12 **Abstract**

13 Efficiency-maximizing modeling strategies are applied to 3 km simulations of the Southern  
14 Ocean in past, present, and future climates. The model setup exploits reduced-resolution spin-up and  
15 transient simulations to initialize a regionally refined, high-resolution ocean model during short time  
16 periods. Several cost efficient, high resolution modeling approaches are applied to simulations of the  
17 Southern Ocean in past, present, and future climates. The results are compared with satellite altimetry  
18 data and more traditional eddy-present simulations and evaluated based on their ability to reproduce  
19 observed mesoscale activity and to reveal a response to climate change distinct from natural  
20 variabilitycompared with observations and an ensemble of medium resolution, eddy present simulations  
21 and evaluated based on their ability to reproduce observed mesoscale activity and to reveal a response to  
22 climate change distinct from natural variability. The high-resolution simulations reproduce the observed  
23 magnitude of Southern Ocean eddy kinetic energy (EKE) well, but differences remain in local magnitudes  
24 and the spatial distribution of EKE. The coarser, eddy-permittingpresent ensemble simulates a similar  
25 pattern of EKE, but underrepresents observed levels by 550%. Five years of simulated data in each time  
26 period is found to produce consistent results when evaluating mean conditions and assessing change in  
27 the region as a whole. At approximately 1 °C of warming, the high-resolution simulations produce no  
28 change in overall EKE, in contrast to full ensemble agreement regarding to the increase projected EKE  
29 rise withinby the eddy-permitting simulationsensemble and despite full ensemble agreement. At  
30 approximately 4 °C of warming, both datasets produce consistent levels of EKE rise in relative terms,  
31 although not absolute magnitudes, as well as an increase in EKE variability. Simulated EKE rise is  
32 concentrated where flow interacts with topographic bathymetric features in regions already known to be  
33 eddy-rich. Regional EKE change in the high-resolution simulations is consistent with changes seen in at  
34 least four of five eddy-permitting ensemble members at 1 °C of warming, and all ensemble members at 4  
35 °C. However, substantial noise would make these changes difficult to distinguish from natural variability  
36 without an ensemble.

37 **Plain Language Summary**

38 Ocean models struggle to simulate small-scale ocean flows due to the computational cost of high-  
39 resolution simulations. Several cost-reducing modeling strategies are applied to high-  
40 resolution simulations of the Southern Ocean in a changing climate, and they are evaluated with respect  
41 to observations and traditional, lower-resolution modelling methods. The high-resolution simulations  
42 effectively reproduce small-scale ocean flows seen in satellite data and are largely consistent with  
43 traditional model simulations regarding their response to climate change after 4 °C of warming. Small-  
44 scale flows are found to intensify near bathymetric features and to become more variable.

45

46 **1 Introduction**

47 Mesoscale activity in the Southern Ocean has been the subject of much research and interest in  
48 recent years due to the intensification of Southern Hemisphere westerlies (Marshall, 2003), the  
49 phenomena of eddy saturation and compensation (Munday et al., 2013; Bishop et al., 2016), and the  
50 potential for carbon sequestration in the face of ongoing anthropogenic emissions (Sallée et al., 2012;  
51 Landschützer et al., 2015; Frölicher et al., 2015). Satellite observations already reveal an intensification  
52 of eddy activity in the Antarctic Circumpolar Current (ACC) and changes are attributed primarily to wind  
53 stress (Marshall, 2003; Hogg et al., 2015; Martínez-Moreno et al., 2021). Modeling studies have been  
54 able to reproduce the observed changes, as well as project continued intensification throughout the 21<sup>st</sup>  
55 century (Beech et al., 2022), but the modeled results rely on only partially resolved eddy activity relative  
56 to observations, leaving open the possibility for new findings or greater clarity.

57 Advances in computational capabilities have enabled ocean modeling science to make great  
58 progress in overcoming the substantial computational burden of simulating the mesoscale.~~s~~ but However,  
59 shortcomings remain, particularly in the Southern Ocean where the Rossby radius can be as small as 1  
60 km, increasing the computational cost of resolving eddies (Hallberg, 2013). Even model resolutions that  
61 can generally be considered eddy-resolving are only eddy-permitting poleward of 50° if grid spacing~~they~~  
62 does not vary in space (Hewitt et al., 2020). This highlights an efficiency challenge in simulating the  
63 mesoscale with traditional model grids; resolutions necessary to resolve high-latitude, small-radius eddies  
64 are both prohibitively expensive and unnecessary to resolve mesoscale eddies in the lower latitudes.  
65 Fortunately, a growing number of ~~modelling~~ alternatives to traditional grids now enable dynamic spatial  
66 allocation of resources (Danilov, 2013; Ringler et al., 2013; Danilov et al., 2017; Jungclaus et al., 2022),  
67 creating the opportunity to more efficiently resolve the mesoscale.

68 As resource allocation in high-resolution modeling becomes spatially flexible in the pursuit of  
69 more efficient configurations, the temporal component must also be scrutinized for efficiency. Traditional  
70 modeling approaches require long spin-up periods in order to equilibrate the deep ocean and reduce

71 model drift (Irving et al., 2021). Although the impacts of drift are not negligible, ~~they~~ generally affects  
72 large-scale processes in the deep ocean; mesoscale processes that require high resolutions to simulate are  
73 typically fast-to-equilibrate and will appear relatively quickly wherever large-scale ocean conditions lead  
74 to their creation. Admittedly, one cannot entirely disentangle the two scales, as mesoscale activity does  
75 affect the position of fronts, stratification, and the paths of ocean circulation (Marshall et al., 2002;  
76 Marzocchi et al., 2015; Chassignet and Xu, 2017). Yet, with equilibration times for the deep ocean on the  
77 scale of thousands of years (Irving et al., 2021), the possibility, and ultimately necessity, to reduce the  
78 resolution of spin-up runs relative to production runs must be investigated.

79 Advancing the concept of dynamic temporal allocation of resources further, the traditional  
80 transient climate change simulation also represents an efficiency bottleneck for some applications; by  
81 modifying the climate continuously in time, each year of a transient simulation is effectively a single  
82 realization of a global mean climatic state that varies from the following and preceding years by only a  
83 fraction of a degree. For some applications, like hindcasts of real events or trend analysis, this approach  
84 may be desirable, but for assessing the impacts of climate change with limited resources and a low signal-  
85 to-noise ratio, a larger sample of realizations for a consistent climatic state may be more suitable.

86 Aside from oceanic concerns, the atmosphere can have substantial impacts on mesoscale activity  
87 in climate models. Most simply, with a coupled atmosphere, absolute surface winds will react to ocean  
88 eddy activity, whereas atmospheric forcing will not, resulting in more eddy killing by wind stress  
89 (Renault et al., 2016). Additionally, an atmosphere coupled to a high-resolution ocean must be of  
90 similarly high resolution for certain mesoscale interactions to be resolved (Byrne et al., 2016). Ultimately,  
91 the modeled atmosphere further escalates the already exponential cost of increasing ocean resolution by  
92 requiring more computational resources in order for the benefits of the resolved mesoscale to fully  
93 transfer to the broader climate.

