing the warmest and driest winter in record of the last 30 years (Toreti et al., 2022b), resulting in strong  
840 hydrological drought and unusually low streamflow in the Po River, which is also related to the snow drought in the Italian  
841 Alps that winter (Koehler et al., 2022). A study looking at the impacts of the 2017-2022 drought and heatwaves in forest areas  
842 of Tuscany found that the most severe impacts were observed on the evergreen Mediterranean tall woodlands and the aged  
843 coppices (on holm oak trees), including defoliation and mortality (Bussotti et al., 2023). The study suggests that the impact of

844 the 2022 prolonged drought on forests could have been larger, but it seems that the trees might be responding to current climate  
845 change via rapid acclimation based on epigenetic modifications (Rico et al., 2014).  
846

847 In **Spain**, in the period 2018-2019, there was some recovery or stabilisation in terms of forest defoliation and discoloration  
848 following the drought of 2017 due to an increase in precipitation (AIEF 2019). However, more recent reports over parcels in  
849 North-eastern Spain reveal a deterioration in defoliation in the period of 2019-2021 due to more severe heat and drought  
850 conditions and, in particular, due to extreme events occurring during critical vegetation growth periods (GAN-NIK 2019). In  
851 the period of 2018-2020, physical damages such as drought and wind are the main drivers of forest defoliation, followed by  
852 insects. Both drivers exhibit forest damages 3 to 5 times larger than every other driver (e.g., fungi, fires, etc.), and their impacts  
853 have increased dramatically since 2014 (AIEF 2020). In this period, physical damages and insects together with forest fires  
854 are the three main drivers of tree mortality in Spain (AIEF 2020). In 2022, Spain has experienced almost 270,000 ha of burned  
855 area, a drastic increase from previous years amounting up to 3 to 6 times larger surface area compared to 2018-2021. In the  
856 2018-2021 period, around 300 fires per year were recorded versus 400 fires in 2022, indicating not only more fires and larger  
857 burned area, but also larger burned area per fire on average (see Figure 3).  
858

859 Although **Portugal** (Western Iberia) has recently shown increasing frequency of drought conditions coupled with heatwave  
860 events (Bezák and Mikoš, 2020; Vogel et al., 2021; Ribeiro et al., 2020), leading to exacerbated limiting climatic conditions  
861 for plant growth, the situation of Maritime pine (*Pinus pinaster*, one of the most frequent species) is according to Kurz-Besson  
862 et al., (2016), not completely discouraging. Detailed information regarding defoliation in Portugal is unavailable since 2006  
863 (ICP Forests 2007). Also, data of damaged wood by insects was not available.

864 Since 1980, the mean annual burnt area has been around 115,000 ha with a large interannual variability, and including  
865 particularly severe years, such as 2003 (~425,000 ha), 2005 (~350,000 ha), or the record value of 2017 (~540,000 ha, EFFIS  
866 2023). The inter-annual variability of burned areas in Portugal is attributable to high temperatures and drought as a result from  
867 the amount of precipitation during and prior the fire season (from May to September). In addition, the occurrence of  
868 atmospheric circulation patterns in the summer induces extremely hot and dry spells over Western Iberia (Pereira et al., 2005;  
869 Russo et al., 2017). Dry conditions contributed extensively to the massive wildfires that took place in Portugal during 2017  
870 (Turco et al., 2019; San-Miguel-Ayán et al., 2020). The total burned area in Portugal in 2017, corresponds to nearly 60% of  
871 the total burned area in Europe in 2017. The economic losses due to the 2017 wildfires in Portugal totalled almost 1.2 billion  
872 USD, and the local insurance sector declared it as the costliest natural disaster in the country's history with pay-outs exceeding  
873 295 million USD (AON, 2018).

874 Following the information from the Global Forest Watch (GFW, 2023, Figure 4), from 2000 to 2020, Portugal experienced a  
875 reduction of 104,000 ha (-3.4%) in tree cover. From 2001 to 2021, Portugal lost 1.13 million ha of tree cover, equivalent to a  
876 49% decrease in tree cover since 2000, with 10% of the loss occurring between 2018 and 2021. For the same period, 0.57% of

877 tree cover loss occurred in areas where the dominant drivers of loss resulted in deforestation, which in case of permanent  
878 deforestation was dominated by urbanisation and shifting agriculture.

#### 879 **4. Drought legacy**

##### 880 **4.1. Drought legacy effects**

881 Beyond the immediate damage caused by drought and heat to vegetation, there can be long-term effects that can persist for  
882 many years. Therefore, the short-term assessment of damage can strongly underrepresent the overall damage caused by an  
883 event in forest ecosystems. The duration of a legacy damage can vary between different aspects of the observed ecosystem.  
884 For example, the carbon cycle recovery and compositional change can take several years (Mueller & Bahn 2022). More  
885 specifically, long recovery periods were found in a temperate forest, in which severe droughts caused growth reduction lasting  
886 up to 6 years, depending on tree species (Orwig and Abrams 1997). Further complicating the damage assessment is that over  
887 long periods the target vegetation adapts to the persistent conditions. For example, structural changes related to hydraulic traits  
888 in trees before an extreme climate event can mitigate or enhance the damage caused during an extreme event, depending on  
889 the direction of the shift in plasticity (López et al., 2016), and an interspecies comparison showed that trees growing in drier  
890 sites were more drought resistant (Orwig & Abrams 1997).

891 Since the period in which damage after an extreme event can occur is long, it is not a trivial matter to disentangle the damage  
892 caused by a specific event and the conditions that followed which can enhance or maintain the hazard level present. Here, we  
893 face the non-trivial task of separating the effects of the different years in a consecutive drought. We first address the long-term  
894 changes in water availability due to extreme droughts, to better understand the long-term conditions that the vegetation will  
895 experience. Next, we describe the expected or observed legacy damage from the 2018-2022 drought events to forest  
896 ecosystems. While the focus of this section is on damage, it is worth noting that also long term positive effect can occur after  
897 a climate extreme event (Mueller & Bahn 2022).

##### 898 **4.2 The connection of vegetation drought legacy with groundwater drought legacy**

899 Groundwater is a key component of the terrestrial water cycle and contributes dynamics and feedbacks with vegetation process  
900 at time scales far beyond the weather and seasonal time scale (Aesbach-Hertig and Gleeson, 2012), which are especially  
901 important for the evolution and persistence of droughts. The vegetation water supply under meteorological and hydrologic  
902 drought is determined by the redistribution of moisture in the shallow subsurface (soil) and its hydraulic connection with  
903 groundwater (GW) (Yu et al., 2017). Thus, the impact and legacy of drought strongly depends on the local and regional  
904 distribution of soil moisture, infiltration and groundwater recharge, capillary rise, and baseflow along river corridors. These  
905 fluxes and their spatiotemporal dynamics are a function of the heterogeneity of the subsurface, land surface processes, and  
906 climatology. The feedback of groundwater with vegetation is strongly non-linear and occurs via capillary rise of water from  
907 the free water table or direct extraction of water from GW due to root water uptake. Both processes can be especially

908 pronounced under drought conditions and depend on the vegetation type and associated root depth distribution (Fan et al.,  
909 2017). In turn, if the free GW table is at the critical depth along e.g. a hillslope, even small changes on the order of  $10^{-1}$ m may  
910 result in significant feedback with root water uptake and changes of evapotranspiration (Kollet et al., 2008). For example,  
911 Rabbel et al., (2018) showed sap flow density data for a Norway Spruce stand in the Eifel mountains, Germany, from  
912 observations in a riparian zone and nearby hillslope exhibiting shallow and deeper water table depth. In the riparian zone, the  
913 shallow routing spruce exhibited generally large evapotranspiration compared to the hillslope. Thus, GW drought legacy that  
914 is manifested in increased GW table depths will impact drought legacy effects in forests in all types of vegetation and land  
915 surface process. Because water use by vegetation is consumptive, vegetation constitutes a sink for GW under these conditions.  
916 Thus, a positive feedback loop may arise in which GW drought legacy influences vegetation drought and, in turn, vegetation  
917 influences GW drought legacy. Since the timescale of GW drought legacy acts far beyond the weather and seasonal time scale  
918 (Aesbach-Hertig and Gleeson, 2012; Loon, 2015), one can expect a strong connection to shallow moisture redistribution and  
919 drought legacy over very large time scales in regions of critical groundwater depths. While there is a dependence on climate,  
920 and local and regional terrestrial conditions, the basic physical principles of the processes described above are universal.  
921 To assess the connection of drought legacy with groundwater drought legacy from observations, the state of GW (including  
922 soil water) must be known in space and time. Commonly the state of GW is observed in boreholes via in-situ GW table or  
923 piezometric head measurements. These measurements provide information at the point scale in space and commonly at low  
924 frequency in time, because they are usually performed manually and, thus, not logged continuously. This leads to discontinuous  
925 images of the GW state in space-time, which commonly is interpolated with the help of models, inversion, and data  
926 assimilation. Note, however, no collated GW observational data base exists over Europe or for specific countries. Thus, the  
927 data remains fragmented and dispersed across a large number of political and private institutions and is not publicly available.  
928 This renders a formal analysis of the connection infeasible within the scope of this study; only the general principles can be  
929 discussed here.

930 In Mid Europe, dispersed bore hole observations of groundwater levels reveal that the 2018 drought was indeed one of the  
931 most severe in decades and comparable with the drought of 1976 (Schuldt et al., 2018). In 2018, in many observation wells,  
932 groundwater levels were at or close to the lowest levels ever observed by in-situ measurements (Bakke et al., 2020) resulting  
933 in the cessation of capillary rise, reduction of root water uptake and severe drought stress also beyond the year 2018 (Schuldt  
934 et al., 2020). For example, Süßel and Brüggemann (2020) studied tree water relations in 2018 in mature oak stands in southwest  
935 Germany. They found that sites with continuous capillary rise toward the root zone maintained a canopy conductance at 50%  
936 of the maximum, while sites with hydraulic disconnection from the water table showed a collapse of conductance and  
937 significant leaf shedding. In these settings, the long-term effect of droughts may be especially pronounced, because  
938 groundwater recovery after drought is a slow process leading to strong memory effects and an increased probability of drought  
939 at the interannual time scale which was indeed observed in the ensuing years 2019 and 2020 in addition to precipitation deficits  
940 (Hartick et al., 2021). It is important to note that vegetation stress under the 2018 to 2022 drought conditions also showed  
941 distinct spatial patterns from observations, with limited stress along river corridors and extreme stress in the upper parts of

942 hillslopes along ridges (Cartwright et al., 2020). These patterns are directly related to groundwater processes that are the  
943 groundwater discharge and recharge, respectively. Under drought conditions, along river corridors, groundwater discharges as  
944 baseflow toward the stream constituting essentially an outcrop of the groundwater table, thus, leading to shallow groundwater  
945 tables connected to the land surface via capillary rise and root water uptake. In contrast, along hillslopes and ridges, capillary  
946 rise for root water uptake is mainly sustained by shallow soil water without connection to the groundwater compartment leading  
947 to tight coupling of root water uptake and plant stress with quite limited soil moisture storage. In the case of GW, these patterns  
948 are well-known and reflected in in-situ groundwater measurements. However, the lack of remote sensing information for the  
949 subsurface, data scarcity and fragmentation lead to a much more incomplete spatial coverage of information. Preliminary  
950 inspection of LAI products from remote sensing do not show a systematic pattern at the large scale depending on topography  
951 or potential groundwater convergence zone. In future, a merger of in-situ, remotely sensed and model data with ensuing in-  
952 depth analyses are required in order to identify potential tree legacy effects induced by groundwater drought legacy. In this  
953 context, data from hyperspectral remote sensing on photosynthetic activity may be useful.