94 To address the computational inefficiencies outlined above, an experimental novel simulation  
95 configuration is proposed, combining several experimental modeling approaches. Simulations will exploit

96 the multi-resolution Finite volumE Sea-ice Ocean Model (FESOM) (Danilov et al., 2017) employing a  
97 high-resolution unstructured mesh that concentrates computational resources on the Southern Ocean,  
98 while maintaining grid resolution in the remainder of the global ocean that can still be considered high-  
99 resolution, as in, for example, HighResMIP (Haarsma et al., 2016). The multi-resolution strategy  
100 overcomes the efficiency challenges of resolving high-latitude eddies without needlessly increasing  
101 tropical resolutions, as well as limiting the focus and computational requirements to one hemisphere. The  
102 high-resolution simulations will make use of a spin-up simulation on a medium-resolution, eddy-  
103 permitting mesh to avoid the computational burden of allowing an eddy-resolving ocean to equilibrate  
104 deep, slow-changing processes. The eddy-permitting mesh will also be used to simulate the transient  
105 periods between shorter, high-resolution time slices, increasing the signal-to-noise ratio of the results by  
106 separating the production data further in time and the progression of anthropogenic climate change.  
107 Finally, the ocean model will be forced with atmospheric data from existing coupled simulations  
108 (Semmler et al., 2020). Although this will not facilitate mesoscale atmosphere-ocean interaction, the  
109 simulation will reflect the climatic development of an eddy-permitting simulation of the future  
110 atmosphere without the additional computational requirements.

111 The Southern Ocean is one of the world's hotspots for mesoscale activity and a region where  
112 substantial change is anticipated in the context of anthropogenic climate change (Beech et al., 2022).  
113 Simultaneously, the high latitude of the region makes eddy-resolving model simulations computationally  
114 demanding and observational data relatively scarce (Auger et al., 2023; Hallberg, 2013). Yet, as the  
115 climate changes, the importance of the Southern Ocean grows as a heat and carbon sink, an ecosystem,  
116 and a medium for feedback between the atmosphere and ocean (Byrne et al., 2016; Frölicher et al., 2015).  
117 Thus, the study of the Southern Ocean demands innovation in the modeling field to produce high-  
118 resolution simulations at reduced computational cost. This study maximizes grid resolution relative to  
119 computational cost using an unstructured, multi-resolution grid, a medium-resolution spin-up simulation,  
120 and atmospheric forcing from lower-resolution coupled simulations in order to focus resources as much as

121 possible on resolving mesoscale activity in the study region. The resulting simulations enable an  
122 exploratory analysis of the past, present, and future of the Southern Ocean with a fully resolved  
123 mesoscale. Simulations with this cost-efficient, high-resolution configuration are presented in comparison  
124 to a comprehensive ensemble of eddy-permitting simulations to assess the performance of the efficiency-  
125 focused approach in reproducing mesoscale activity and its response to climate change.

126 **2 Methods**

127 **2.1 Experimental setup**

129 This analysis ~~contrasts is broadly a comparison of results from a subset of simulations from AWI-~~  
130 ~~CM-1-1-MR's contribution to the sixth phase of the Coupled Model Intercomparison Project (CMIP6;~~  
131 ~~(Semmler et al., 2020). AWI CM-1-1-MR's contribution to CMIP6~~ (hereafter referred to as ~~the~~ AWI-  
132 CM-1 ~~ensemble~~) ~~(Semmler et al., 2020)~~ ~~with and~~ single-member stand-alone ocean simulations using an  
133 updated version of FESOM (FESOM 2.5) and a mesh substantially refined to a resolution ~~reaching less~~  
134 ~~than surpassing~~ 3 km in the Southern Ocean (hereafter referred to as ~~the~~ SO3 ~~simulations~~) (Supplementary  
135 Figure 1). Observations of ocean surface velocity derived from satellite altimetry data are also used to  
136 evaluate ~~the model performance of each simulation~~ ~~model performance for both modeled datasets during~~  
137 ~~the period of overlap with the altimetry record~~. The AWI-CM-1 simulations ~~consist of the five-member~~  
138 ~~ensemble of historical simulations and the five-member ensemble of climate change projections under~~  
139 ~~shared socioeconomic pathway (SSP) 3-7.0 which were performed by AWI-CM-1-1-MR in CMIP6~~  
140 (Semmler et al., 2020). ~~These are~~ state-of-the-art CMIP6 experiments and benefit from the multiple  
141 ensemble members and long spin-up times that CMIP simulations typically boast. However, while the  
142 AWI-CM-1 ensemble reproduces eddy activity remarkably well within the context of CMIP6 (Beech et  
143 al., 2022), high-resolution ocean modeling now far surpasses even the highest ocean resolutions in the  
144 CMIP6 ensemble. Conversely, the SO3 simulations push the limits of ocean resolution but rely on several

← **Formatted:** Add space between paragraphs of the same style

← **Formatted:** Indent: First line: 0 cm

145 measures for maximizing computational efficiency that may impact the robustness of the simulations.  
146 Details on the experimental setup for CMIP6 and ScenarioMIP are widely available (Eyring et al., 2016;  
147 O'Neill et al., 2016) and information more specific to AWI-CM-1-1-MR's contribution has been  
148 published previously (Semmler et al., 2020). The following sections will outline the details of the SO3  
149 simulations.

150 ~~To produce initial conditions for the high-resolution model simulations on the SO3 mesh, The~~  
151 ~~model experiments with SO3 consist of~~ a medium-resolution, eddy-permitting, ocean-only transient  
152 ~~simulation was first run~~ from 1851 ~~to~~ 2100 ~~using the same ocean mesh employed by AWI-CM-1-1-MR~~  
153 ~~in CMIP6~~ (Semmler et al., 2020). ~~This mesh has~~ and three shorter simulations with the SO3 mesh at  
154 ~~different time periods during the progression of anthropogenic climate change. The medium resolution~~  
155 ~~transient run is a stand-alone ocean simulation using a medium resolution mesh that has~~ been shown to  
156 effectively reproduce eddy activity in active regions while maintaining a computational cost comparable  
157 to a traditional  $\frac{1}{4}$  ° model (Beech et al., 2022). The ~~transient simulation model was~~ initialized with  
158 conditions for ocean temperature and salinity, as well as sea ice concentration, thickness, and snow cover  
159 taken from the end of the first year (1850) and first ensemble member (r1i1p1f1) of AWI-CM-1-1-MR's  
160 historical simulations in CMIP6 (Semmler et al., 2018, 2020, 2022a, b). In this way, the model undergoes  
161 a semi-cold start in which ocean conditions are not exact continuations of the previous coupled  
162 simulation, but ~~should be far closer to equilibrium than a true cold start initialization nonetheless benefit~~  
163 ~~from more realistic and partially equilibrated ocean properties. The stand-alone ocean is eddy-permitting~~  
164 ~~transient simulation was~~ forced using atmospheric data from the same ensemble member of the historical  
165 CMIP6 simulations until 2014 (Semmler et al., 2022a), and thereafter using the first ensemble member of  
166 AWI-CM-1-1-MR's ScenarioMIP simulations for ~~shared socioeconomic pathway (SSP)~~ 3-7.0 (Eyring et  
167 al., 2016; O'Neill et al., 2017; Semmler et al., 2022b). This approach to forcing takes advantage of a  
168 coupled simulation, CMIP6, to produce a forcing dataset of better temporal and spatial coverage than the

169 observational record and which maintains a realistic transient climate throughout anthropogenic impacts  
170 during the 21<sup>st</sup> century.