#### 954 **4.3 Drought legacy effects in forests – the accumulation of long-term damages due to soil moisture deficit**

955 Legacy of a drought event in forests can take many forms (Müller & Bahn 2022, Rukh et al., 2023), depending on the tree  
956 demographic processes that are most affected (See Section 1.4 for more on soil moisture deficit and Rousi et al., 2023). The  
957 mortality of adult trees can create gaps in a forest, influencing the long-term profitability of an economic forest but also the  
958 carbon and water cycle and species composition. Forest gaps also increase solar radiation, temperature and dryness in the  
959 understory and the soil, which may lead to further damage caused by soil hydrophobicity aggravating soil dryness, horizontal  
960 translocation of water, nutrients and soil, and additional dryland mechanisms of ecosystem functioning (Grünzweig et al.,  
961 2022). Similarly, the mortality or diminished vitality of saplings can impede these processes, slowing down the overall  
962 recovery of the forest. Additionally, damage that does not cause mortality may weaken the trees and make them more  
963 susceptible for future droughts or to a different type of extreme events, e.g. storms (Gliksman et al., 2023) or fires and pests  
964 as described in detail in previous sections. We present several examples for the damage of drought during the 2018-2022  
965 period on forests in Europe. However, we expect that future literature will examine this topic more in depth in the years to  
966 follow 2022, as either examination of recovery rates if the drought will come to an end, or, if the drought will continue for  
967 several years longer, then it would be possible to study the ongoing adaptation to drought. Below, we offer examples mostly  
968 relating to saplings and young trees as the more reliant aspects of legacy that can be observed during this drought period.

969 When assessing the long-term damage to seedling establishment there is variation depending on location and the target tree  
970 species studied (Salomon et al., 2022). In a large field study in Central Eastern Germany, the drought of 2018 caused defoliation  
971 on average 65% of the saplings across multiple tree species, and for several species, the rate of affected saplings reached 85%  
972 and more (Beloïu et al., 2020). Although the sapling showed a rapid recovery in the following year, in 2019 and 2020 still 25-  
973 32% of the saplings showed damage (Beloïu et al., 2022). More localised reports are also present such as the loss of 50,000  
974 seedlings at a single large Sitka spruce orchard in Galloway, Scotland because of the 2018 and 2020 droughts (Locatelli et al.,

975 2021). Similarly, in Poland at the Brodnica Forest District (RDSF Torun) in 2018, around 20% of the trees planted did not  
976 survive the drought season. This means that nearly 30 ha of young forest had to be replanted, with losses in excess of around  
977 33,000€ (150,000 PLN; LASY, 2023). Similar damages were observed in many other locations in Germany including damage  
978 and mortality of young spruce and beech trees (BMEL 2019).

979 In Scotland, Locatelli et al., (2021) observe notable mortality rates among younger forest stands managed by the private sector,  
980 encompassing both restored sites and newly planted forests.

981 Growth reductions were also observed in North Germany following 2018 due to insufficient water recharge during the winter  
982 of 2018/2019 (Scharnweber et al., 2020), and similarly in Germany in 2019 and 2020 (Beloïu et al., 2022). Additionally,  
983 relating to growth reduction due to 2018, the GPP of the forests in Switzerland recovered during 2019 (due to normal amount  
984 of precipitation but with heat waves) in about 50% of the forested area but 49% remained damaged at the levels of 2018,  
985 showing a strong legacy effect (Sturm 2022).

## 986 **5. Discussion**

987 For **conifers**, no significant differences in **defoliation** were observed in the Northern zone or within the individual countries  
988 situated in it (Figure 2). This suggests a relative stability in conifer health in this region, despite variations in environmental  
989 conditions. Conversely, the Central zone exhibited a substantial and statistically significant increase in defoliation levels during  
990 the period of 2018-2022 compared to the reference period. This discrepancy was particularly evident in the Czech Republic,  
991 Belgium, and France, where the differences were highly significant. Additionally, significant differences in defoliation were  
992 noted in Germany, indicating a widespread trend of deteriorating conifer health in this region. In the Southern zone, notable  
993 deviations during the dry period of 2018-2022 compared to the reference period were observed, with Spain also registering  
994 significant differences. Overall, our findings suggest that conifers in the Northern zone exhibit a greater resilience to drought  
995 and heat stress compared to those in other regions.

996 Regarding **broadleaves defoliation**, we observed a highly significant disparity in defoliation levels between the dry period of  
997 2018-2022 and the reference period in the Central zone. This discrepancy was particularly pronounced in France, where the  
998 differences were highly significant. Additionally, significant differences in defoliation were noted in the Czech Republic and  
999 Germany, suggesting a region-wide trend of increased defoliation among broadleaved trees in response to environmental  
1000 stressors such as drought and heat. These findings suggest that broadleaved trees, naturally distributed across large parts of  
1001 Central Europe, are facing significant challenges due to the escalating frequency and duration of drought and heat events  
1002 associated with climate change. Also in the Southern zone, similarly significant differences in defoliation were detected  
1003 between the two investigated periods, with Italy showing highly significant differences and Spain registering significant  
1004 differences. This indicates that broadleaved trees in the Southern zone, which are adapted to Mediterranean climates, are also

1005 susceptible to the impacts of drought and heat stress. Data for broadleaved trees in the Northern zone were not applicable,  
1006 suggesting potential limitations in data availability or species distribution in this region.

1007 The observed severity of damaged wood caused by **insect infestation** across Central Europe during the study period of 2018-  
1008 2022 compared to the reference period is of particular concern, especially in Central Europe, but also in Sweden (Figure 3).  
1009 These findings align with projections indicating a significant increase in bark beetle disturbance in Europe due to climate  
1010 change. Studies suggest that the level of bark beetle disturbance could increase up to sevenfold by 2030 compared to the period  
1011 from 1971 to 1980 (Seidl et al., 2014). Additionally, projections for the 21st century indicate a potential twofold increase in  
1012 bark beetle disturbance, contingent upon the level of climate forcing and forest conditions (e.g., Dobor et al., 2019; Dobor et  
1013 al., 2020b). The cumulative growing stock affected by bark beetles is projected to increase substantially under moderate climate  
1014 change scenarios, with even greater impacts anticipated under hot and wet climate change scenarios compared to baseline  
1015 conditions (Sommerfeld et al., 2020).

1016 Contrary to expectations, we did not find significant differences in **forest fire** outbreaks between the dry period of 2018-2022  
1017 and the reference period of 2010-2014 (Figure 4). This trend is observed consistently across the Northern, Central, Alpine, and  
1018 Southern zones. Also, on request to individual offices (e.g. in Austria), it was found that there were neither more fires nor  
1019 larger burnt areas in the years 2018 - 2022 compared to the reference period. These findings indicate a complex interplay of  
1020 factors influencing fire activity, including climatic conditions, prevention measures, forest management, awareness raising,  
1021 and firefighting effectiveness, which may vary across regions. However, countries in the Southern zone experienced severe  
1022 impacts from forest fires not only during the period of 2018-2022. Our decision to include data from 2017, despite not being  
1023 originally part of the study design, provided insights into the significant impact of fires during that year, particularly evident  
1024 in Portugal, where a vast area of forest land was affected. This emphasises the importance of considering extreme events and  
1025 their implications for forest management and conservation efforts. Further research is needed to explore the underlying drivers  
1026 of fire activity and develop effective strategies to mitigate the impacts of forest fires in vulnerable regions and highlights the  
1027 need for effective fire management strategies. However, research in the USA has unequivocally attributed forest fires to climate  
1028 change: In Northern and Central California a fivefold increase in the summer burned forest area between 1996 and 2021  
1029 compared to 1971 - 1995 was reported (Turco et al., 2023). Across the western United States, climate change and other drivers  
1030 have led to a doubling of the cumulative forest fire area since 1984 (Abatzoglou and Williams, 2016). Global projections for  
1031 the twenty-first century indicate that climate change heightens fire weather conditions, impacting a substantial portion of  
1032 burnable land surfaces worldwide (Abatzoglou et al., 2019).

1033 The significant disparities in **tree cover loss** observed across European regions between the dry period of 2018-2022 and the  
1034 reference period of 2010-2014 highlight the complex interactions between human activities, natural phenomena, and climate  
1035 change, emphasising the importance of comprehensive forest management strategies to mitigate the impacts of environmental  
1036 changes on forest ecosystems (Figure 5). The escalating frequency and intensity of extreme weather events, such as storms,

1037 droughts, and wildfires, pose significant threats to forest health and resilience. However, forests are under increasing pressure,  
1038 not only from climate extremes, but also from human activities such as logging, deforestation, and urbanisation. Notably, the  
1039 three zones Northern, Central, and Southern experienced losses of 0.34% of forest land during the analysed period, with  
1040 varying degrees of significance, underscoring the urgent need for proactive measures to address these challenges. Further  
1041 research is needed to better understand the specific drivers behind these disparities and to develop targeted interventions for  
1042 sustainable forest conservation and management.

1043 In the **Northern zone**, it appears that we may be witnessing the initial stages of the impact from drought and heat. However,  
1044 the severity of the situation in the Northern zone does not appear to be pronounced at present. Nonetheless, these findings  
1045 emphasise the vulnerability of the Northern zone to the adverse effects of drought, underscoring the imperative for ongoing  
1046 monitoring and conservation initiatives to mitigate potential future impacts. In analysing Europe-wide data, we discovered  
1047 indications that the Northern zone experienced adverse effects during the drought years of 2018-2022. There was a notable  
1048 increase in the proportion of moderately to severely defoliated trees by approximately 30% compared to the reference period,  
1049 alongside evidence of damaged coniferous wood in Sweden. Damaged wood by insect pests in the Northern zone was only  
1050 available for Sweden, with very high values in the years 2018, but especially high for 2019, 2020, and 2021. Additionally, tree  
1051 cover loss increased significantly from 0.7% to more than 1%. Intriguingly, conifers did not exhibit a corresponding increase  
1052 in crown defoliation. Although the burned forest area showed a slight increase during the drought period, it was not  
1053 significantly different from the reference period.

1054 Overall, in Fennoscandia, the forest management during the last decades has favoured conifer monocultures, leading Norway  
1055 spruce and Scots pine to be the dominant species (Huuskonen et al., 2021). This means that the large forest ecosystems are  
1056 likely to be more vulnerable to climate extremes. However, the example of Norway may make it clear that Scandinavia is  
1057 probably the area where climate change has had the least consequences for forest ecosystems. In Norway, larger seasonal  
1058 differences in precipitation/drought and temperature are expected. Periods of drought are replaced by periods of heavy rains  
1059 and flooding. The consequences are moderate for forestry – but can be severe for agriculture in particularly during dry seasons  
1060 – and also for hydroelectric dams. So far, the effects seem to cancel each other out. For example, winter, spring and summer  
1061 2021 were dry, but then Norway had an autumn and winter with more rain than usual, groundwater levels went above normal  
1062 and hydroelectric dams were filled. Insect attacks after the 2018 drought could have become severe, but cold and wet preceding  
1063 years probably mitigated this. Overall, the major concern in Norway is periods of drought followed by periods of heavy rains  
1064 leading to passing floods.

1065 Differences in early detection, forest road network density, and the number of local voluntary fire brigades are the main reasons  
1066 why there was such a variation in forest fires and damages in the Nordic Countries (Lehtonen and Venäläinen, 2020).

1067 Also in the British Isles, the amount of damage was not exceptional during the investigation period. Only some indirect signs  
1068 were detectable: a survey published by Forest Research (2021) shows that the effects of the previous years of drought damage  
1069 were clearly noticeable for forest visitors: 77% in the UK (76% in England) agreed that ‘action should be taken by authorities  
1070 and woodland managers to protect trees from damaging pests and diseases’. Regarding insects, no damage data was found.