171 In the years 1950, 2015, and 2090, ~~the model~~FESOM is reinitialized with the ~~higher~~-resolution  
172 ocean grid, SO3 (Supplementary Figure 1), using the same semi-cold start approach and forcing dataset  
173 ~~that was implemented for the eddy-permitting transient simulation described previously. These years were~~  
174 ~~chosen to represent a historical period, beginning in 1950, when the effects of climate change on EKE~~  
175 ~~should be small or none~~ (Beech et al., 2022); ~~a near-present period, beginning in 2015, in which the~~  
176 ~~simulations will overlap with satellite altimetry data; and a projected period, beginning in 2090, which~~  
177 ~~should include a strong climate change signal. The latter two simulated periods represent 1.07 °C and~~  
178 ~~3.74 °C of warming, respectively, in the first ensemble member of the AWI-CM-1 ensemble defined as a~~  
179 ~~rise in the 21-year running mean of global mean two-meter air temperatures. Warming of the ensemble~~  
180 ~~mean is similar: 1.08 and 3.76 °C respectively, and warming is henceforth approximated as 1 °C and 4 °C~~  
181 ~~in Figure 4 and the text, as well as~~ ~~I~~initial conditions ~~for these shorter time-slice simulations are taken~~  
182 from the end of the previous year of the ~~eddy permitting~~eddy-permitting transient simulation. ~~The high-~~  
183 ~~resolution simulations are each integrated for six years with the first year ignored as a true spin-up,~~  
184 ~~leaving five years of data for each time period. While model drift may be a concern with such a short true~~  
185 ~~spin up period, this should affect each of the high resolution time slices similarly and to a limited extent~~  
186 ~~due to their short integration lengths. Thus, the differences between the high resolution ocean simulations~~  
187 ~~should primarily reflect anthropogenic climate impacts simulated during the eddy permitting transient~~  
188 ~~run.~~ The high-resolution grid is, in truth, a regionally refined mesh in which a 25 km global resolution is  
189 ~~increased-refined~~ to approximately 2.5 km, ~~following~~ ~~Danilov, (2022)~~, primarily south of 40 °S, but with  
190 other pertinent regions, such as the Agulhas Current and several narrow straits, also refined. In this way,  
191 the model is able to simultaneously achieve eddy-rich conditions in the Southern Ocean and many of the  
192 nearby active regions, as well as a global resolution that would still be considered high in the context of  
193 CMIP6 (Hallberg, 2013; Hewitt et al., 2020). ~~While model drift may be a concern with such a short true~~

194 spin-up period, this should affect each of the high-resolution time slices similarly and to a limited extent  
195 due to their short integration lengths. Thus, the differences between the high-resolution ocean simulations  
196 should primarily reflect anthropogenic climate impacts simulated during the eddy-permitting transient run  
197 and present in the forcing dataset. The high resolution simulations are each integrated for six years with  
198 the first year ignored as a true spin-up, leaving five years of data for each time period. While model drift  
199 may be a concern with such a short true spin-up period, this should affect each of the high-resolution time  
200 slices similarly and to a limited extent due to their short integration lengths. Thus, the differences between  
201 the high-resolution ocean simulations should primarily reflect anthropogenic climate impacts simulated  
202 during the eddy-permitting transient run.

203 **2.2 Model configuration**

204 The Finite volume Sea-ice Ocean Model version 2.5 is a post-CMIP6 era model, having been  
205 refactored to a finite-volume configuration from the finite-element version (FESOM1.4, Q. Wang et al.,  
206 2014) employed in CMIP6, and transitioned to arbitrary Lagrangian Eulerian (ALE) vertical coordinates,  
207 among other improvements (Danilov et al., 2017; Scholz et al., 2019, 2021). FESOM's most  
208 distinguishing feature among mature ocean models is the unstructured horizontal grid that exploits  
209 triangular grid cells which can smoothly vary in size to change the horizontal grid resolution in space. In  
210 these simulations, full free surface, or  $z^*$ , vertical coordinates were used, allowing the vertical model  
211 layer thicknesses to change in time. Gent-McWilliams eddy parameterization (Gent and McWilliams,  
212 1990) is scaled with resolution according to Ferrari et al. (2010) and vertical mixing is simulated by a  $k$ -  
213 profile parameterization scheme (Large et al., 1994).

214 The SO3 mesh consists of over 22 million surface elements (triangle faces) or 11 million surface  
215 nodes (triangle vertices) and 70 vertical layers. The simulations produce about 1.1 terabytes of data per  
216 year of 3D data stored on nodes. For reference, the medium-resolution mesh used in the AWI-CM-1  
217 ensemble is 1.6 million surface elements or 0.83 million surface nodes and 46 vertical layers and  
218 produces approximately 56 GB per year of 3D data stored on nodes. The model was run on 8192 CPU

219 cores and with a typical throughput of approximately 0.65 simulated years per day, consuming  
220 approximately 5.5 million CPU hours in total despite the various cost-saving modeling approaches. It  
221 should be noted, however, that the throughput in high-resolution production simulations like this is highly  
222 dependent on the volume and choice of data being saved. The simulations and following analysis were  
223 performed using the high-performance computing system, Levante, at the German Climate Research  
224 Computing Center (DKRZ).

225 The ocean model is forced by several atmospheric variables at a six-hour resolution, although one  
226 forcing variable, humidity, is interpolated monthly data. The forcing data is first interpolated to a regular  
227 grid which can be interpreted by the model and appliedsupplied to the model on the regular atmospheric  
228 grid used in the coupled setup during AWI-CM-1-1-MR's CMIP6 simulations (Semmler et al., 2018) and  
229 interpolated to the multi-resolution grid used in the respective simulations by FESOM. Runoff data is a  
230 monthly climatology and dynamic ice sheet coupling is not included, meaning the freshwater influx from  
231 the Antarctic continent does not react to warming which may impact certain processes, such as the timing  
232 and intensity of sea ice loss (Pauling et al., 2017; Bronselaer et al., 2018).

## 233 2.3 Geostrophic Modeled ocean velocity dataies

234 Ocean velocities in the SO3 simulations are saved on a daily timescale as direct model output,  
235 whereas  
236 (Semmler et al., 2018) in the AWI-CM-1 ensemble, only monthly data is available and daily data  
237 must first be derived from sea surface height data and geostrophic balance as in equations (1) and  
238 (2). Geostrophic balance is an idealized approximation that does not match real ocean velocities for  
239 several reasons, including the presence of ageostrophic flow, such as Ekman transport, as well as  
240 assumptions made in the derivation of equations (1) and (2). Specifically, geostrophic balance between  
241 the Coriolis effect and the pressure gradient is valid under the assumption that the curl of horizontal  
242 velocities or vorticity is small relative to the magnitude of overall flow. In models, this assumption is

Formatted: Not Highlight

Formatted: Not Highlight

243 relatively close to reality in coarse-resolution simulations where geostrophic flow dominates, but on  
244 higher-resolution meshes, where submesoscale flows are well-resolved, these omitted terms become  
245 larger. Therefore, while using geostrophic velocities for both high-resolution and coarse-resolution  
246 modeled datasets would be methodologically consistent, the error introduced would be systemically larger  
247 for the finer-resolution dataset than the coarser. Therefore, we do not consider the use of geostrophic  
248 velocities for both modeled datasets in this analysis to bring the data into closer agreement. Rather, for the  
249 AWI-CM-1 dataset, where daily ocean velocities were not saved (Semmler et al., 2018), geostrophic  
250 velocities derived from sea surface height with equations (1) and (2) are the best possible choice, and  
251 fortunately, as described earlier, the error introduced by the assumptions of geostrophic balance will be  
252 small. For the SO3 simulations, direct model output was saved and is preferred, particularly given the  
253 high resolution of the mesh. (Taburet et al., 2019)

254  $u = -g/f^* \partial \text{SSH} / \partial y$  (1)

255  $v = g/f^* \partial \text{SSH} / \partial x$  (2)

256

257 The omission of Ekman transport, the primary source of ageostrophic oceanic flow from atmospheric  
258 influences, can be relatively well addressed in the SO3 dataset by selecting modeled velocities just below  
259 the Ekman layer. At depths of 25-30m below sea level, the bulk of Ekman transport can be avoided (Price  
260 et al., 1987), while velocities should not substantially differ from those at the surface. What ageostrophic  
261 flow remains in the model output velocities should be primarily large-scale and overshadowed small  
262 relative to geostrophic flow in the high-energy regions of the ocean, including the ACC (Yu et al.,  
263 2021).

264 **2.4 Altimetry data**

265 An observational data product of gridded, daily geostrophic velocities derived from along-track  
266 satellite altimetry from crossover data is taken from the Data Unification and Altimeter Combination

267 System (DUACS) (Taburet et al., 2019). The gridded product has a resolution of 0.25 °, although  
268 effective resolution at high latitudes may be much lower (Ballarotta et al., 2019). Recently, improved data  
269 has become available in the ice-covered regions of the Southern Ocean (Auger et al., 2022), but does not  
270 yet cover the full present-day simulated period (2016-2020) in this study. Absolute velocities from the  
271 gridded altimetry product were used to calculate anomalies and EKE using equations (3) and (4) below  
272 for consistency with the modeled dataset.

273 ~~To avoid including ageostrophic contributions to ocean surface velocity in this analysis, model output~~  
274 ~~velocity between 25 m and 30 m depth is used for the SO3 dataset. This depth should be close enough to~~  
275 ~~the surface to closely match surface geostrophic flows while also avoiding Ekman transport, a major~~  
276 ~~contributor to ageostrophic ocean flow. What ageostrophic flow remains in the model output velocities~~  
277 ~~should be primarily large scale and overshadowed by geostrophic flow in the high energy regions of the~~  
278 ~~ocean, including the ACC (Yu et al., 2021).~~

279  $u = g/\rho^* \partial \text{SSH} / \partial y$  (1)

280  $v = g/\rho^* \partial \text{SSH} / \partial x$  (2)

281 **2.5 EKE analysis**

282 Velocity anomalies are defined by subtracting the multi-year monthly climatology of each  
283 respective 5-year period from daily velocities with equation (3).

284  $u'_i = u_i - \bar{u}_m$  (3)

285 Where  $u_i$  is the daily zonal velocity,  $'$  denotes an anomaly, and  $\bar{u}_m$  is a monthly mean. For meridional  
286 velocities ( $v$ ) substitute  $u$  with  $v$ .

287 Eddy kinetic energy is calculated from ocean velocities according to equation (4).

288  $EKE_i = 0.5(u'^2 + v'^2)$  (4)

**Formatted:** Font: Bold, Not Italic

**Formatted:** Font: Bold, Not Italic

289 Where  $(\cdot)$  denotes a daily value and  $(\cdot - \bar{\cdot})$  denotes an anomaly.

290 EKE was calculated on the native grid of each dataset and then interpolated to a  $0.25^\circ$  grid for all

291 analyses. IEKE in Figures 1 and 3, EKE was first calculated on a daily timescale and coarsened to five-

292 day means before analysis to reduce computational costs during post-processing. Area-integrated EKE

293 (Figure 1, 3) is calculated by summing the area-weighted EKE of each grid cell in the study region

294 defined as the zonal band between  $45^\circ\text{S}$  and  $65^\circ\text{S}$ , with the The Brazil/Malvinas confluence region

295 between  $57^\circ\text{E}$  and  $29^\circ\text{E}$  and northward of  $40^\circ\text{S}$  is removed to focus the study on a region with

296 consistent physical drivers theorized to be responsible for the changes in eddy activity (Beech et al.,

297 2022). As a precaution, Each dataset was linearly detrended before analysis in

298 Figures 1 and 3 to avoid artificially increasing the range of the later distributions due to the accelerating

299 climate change signal. Select statistical properties are reported in Supplementary Tables 1-3 to indicate

300 deviations from normality (D'Agostino and Belanger, 1990; Fisher, 1997) and autocorrelation (Durbin

301 and Watson, 1950). Rather than attempt to manipulate the data to meet certain statistical assumptions,

302 complex statistical tests are avoided and the statistical properties reported can be used to interpret the

303 EKE data in a physical sense. EKE anomalies (Figure 1) were calculated by subtracting the 2016-2020

304 mean of area-integrated EKE from the EKE 5-day mean values data of each period. Normalized EKE

305 was calculated by further dividing EKE anomaly by the standard deviation of EKE during the 2016-2020

306 period. In Figure 4, ensemble agreement is determined by ordering the  $\Delta\text{EKE}$  values within each grid cell

307 from lowest to highest, plotting the positive values in increasing order from left to right and negative

308 values in decreasing order from left to right.