1071 However, the great spruce bark beetle (*Dendroctonus micans*) is today an established pest in Southern Scotland (Scottish  
1072 Forestry 2023a). Sitka spruce is Scotland's most important commercial tree species and the primary host of this pest. The 'D.  
1073 *micans* distribution map in Scotland' clearly shows its expansion northwards in the period 2018 until 2022 (Scottish Forestry  
1074 2023b). A synopsis of spatial modelling research (Forest Research 2008) even expects an improvement of tree growth due to  
1075 a warmer climate in Scotland in the future: particularly in Southern and Eastern Scotland for high-quality broadleaved trees  
1076 on suitable deep, fertile soils and for conifers on sites where water and nutrients are not limiting. However, a breeding  
1077 population of European spruce bark beetle (*Ips typographus*) has now become established in South-east England probably  
1078 arriving by flight across the English Channel following a large-scale dispersal from continental Europe due to extreme weather  
1079 in 2021-2022 (Inward et al., 2024). This poses a future threat to the spruce in the UK, which is the dominant timber species. It  
1080 should also be noted that when it comes to drought damages recorded in England and Scotland in 2018, wildfires only came  
1081 in third place, while impacts on freshwater ecosystems and water quality ranked higher (Turner et al., 2021).

1082 The observation of harm that are clearly due to rising temperatures and drought in the **Central zone**, make it evident that these  
1083 forests are facing significant impacts and challenges. The severity of the situation in the Central zone is underscored by  
1084 pronounced increases in crown defoliation observed in both coniferous and broadleaved trees, alongside an extraordinary rise  
1085 in bark beetle-infested wood and an overall increase in tree cover loss. These findings paint a concerning picture for the Central  
1086 zone's forest resilience, highlighting the vulnerability of its forests to climatic stressors. The cumulative effects of rising  
1087 temperatures and prolonged drought periods have evidently taken a toll on the forest ecosystems in Central Europe. The less  
1088 drought-adapted ecosystems of Central and Northern Europe experienced a record hot drought (Buras et al., 2020) that caused  
1089 early-wilting during summer 2018 in about 11% of the Central European forested area. The most affected forests were in  
1090 Central and East Germany, and in the Czech Republic (Brun et al., 2020). The drought and heat of 2018 were the prerequisites  
1091 for the forest damage caused in Central Europe in the period 2019-2020, while the main driver was an above-average water  
1092 vapour pressure deficit (Senf and Seidl, 2021a). The low soil moisture content in 2018 and the higher-than-normal water  
1093 vapour pressure deficit of the following two years were viewed as the main drivers for the forest disturbances of about 4.74  
1094 million ha during 2018-2020, mainly in Germany, the Czech Republic and Austria (Senf et al., 2021). The main cause for tree  
1095 mortality in 2018 is likely due to physiological damage as greenness was strongly reduced in Austria, Germany, and  
1096 Switzerland during 2018 (Schuldt et al., 2020). Reduced greenness was also observed in the spring of 2019 when compared to  
1097 the greenness before the drought in spring 2018 (Brun et al., 2020). During the hottest summer on record in Europe in 2022,  
1098 large parts of the temperate forest regions were negatively affected, and forest greenness decreased more strongly than any  
1099 other summer since 2002 by breaking the former record drought in 2018 (Hermann et al., 2023, Buras et al., 2023). These  
1100 observations of changes in forest greenness are based on satellite-derived Normalised Difference Vegetation Index (NDVI).

1101 Over the last decades, an increased occurrence of spruce bark beetles (*Ips typographus* L.) in Central Europe emerged  
1102 (Fernandez-Carrillo et al., 2020). Between 2018 and 2022, drought and heat facilitated the outbreak of an unprecedented size  
1103 on standing timber in Central Europe – especially in the Czech Republic, Germany, and Austria (e.g. Hlásny et al., 2019, 2021,  
1104 Nardi et al.2023, Kautz et al., 2023). For example, in Austria and Germany >50 % and in the Czech Republic > 90% of all

1105 harvests in 2019 were related to salvage logging (Senf and Seidl, 2021a). However, not only the climatic conditions were  
1106 important, but also the species composition of the affected stands, with Norwegian spruce monocultures being particularly  
1107 vulnerable.

1108 Economic losses in the forestry sector of Central Europe were also considerable during the period 2018 until 2022. The exact  
1109 costs are difficult to determine because our understanding of the economic impacts of disturbances remains incomplete (Knoke  
1110 et al., 2021). Consequential damage along the value chain or losses due to immaturity of harvested trees can still be calculated,  
1111 but the destabilisation of the remaining and neighbouring stands, the fall in market prices, or the heat effect on forest workers  
1112 and machines is extremely difficult to quantify.

1113 In addition to the drought, storms need still be considered. Currently, one cannot necessarily determine that the storms in  
1114 Germany are increasing substantially, but, for example, the damage caused by windthrow increased remarkably in 2018-2022  
1115 (BMEL 2023a). In addition to various silvicultural reasons, there is a development in Germany towards less severe winters  
1116 and an increase in precipitation outside the growing season (UBA 2015). Heavy or prolonged rainfall can result in roots not  
1117 being able to hold onto the soil sufficiently to withstand strong winds. At the same time, stands weakened by drought are also  
1118 significantly more vulnerable to strong winds.