### 309 3 Results

#### 310 3.1 Agreement with observations

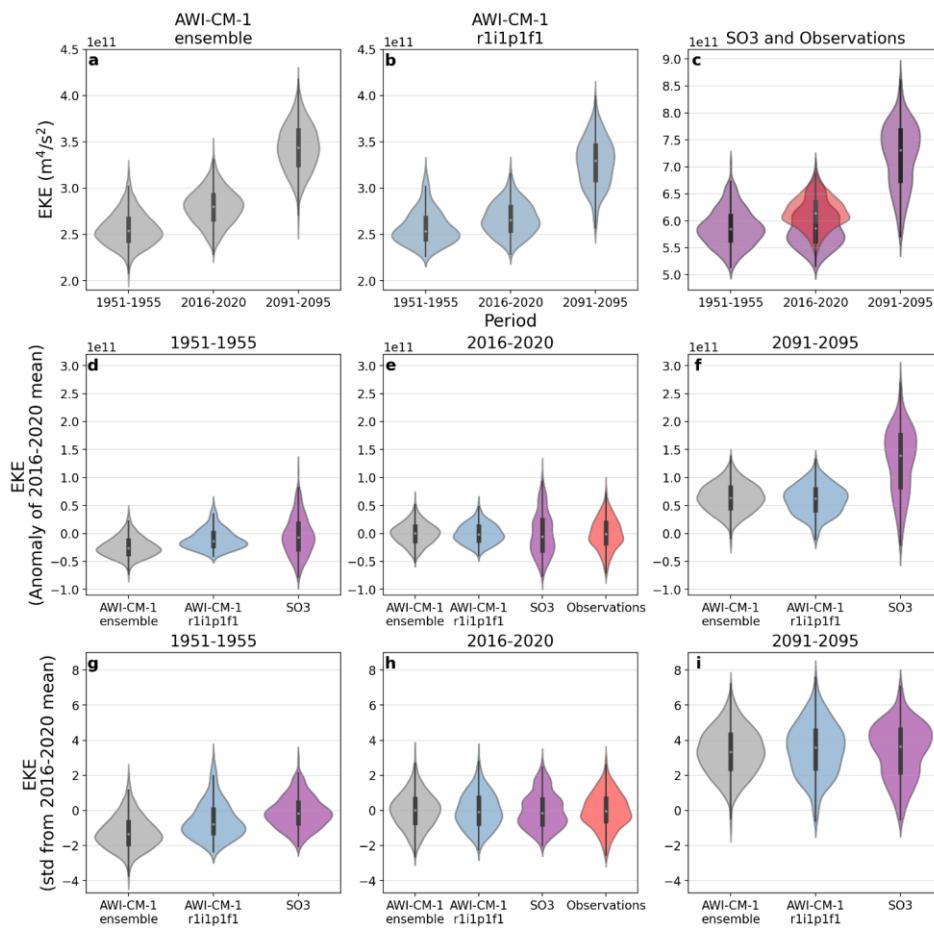

311 During the five-year period of overlap with observations, the SO3 simulation is a drastic

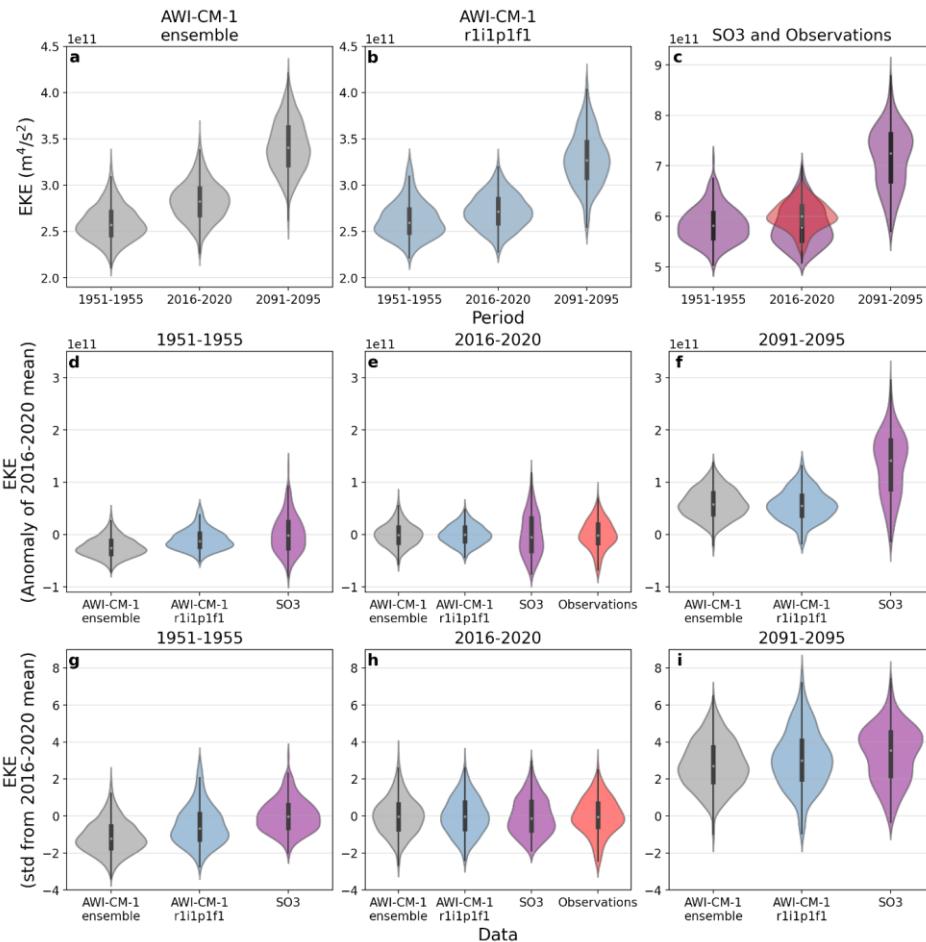

312 improvement on the AWI-CM-1 ensemble in reproducing median observed EKE (Figure 1a, c); only a

← **Formatted:** Add space between paragraphs of the same style

313 slight underrepresentation of EKE remains in the SO3 simulation, although the simulated distribution  
314 ~~remains is somewhat distinct from observations, whereas~~<sup>5</sup> ~~in comparison,~~ the AWI-CM-1 ensemble, ~~being~~  
315 ~~effectively eddy-permitting in the Southern Ocean,~~ underrepresents observations by ~~approximately~~<sup>about</sup>  
316 ~~550%~~ (Figure 1a, c, ~~note the different y-axis~~). EKE in SO3 appears more variable than the observations  
317 ~~considering as can be inferred from the its~~ larger range, (Figure 1c, e) ~~and~~<sup>4</sup>, ~~and in general, the modeled~~  
318 ~~datasets display greater deviations from a normal distribution than the observations (Figure 1a, b, c;~~  
319 ~~Supplementary Table 2).~~ ~~ts~~ distribution appears less Gaussian than observations or the eddy permitting  
320 ~~dataset (Figure 1a, b, c).~~ Taking the AWI CM 1 ensemble as an example, there is no consistent pattern of  
321 ~~multimodality or skewness and the ensemble mean more closely approximates the normal distribution~~  
322 ~~than the individual members (Figure 3), suggesting that deviations from normality could be primarily due~~  
323 ~~to sample size rather than the character of the data.~~ (Beech et al., 2022) ~~Nonetheless, i~~Relative to the  
324 AWI-CM-1 model bias and the magnitude of EKE resolved, the ensemble spread within the AWI-CM-1  
325 dataset is small (Figure 3), suggesting that a single ensemble member of five years duration is sufficient  
326 to assess how well a model captures the ~~overall~~ magnitude of ~~overall~~ Southern Ocean EKE (Figure 1c).

338 From a regional perspective, the SO3 simulation accurately reflects local magnitudes of observed  
339 EKE and also generally captures the spatial distribution well (Figure 2). However, there are regional  
340 shortcomings, such as between 90 and 145 °E. Grid resolution in this region should be sufficient to  
341 resolve eddy activity (Supplementary Figure 1), indicating that the bias arises from another source. In the  
342 AWI-CM-1 ensemble, the regional representation of EKE reinforces a broad underrepresentation relative  
343 to observed magnitudes, but the major geographic features of eddy activity are fairly well represented  
344 (Figure 2). Once again, the ensemble spread within the AWI-CM-1 simulations reveals remarkable  
345 consistency, this time in terms of the spatial pattern and regional magnitudes (Supplementary Figure 2),  
346 reinforcing the conclusion that a single ensemble member of five years duration is sufficient to assess the  
347 mean state of EKE in the Southern Ocean. The consistency of the AWI-CM-1 ensemble further suggests  
348 that regional shortcomings in eddy activity in the SO3 simulations are not a product of variability within a  
349 single realization of Southern Ocean conditions (Supplementary Figure 2).

353

354     3.2 EKE change and significance

355           Southern Ocean eddy activity has been shown to intensify over the recent decades both using  
356           satellite altimetry (Martínez-Moreno et al., 2021), and the complete AWI-CM-1-1 dataset from CMIP6  
357           (Beech et al., 2022). Even after reducing the AWI-CM-1 CMIP6 dataset to five-year periods preceding  
358           the apparent change (1951-1955) and at the end of the altimetry era (2016-2020), this intensification is  
359           still discernable within the AWI-CM-1 ensemble (Figure 1a). Despite this, the SO3 simulations do not  
360           demonstrate any substantial change in EKE magnitude over the same period (Figure 1). Further reducing  
361           the ensemble to its individual members (Figure 3), the EKE rise is still relatively, relatively, clear, robust in  
362           each case, including clear separation of the datasets -considering the median, mode, and first and third  
363           ~~quartiles, distribution~~ of the data distributions (Figure 3). However, the, first ensemble member, from  
364           which the atmospheric forcing of SO3 is taken, demonstrates less EKE rise than the ensemble average  
365           (Figure 3), suggesting that natural variability in atmospheric conditions may contribute to the  
366           disagreement. Further investigation reveals several differences between the SO3 simulations and the  
367           AWI-CM-1 ensemble members that may play a role. Mean zonal ocean velocity in SO3 is faster and  
368           broader than the AWI-CM-1 ensemble (Supplementary Figure 3), meaning wind speed intensification  
369           may be misaligned with peak ocean velocities in SO3, particularly around 47 to 51 °S. Moreover,  
370           considerably less zonal wind stress is imparted to the ocean in SO3 despite identical wind speeds as the  
371           first AWI-CM-1 ensemble member (Supplementary Figure 4), possibly due to the higher ocean surface  
372           velocity.  
373           suggesting again, that natural or internal variability is not responsible for the discrepancies between  
374           simulations. Therefore, despite the first AWI-CM-1 ensemble member, from which the SO3 simulations  
375           receive their atmospheric forcing, producing lower than average EKE rise over this period (Figure 3), it is  
376           likely that other factors (Renault et al., 2016) also contribute to the lack of change in the SO3  
377           simulations. (Renault et al., 2016)

Formatted: Style1, Line spacing: single

378 The intensification of EKE becomes clear in both the AWI-CM-1 ensemble (Figure 1a), its  
379 members (Figure 3), and the SO3 simulations (Figure 1c) by the end of the 21<sup>st</sup> century. Over this period,  
380 the variability of EKE, indicated by the range of the distribution, also increases for each dataset (Figure  
381 1f, i). EKE rise in SO3 is approximately ~~three times twice~~ that of the AWI-CM1 ensemble in absolute  
382 terms (Figure 1f), but expressing EKE as a relative value normalized by the mean and standard deviation  
383 of each dataset during the observational period (Figure 1g, h, i), reveals greater consistency between the  
384 changes until the end of the 21<sup>st</sup> century. EKE in each dataset appears to increase by approximately ~~3.53~~  
385 standard deviations, and the range of EKE distributions increases by approximately ~~two one~~ to ~~three two~~  
386 standard deviations (Figure 1h, i). However, the datasets also tend to become more autocorrelated, which  
387 can inflate the distribution range (Supplementary Tables 1, 3).

389

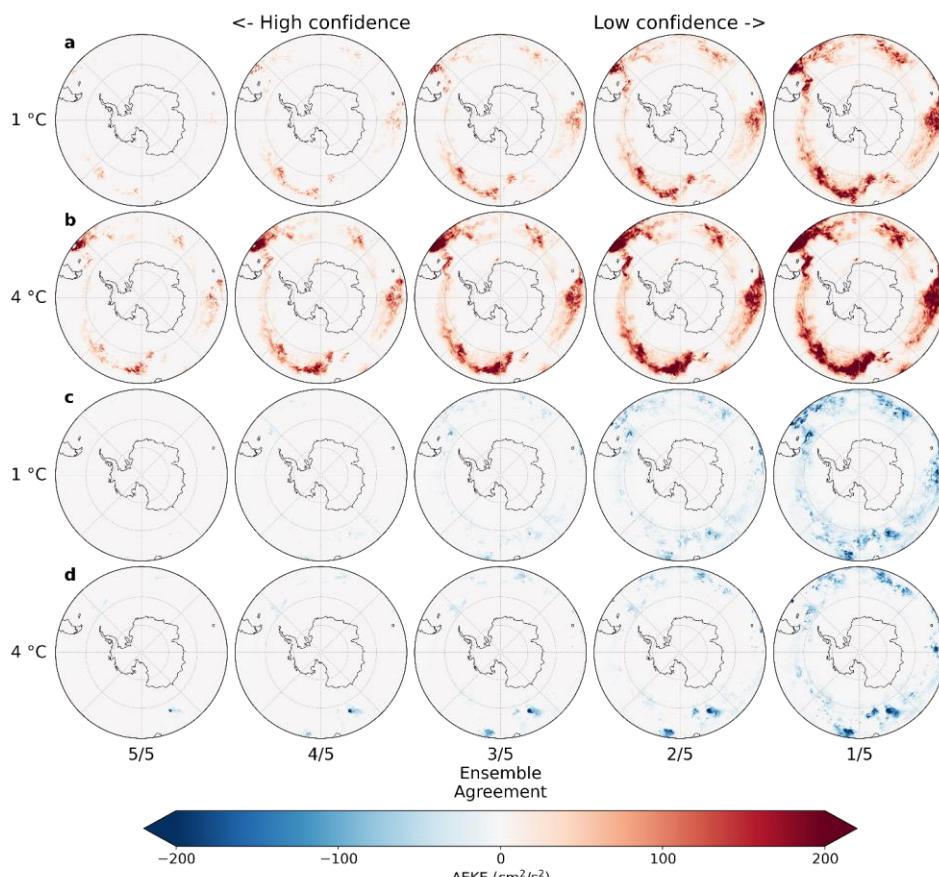

390 **Figure 3. Ensemble spread of EKE in AWI-CM-1.** **a)** Violin plots of area-integratedmean Southern  
 391 Ocean EKE in the AWI-CM-1 ensemble. **b)** Violin plots of mean Southern Ocean EKE in each member  
 392 of the AWI-CM-1 ensemble. Grey plots represent the period 1951-1955, blue plots represent 2016-2020,  
 393 and purple plots represent 2091-2095.

394 Before considering the regional impacts of warming on EKE in the SO3 simulations, it is useful  
 395 to refer to the ensemble spread within the AWI-CM-1 simulations to approximate the reliability of a  
 396 single ensemble member in revealing the ensemble-mean change as an analogue to the signal-to-noise  
 397

← **Formatted:** Add space between paragraphs of the same style

398 ratio. At 1 °C of warming, EKE change in the ensemble is weak, with at least one ensemble member  
399 tending to show little or no EKE change in most regions (Figure 4a,c). Only a few clear patterns of  
400 change emerge throughout the ensemble, namely the regions of EKE intensification downstream of the  
401 Kerguelen Plateau and the Campbell Plateau where four to five out of five ensemble members show clear  
402 EKE intensification (Figure 4a). It should be noted that even in these regions of relatively high confidence  
403 (4 to 5 ensemble members, Figure 4a) EKE rise can be interspersed with lower-confidence (1 to 2  
404 ensemble members, Figure 4c) EKE decline; this is also illustrated by the ensemble mean changes  
405 themselves (Supplementary Figures [52](#), [63](#)). Despite this, the consistency of EKE rise in these regions,  
406 and their geographic positions in already EKE-rich regions, suggests that the intensification patterns are  
407 robust changes within substantial noise. This level of noise suggests that EKE changes in the SO3  
408 simulations at 1 °C of warming will be difficult to distinguish from natural variability when taken on their  
409 own; indeed, in the SO3 simulations, the large variability of both sign and magnitude of change within  
410 relatively small spatial scales does not lend confidence to any significant change at 1 °C of warming  
411 (Figure 5c). However, building on the changes observed in the AWI-CM-1 ensemble, the intensification  
412 of EKE downstream of the Kerguelen and Campbell Plateaus seems to be reinforced by the high-  
413 resolution simulations.