1119 Regarding the **Alpine zone**, it must be noted that accessing data was particularly challenging. We were unable to precisely  
1120 identify which datasets specifically pertained to Alpine areas. Concerning fires in Alpine forests, we could only obtain data  
1121 from Austria and Switzerland for both periods, where we did not observe any significant differences. Based on this research,  
1122 we did not observe a significant increase in the impacts of drought and heat in the Alps during the period of 2018-2022. But it  
1123 should be noted that mountain forests are particularly under pressure from climate change impacts due to their temperature  
1124 limitation and high exposure to warming (Albrich et al., 2020). Such impacts can vary greatly with elevation and topography  
1125 (e.g. Lindner et al., 2010, Thrippleton et al., 2020) and require a careful study addressing the target species and the abiotic  
1126 conditions. The main tree species in central European mountain forests are Norway spruce, European beech and silver fir. All  
1127 of them are late-successional and shade-tolerant (Dyderski et al., 2023) and sensitive to drought stress. Additionally, drought  
1128 can also destabilise mountain forests and result in soil erosion, landslides, and rock-falls. Warmer temperatures and a  
1129 shortening of cold periods can lead to reduced snow cover and trigger the distribution of harmful organisms or alien and  
1130 invasive species and therefore can have a strong impact on biodiversity (Eriksen & Hauri 2021). Since the length of the growing  
1131 season decreases with altitude, a warmer climate could also lead to more growth so long as there is enough access to water.  
1132 This was confirmed by a study that measured tree aboveground biomass increment in temperate mountain forest (e.g. Thom  
1133 and Seidl 2022, Dyderski et al., 2023). Tree lines will shift upwards over a longer period and tree species from the lowlands  
1134 will establish at higher altitudes. A simulation of forest dynamics in the Northern Alps predicts for the first half of the current  
1135 century a probability for increasing gains in stem density, structural complexity, and tree species diversity (Thom et al., 2022).  
1136 An inventory of Alpine drought impact reports by Stephan et al., (2021) shows that the pre-Alpine areas are more affected  
1137 than those at higher elevations. Additionally, most reported impacts were categorised as agriculture and public water supply,  
1138 while impacts on forestry and terrestrial ecosystems were less mentioned. According to that study, drought impacts occur

1139 mostly in summer and early autumn, likely due to snowmelt in spring, which mitigates water shortages. At the same time, that  
1140 study also observed a spatial heterogeneity across the Alps with, surprisingly, more impacts in the Northern Alpine regions.  
1141 Eriksen and Hauri (2021) mention that forest fires have traditionally been more common on the southern side of the Alps and  
1142 that those countries have an improved handling of forest fires.

1143 Fire is one of the major natural disturbances in the European Alpine forests and shows heterogeneity in frequency, spatial  
1144 extent and seasonality, driven by climatic, environmental and anthropogenic factors (Morresi et al., 2020). However, if there  
1145 is an increased danger of forest fires in Alpine regions, it is not so easy to identify such a pattern, because each Alpine country  
1146 has its own forest fire documentation system with different attributes, criteria, and accuracies (Müller et al., 2020). According  
1147 to the values compiled for this review for the period 2018 to 2022, it does not appear that the occurrence of forest fires in the  
1148 Alps are very different from the long-term average (Table 3).

1149 A supra-regional body would be required to unify the different data sources for the Alps In order to understand the impact of  
1150 climate change on the Alps, a larger context needs to be considered across national borders, since many systems do not stop  
1151 at national borders (e.g. river basins such as the Danube or the Rhône). Cooperation across national borders and disciplines  
1152 (climate research, ecology) is necessary.

1153 Observing the obvious damage attributed to increasing temperatures and drought conditions in the **Southern zone**, it becomes  
1154 apparent that forests are encountering significant repercussions. The gravity of the situation in the Southern zone is accentuated  
1155 by marked increases in crown defoliation, particularly noticeable in broadleaved trees. While data on damage caused by wood-  
1156 boring insects are unavailable, it suggests that insect pests might not pose a major threat during the investigated drought years  
1157 from 2018 to 2022. Nevertheless, there is a significant increase in tree cover loss compared to the reference period. Assessing  
1158 the incidence of wildfires, it's not possible to assert that the situation worsened significantly during the period of 2018-2022.  
1159 However, the exceptionally severe year of 2017, particularly in Portugal, with staggering losses, necessitates its inclusion in  
1160 this study. The devastation caused by wildfires presents a challenge for Southern Europe. However, wildfires are also generally  
1161 part of the South-western European ecosystems. Italy was also strongly affected by the windstorm Vaia in 2018. Based on our  
1162 research, we could not find an increase in impacts on forest ecosystems with regard to insect infestation or physiological  
1163 damage such as defoliation between the period 2018 and 2022 examined here and the years before. Up to 2018, 3 million  
1164 hectares of forests have been reported to be converted into shrublands or grasslands in the Mediterranean countries of the  
1165 European Union. Fire and drought are the main drivers underlying this deforestation (Karavani et al., 2018).

1166 In Spain, over the period 2018-2019, there was even some recovery in forest health in Spain which contrasts with the larger  
1167 levels of damage recorded across Europe, in particular in Central Europe, which experienced both drier conditions and larger  
1168 levels of vegetation damage (AIEF 2019, ESOTC 2019).

1169 The situation for Maritime pine (*Pinus pinaster*, one of the most common species) in Iberia is according to Kurz-Besson et al.,  
1170 (2016) is not completely discouraging. According to Kurz-Besson et al., (2016), wood radial growth and density highly benefit  
1171 from the strong decrease of cold days and the increase of minimum temperature. Yet, the benefits are hindered by long-term  
1172 water deficit, which results in different levels of impact on wood radial growth and density. Despite the intensification of long-

1173 term water deficit, tree-ring width appears to benefit from the minimum temperature increase, whereas the effects of long-term  
1174 droughts significantly prevail on tree-ring density. Since the particularly extreme year of 2017, severe measures have been  
1175 applied and comparing the periods 2007-2017 and 2018-2022, the total number of fires decreased in half, particularly on days  
1176 of high fire danger. Larger fires have slowed since 2017. Fires with a burnt area of more than 1,000 ha reduced from an average  
1177 of 19 events to 8 in more recent years. Although forest losses are decreasing in the last period, Portugal has seen an increasing  
1178 trend in forest loss due to fires between 2001 and 2019 (Tyukavina et al., 2022). Fires occurring from recent forest loss due to  
1179 other drivers were excluded, e.g. burning of felled logs following mechanical canopy removal, which is common in slash-and-  
1180 burn agriculture and large-scale deforestation. In this sense, the decrease in fire events may not have been so obvious without  
1181 the unique events of 2017, indicating the difficulties of interpreting long term trends of damage.