414

415 **Figure 4. Ensemble agreement regarding EKE change.** EKE rise (a, b) and decline (c, d) within the  
 416 AWI-CM-1 ensemble after one (a, c) and four (b, d) °C of warming or between 1951-1955 and 2016-  
 417 2020 and 2091-2095, respectively, arranged in order of decreasing ensemble agreement regarding change  
 418 in each grid cell. Ensemble agreement refers to the number of ensemble members that simulate at least the  
 419 pictured magnitude of mean EKE rise or decline for each grid cell. Mean EKE change is defined as the  
 420 difference of mean EKE between 1951-1955 and each of the two latter periods, as in Supplementary  
 421 Figures 5 and 6 but arranged in ascending order of magnitude for each grid cell and for positive and  
 422 negative signs separately. Rank 5/5 indicates the lowest magnitude of mean EKE rise (a, b) or decline (c,

**Formatted:** Font: Bold

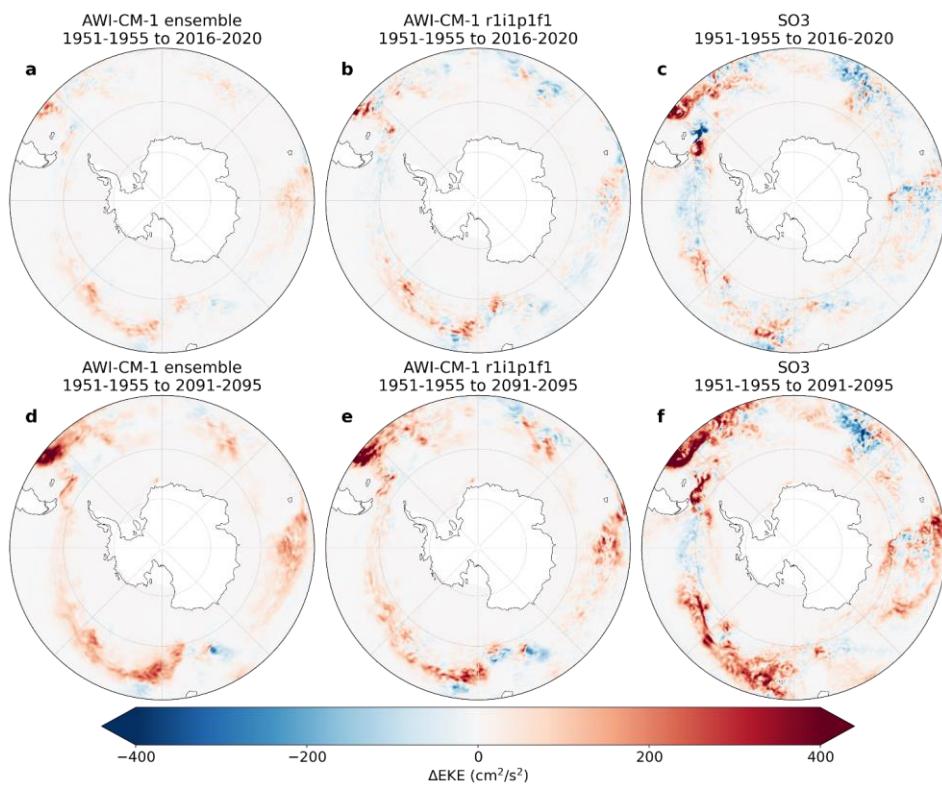

423 d) within the ensemble for a given grid cell, meaning the entire ensemble agrees on at least this much  
424 change. Rank 1/5 indicates the highest magnitude of EKE rise or decline within the ensemble for each  
425 grid cell, representing the upper limit of projected EKE change.

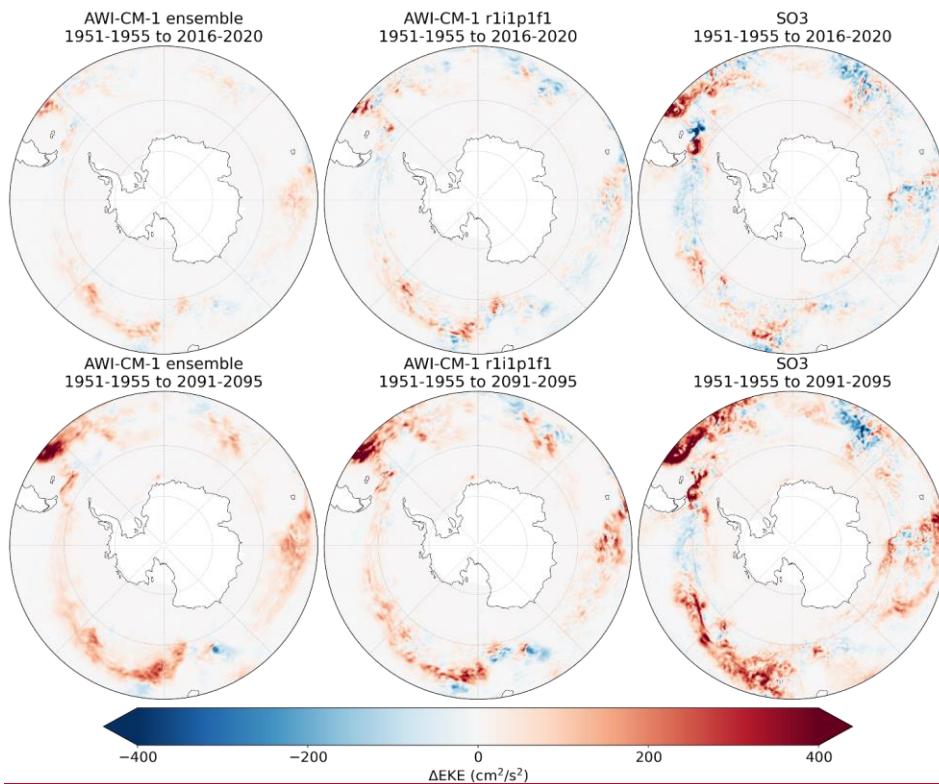

426

427 At 4 °C of warming, change in eddy activity becomes clearer; EKE intensification downstream of  
428 the Kerguelen and Campbell Plateaus is now consistent throughout the entire AWI-CM-1 ensemble, along  
429 with additional intensifications south of the Falkland/Malvinas Plateau, around the Conrad Rise, and  
430 along the Antarctic Slope Current at approximately 5 °E (Figure 4b). Four fifths of the ensemble also  
431 include a broad increase in EKE throughout the ACC across most longitudes. Interestingly, a consistent  
432 pattern of EKE decline also emerges upstream of the Campbell Plateau in the entire ensemble (Figure 4d).  
433 The spatial pattern of EKE rise is relatively consistent regardless of confidence, with only the magnitude  
434 increasing in the lower confidence composites (Figure 4b). The same tendency is observable between the  
435 EKE changes at 1 and 4 °C of warming, where the magnitude of change is greater after further warming  
436 but follows the same spatial pattern. Thus, regions of intensification can be identified more reliably than  
437 the magnitude of change and tend to be concentrated where flow interacts with topographic features, in  
438 already eddy-rich regions (Figure 2). Conversely, low confidence EKE decline appears nearly throughout  
439 the Southern Ocean in at least one ensemble member, but only consistently upstream of the Campbell  
440 Plateau and, to a far lesser extent, downstream of the Drake Passage and Campbell Plateau (Figure 4d).  
441 Changes of negative sign tend to be of lower magnitude at 4 °C of warming than at 1 °C. This suggests  
442 that in any given single ensemble simulation, a robust general intensification of EKE tends to occur~~the~~  
443 general EKE response to climate change in the Southern Ocean is that of intensification, and the  
444 interspersed signals of decline tend to be the result of ~~but can be interspersed with spurious signals of~~  
445 decline~~natural variability~~. Yet, small regions of high-confidence EKE decline ~~are also possible, also~~  
446 appear~~however~~uncommon. Consequently, it would be difficult to confidently separate reliable EKE  
447 change from natural variability in simulations without an ensemble to compare with. In the SO3

448 simulations, EKE rise downstream of the Drake Passage and Kerguelen and Campbell Plateaus is  
449 substantial (Figure 5f). EKE rise is also projected south of the Falkland/Malvinas Plateau, around the  
450 Conrad Rise, and along the Antarctic Slope Current at approximately 5 °E, and a slight EKE decline  
451 appears upstream of the Campbell Plateau. All of this is comparable to the AWI-CM-1 ensemble, and the  
452 interspersed areas of EKE decline within these regions, for example, around the Conrad Rise, are not  
453 improbable based on the example set by AWI-CM-1 (Figure 4d). However, considering that some high-  
454 confidence EKE decline is present in the AWI-CM-1 ensemble, it is difficult to confidently dismiss  
455 regional EKE decline in the SO3 simulations as noise.