## 1182 **6. Outlook**

### 1183 **6.1 Future trends and biophysical feedbacks of forest cover changes**

1184 Future global warming is expected to lead to more frequent and intense periods with heat and dry conditions in European  
1185 regions (e.g. Seneviratne et al., 2021), which will further enhance climate related risks on European forests. Furthermore,  
1186 extreme levels of compound heat and drought stress are projected to occur successively year after year with much higher  
1187 likelihoods in the next few decades compared to recent years (Suarez-Gutierrez et al., 2023). For example, Hari et al., (2020)  
1188 found a sevenfold increase in the occurrence of consecutive droughts as of 2018-2019 in Europe under the highest  
1189 Representative Concentration Pathway RCP 8.5. Gazol & Camarero (2022) expect an increase in forest drought mortality over  
1190 the next decades due to more frequent compound events of extreme drought and heat waves. Martinez del Castillo et al., (2022)  
1191 project severe future growth declines of European beech forests ranging from -20% to more than -50% by 2090, depending  
1192 on the region and climate change scenario (i.e. CMIP6 SSP1-2.6 and SSP5-8.5).

1193 This is in line with CMIP6 (SSP2-4.5) multi-model mean simulations, which support the notion that mean annual precipitation  
1194 decreases increasingly strongly the closer one gets to the Mediterranean, linked to roughly similar spatial changes in surface  
1195 runoff (see *IPCC AR6*). At the same time, evapotranspiration increases the further east in Europe one gets (see *IPCC AR6*).  
1196 Combined, those two meteorological aspects lead to a pronounced surface soil moisture deficit, which increases the  
1197 (hydrological) drought risk substantially (see *IPCC AR6*). Accordingly, forest disturbance regimes are expected to intensify  
1198 with continuing climate change, leading to increasing forest biomass losses due to windthrow, fires and insect outbreaks  
1199 (Forzieri et al., 2021, Patacca et al., 2023).

1200 At the same time, the increase in European forest coverage and green spaces are foreseen as essential measures to combat  
1201 climate change and its impacts (e.g. European Commission 2021). Forests play a key role in the European Green Deal climate  
1202 change mitigation strategy (Fetting 2020). However, more frequent and severe droughts and heatwaves would further increase  
1203 the vulnerability of European forests to disturbance and lead to increasing tree mortality and reduced forest growth. This would  
1204 decrease carbon sequestration in forests (e.g. Albrich et al., 2022) and could counterbalance efforts of reforestation and climate-

1205 smart forest management. Forest damage and reduced forest cover can even locally increase the intensity of hot days in  
1206 Northern mid-latitudes (e.g. Lejeune et al., 2018), and thus could even further enhance forest damage.

1207 Increase in forest cover are seen as important measures to mitigate climate extremes. Changes in forest cover due to land use  
1208 and climate change modulate local and regional climate conditions through changes of land surface properties, such as land  
1209 surface reflectance, water holding capacity and aerodynamic roughness. This affects biophysical land surface processes such  
1210 as the exchange of energy, momentum and water, and the partitioning of turbulent fluxes into sensible and latent heat flux. A  
1211 quantitative understanding of regional and local biophysical effects of such land use changes is required to enable effective  
1212 land-based mitigation and adaptation measures (e.g. Perugini et al., 2017). However, these effects are complex and strongly  
1213 depend on local conditions, and therefore their quantification is still largely unclear.

1214 Biophysical feedbacks of land use changes on near surface temperature can be locally or regionally of the same order of  
1215 magnitude as those associated with the effect from global greenhouse gas forcing (e.g. de Noblet-Ducoudré et al., 2012). The  
1216 first regional climate model (RCM) ensemble experiments in the frame of the CORDEX Flagship Pilot Study (LUCAS)  
1217 investigated the effects of extreme forest cover changes on local and regional climate in Europe (Rechid et al., 2017). The  
1218 LUCAS RCM inter-comparison study by Davin et al., (2020) reveal significant biophysical effects of re-/afforestation on the  
1219 regional and local climate at seasonal scale. It shows an overall agreement of RCMs in winter warming with consistently  
1220 simulated albedo change, but no agreement on the sign of temperature response in summer, with disagreement in evaporative  
1221 fraction. The study concludes that summer temperature response is dominantly driven by land processes, whereas atmospheric  
1222 processes are important for winter response. Breil et al., (2020) found opposing effects of re-/afforestation on the diurnal  
1223 temperature cycle at the surface and in the overlying atmospheric layer: Most RCMs simulate colder summer surface  
1224 temperatures during the day and warmer summer surface temperatures during the night, which is in line with observation-  
1225 based studies. In contrast, the diurnal temperature cycle in the overlying atmospheric surface layer is increased, due to higher  
1226 surface roughness, which increases turbulent heat fluxes. Sofiadis et al., (2022) investigated the impact of re-/afforestation on  
1227 the seasonal cycle of soil temperature over the European continent with the LUCAS RCM ensemble. The multi-model mean  
1228 shows a reduction of the annual amplitude of soil temperature over all European regions, although not all the models show this  
1229 trend. In addition, paired FLUXNET sites were investigated to compare the simulated results with observations. In line with  
1230 models, observations indicate a summer ground cooling in forested areas when compared to open areas.

1231 While most models align with the observed reduction in the annual amplitude of soil temperature, there is notable variability  
1232 in the magnitude of these changes. Addressing the broader climatic implications, Daloz et al., (2022) specifically examined  
1233 the snow-albedo effect of FPS LUCAS RCMs in sub-polar and alpine climates. Additionally, Mooney et al., (2022) explored  
1234 FPS LUCAS simulations in the context of extreme forest cover changes. The findings from these studies collectively indicate  
1235 that re-/afforestation plays a role in diminishing the snow-albedo sensitivity index, thereby contributing to enhanced snowmelt.  
1236 While the direction of change is robustly modelled, there is still uncertainty in the magnitude of change. The results of the FPS  
1237 LUCAS Phase 1 simulations show the importance of biophysical effects and feedbacks from forest cover changes in Europe.

1238 Climate change-driven changes in forest cover in Europe will intensify under further climate change and may become  
1239 regionally and locally self-reinforcing through biophysical processes and feedbacks.  
1240 Trees and forests may adapt to a hotter and drier climate, inter alia, by mechanisms currently predominant in drylands  
1241 (Grünzweig et al., 2022). By hydraulic redistribution, plants transport water from moist to dry soil layers through their root  
1242 system along a water potential gradient, thus improving plant nutrition, extending root lifespan, and preserving hydraulic  
1243 conductance in the xylem during dry periods (Prieto et al., 2012). Non-rainfall water, such as dew and fog are also a source of  
1244 moisture, whereby trees absorb water through leaves and bark, thus alleviating drought-stress and enabling humidity-enhanced  
1245 biotic activity (Earles et al., 2016, Wang et al., 2017). In addition, heat stress in forests can be mitigated by lowering the  
1246 aerodynamic resistance of heat transfer from trees to the surrounding air, a mechanism termed the canopy convector effect  
1247 (Banerjee et al., 2017; Rotenberg and Yakir, 2010). For instance, surface temperatures in forests rose less than those in non-  
1248 forested ecosystems during the 2003 extreme heatwave in Central and Western Europe, thus enabling forests to save water and  
1249 prevent long-term amplification of the consequences of extreme heat (Teuling et al., 2010). These pathways of adaptation may  
1250 diminish or even prevent damage caused by water scarcity and high temperatures.  
1251

## 1252 **6.2 Policies related to drought and heat waves**

1253 Based on the above assessment, it is very clear that recurrent heat wave and drought events lead to very complex and multi-  
1254 faceted impacts to our society. The impacts of enduring heat wave and drought include not only reduced water resources, crop  
1255 failure, limited renewable energy, and pressure on human health, but also others like land use planning and human activities.  
1256 More dramatic consequences are likely given that multiple risk factors for political instability will increase as a consequence,  
1257 e.g. wildfires, plant and human mortality, crop failure, or famine. The recent extreme events like the drought and heat wave in  
1258 Central Europe in 2018 (e.g. Rousi et al., 2023) or the severe floods in the border region between Germany, Belgium,  
1259 Netherlands, and Luxembourg in July 2021 (e.g. Mohr et al., 2023) has clearly demonstrated that the preparedness our society  
1260 to face such extraordinary events is insufficient. This is the case for the forecasting capacities, including impact modelling  
1261 chains, in which several agencies are typically involved and currently often lead to inefficient and late warning for civil  
1262 protection and for the population at large. Moreover, it has become clear from recent events that the population also does not  
1263 know how to act properly under extreme weather conditions. In fact, much more efforts need to be put into place regarding  
1264 information accessibility for the public, e.g., on how to save water under long-term drought, or to protect “endangered groups”  
1265 like old or sick citizens when affected by an enduring heat wave. This is particularly important, as extreme heat and drought  
1266 are expected to not only to be more extreme but also to affect our region for a longer period of the year (e.g. Hundhausen et  
1267 al., 2023) and to occur more frequently over successive years (Suarez-Gutierrez et al., 2023). In fact, some parts of Europe  
1268 like the Iberian Peninsula may be by the late 21st century under the influence of constant drought (e.g. Moemken et al, 2022).  
1269 In the face of these events, the need to act has been recognized by agencies and stakeholders at least in Germany. Joint task  
1270 forces have been put into place to develop tailored forecasts products for the civil protection, public agencies, and the

1271 population, which will serve as a basis both to act under adverse conditions and to develop new policies and streamline  
1272 procedures between public agencies. A key factor will be the adequate communication of information and political measures,  
1273 as this was often an issue in the past. Existing language barriers and accessibility of information must be overcome, leading to  
1274 a raised awareness in the population of the severe impacts of drought and heat on our livelihoods under current and future  
1275 climate conditions.

### 1276 **6.3 Issues due to data availability and reporting**

1277 Different impact reporting strategies and timelines across sectors and across countries hinder the rapid assessments of multi-  
1278 country drought impacts. In particular, we found a systematic lack of consistent reporting for specific regions and ecosystems,  
1279 e.g., grasslands over the Iberian Peninsula. Furthermore, we also find substantial delays or discontinuities in official impact  
1280 reporting efforts, which we found were often no longer available for recent years, e.g. Spain's National Forest Damage  
1281 Inventories were available at the time only until 2020 (AIEF, 2020). Initially, a description of the damage due to heat and  
1282 drought to grassland was also planned. However, the data availability regarding grassland is very limited, although this is the  
1283 second large-scale non-irrigated ecosystem providing many ecosystem services that are important for our well-being.  
1284

1285 A uniform data collection that is accessible across languages would be valuable considering the existing lack of coverage. Our  
1286 intent is to support or initiate a platform where all relevant data for drought damage is collected. This daunting task requires  
1287 the collaboration of many researchers across different subjects.  
1288

### 1289 **6.4 Conclusions**

1290 In conclusion, heat and drought are significant drivers of forest damages, including increased tree mortality, shifts in species  
1291 composition, changes in productivity and carbon sequestration, and increased wildfire risk. Mitigating these damages requires  
1292 a holistic approach that includes forest management, climate change adaptation measures, and global efforts to reduce  
1293 greenhouse gas emissions. Understanding the impacts of heat and drought on forests and implementing appropriate strategies  
1294 to mitigate these impacts is crucial for the conservation and sustainability of forest ecosystems in the face of climate change.

1295 However, there are opportunities to mitigate this damage. The extent to which we comprehend the damage already incurred  
1296 can guide us in making informed decisions for the future, whether in selecting appropriate tree species or implementing  
1297 effective management techniques. But mitigating this damage caused by heat and drought in forests requires a multi-faceted  
1298 approach that includes forest management and monitoring strategies, climate change adaptation measures, and global efforts  
1299 to reduce greenhouse gas emissions. Forest management practices, such as thinning, prescribed burning, and reforestation, can  
1300 help increase forest resilience to heat and drought by reducing competition for water, improving tree vigour, and promoting  
1301 more diverse species composition. Climate change adaptation measures, such as increasing water availability through  
1302 irrigation, improving forest monitoring and early warning systems, and implementing strategies to reduce wildfire risk, can

1303 also help mitigate damage. Finally, global efforts to mitigate climate change by reducing greenhouse gas emissions are essential  
1304 because this is the root cause of heat and drought impacts on forests.