462  
463 **4 Discussion**

464 Intensification of eddy activity in the Southern Ocean is now widely accepted as a consequence  
465 of anthropogenic climate change (Hogg et al., 2015; Patara et al., 2016; Martínez-Moreno et al., 2021;  
466 Beech et al., 2022), and is understood to be caused primarily by stronger westerly winds imparting more  
467 energy to the Antarctic Circumpolar Current (Munday et al., 2013; Marshall, 2003). The results presented

468 here reinforce the notion of EKE intensification and further project increased EKE variability as the  
469 climate warms (Figure 1, 3). By expressing EKE change in terms of ensemble agreement on a cell-by-cell  
470 basis, the results presented here are also able to identify regions of reliable and substantial change as those  
471 where flow interacts with major bathymetric features, and high eddy activity is already known to occur  
472 (Figure 4). Understanding Analysis of regional changes within the Southern Ocean eddy field ~~has~~  
473 generally been limited to regions defined by oceanic sectors (Atlantic, Indian, Pacific) (Hogg et al., 2015),  
474 or incremental longitudinal delimitations (Patara et al., 2016). By expressing EKE change in terms of  
475 ensemble agreement on a cell by cell basis, the results presented here are able to identify regions of  
476 reliable and substantial change as those where flow interacts with major bathymetric features, and high  
477 eddy activity is already known to occur (Figure 4). In future research, regional analyses of ~~both~~ the  
478 significance, rate, and/or cause of EKE trends could focus on the bathymetrically defined~~these~~ regions  
479 identified in this analysis to to avoid confounding results with those of physically unrelated change within  
480 the chosen geographic delimitations~~produce physically related and consistent results.~~

481 The consistency of the AWI-CM-1 ensemble in projecting clear EKE rise in the Southern Ocean  
482 as a whole suggests that a single ensemble member of five-years simulation length should be sufficient to  
483 reliably identify change, even after 1 °C- of temperature rise. Despite this, the SO3 simulations fail to  
484 reproduce the EKE rise that is already observable through observations (Martínez-Moreno et al., 2021). A  
485 potential source for this discrepancy is the uncoupled model setup in the SO3 simulations which omits  
486 ocean-atmosphere feedbacks. In this regard, the SO3 simulations experience lower wind stress imparted  
487 to the ocean surface than AWI-CM-1 ensemble member one by the same surface winds (Supplementary  
488 Figure 4), and a mismatch between peak zonal wind speeds and mean zonal ocean velocities  
489 (Supplementary Figure 3). Confounding the comparison further, is the fact that strengthening winds can  
490 both increase and dampen eddy activity; as westerlies intensify, the additional energy imparted to the  
491 ocean is expected to strengthen eddy activity (Munday et al., 2013; Meredith and Hogg, 2006), but winds  
492 are also known to dampen mesoscale activity through eddy killing (Rai et al., 2021) and this impact is

493 greater in uncoupled model configurations (Renault et al., 2016). While the lack of change at 1 °C is  
494 difficult to explain, the disagreement is limited to these more subtle changes and the simulations tend to  
495 agree on the strong EKE rise at 4 °C of warming.

496 Considering the consistency of the AWI-CM-1 ensemble both in terms of representing regional mean  
497 EKE (Supplementary Figure 2), and projecting overall Southern Ocean EKE change (Figure 2), it appears  
498 that a larger ensemble of high resolution simulations is not necessary to assess local mean states and  
499 changes over the entire region. This also means that the discrepancies between the SO3 simulations and  
500 AWI-CM-1 ensemble remain unexplained. The SO3 simulations failed to reproduce the clear  
501 intensification of EKE present in the ensemble at 1 °C of warming (Martínez Moreno et al., 2021), which  
502 has already been identified in observations (Martínez Moreno et al., 2021). One potential explanation for  
503 this is the atmospheric forcing applied to the SO3 simulations which cannot react to oceanic conditions in  
504 the same way that the real atmosphere or coupled atmosphere of the AWI-CM-1 ensemble can.

505 Consequently, atmospheric forcing has been found to cause 27% more eddy killing by wind stress than  
506 coupled simulations (Renault et al., 2016). Since intensifying wind is widely considered the cause of EKE  
507 intensification in the Southern Ocean (Munday et al., 2013; Meredith and Hogg, 2006) (Meredith and  
508 Hogg, 2006; Munday et al., 2013; Hogg et al., 2015; Beech et al., 2022), the increase may be counteracted  
509 by a simultaneous increase in eddy killing.

510 The remaining discrepancies between eddy activity in SO3 and observations are relatively small,  
511 but Assuming that the medium resolution spin up simulation effectively imparts a generally equilibrated  
512 ocean to the SO3 simulations in terms of baroclinic and barotropic instability, exploring potential sources  
513 of disagreement may help to interpret the simulations and guide future modeling endeavors the remaining  
514 discrepancies between eddy activity in SO3 and observations should be largely identifiable. Greater skew  
515 in the distribution of EKE in the modeled dataset (Supplementary Table 2) could reflect multiple modes  
516 of circulation or seasonality. While seasonality of eddy activity in the ACC is low, seasonal ice cover  
517 likely affects eddy activity in the modeled dataset, and certainly affects the observational dataset by

518 producing gaps in its spatio-temporal coverage. Beyond differences in skew, this could contribute to the  
519 greater range of EKE seen in the SO3 simulations [by systemically obscuring seasonal conditions from the](#)  
520 [observational dataset](#). Regional deficiencies of EKE in SO3 could be explained in terms of grid resolution  
521 [outside of the study region](#); resolving the first Rossby radius of deformation with at least two grid points  
522 is not enough to comprehensively reproduce mesoscale activity (Hallberg, 2013; Sein et al., 2017), [and](#)  
523 [meaning](#) grid refinement may need to be expanded to upstream regions that impact eddy dynamics in the  
524 Southern Ocean. Other sources of bias may include ocean-atmosphere interactions which are absent or  
525 unrealistic within the uncoupled simulations (Byrne et al., 2016; Rai et al., 2021; Renault et al., 2016). As  
526 well, some small-scale, slow-to-equilibrate ocean processes may be resolved in the high-resolution  
527 simulations, but not be integrated long enough for their effects to impact eddy activity (van Westen and  
528 Dijkstra, 2021; Rackow et al., 2022). Finally, the gridded altimetry product itself may be responsible for  
529 some disagreement, as the along-track data is known to underrepresent eddy activity at scales less than  
530 150km and 10 days (Chassignet and Xu, 2017), which will be particularly impactful at high latitudes.

531 To distinguish a meaningful signal of anthropogenic impacts from natural variability, this  
532 analysis relies primarily on consistency among ensemble members (Figures 3, 4). This is distinct from  
533 more traditional methods like assessment of error relative to observations or ensemble mean, commonly  
534 applied to weather forecasting (Ferro et al., 2012), [but can be compared to measures of ensemble](#)  
535 [agreement used extensively in the IPCC reports](#) ADDIN ZOTERO\_ITEM CSL\_CITATION

539 D9"]}, {"itemData":{"id":500,"type":"article-journal","abstract":"Mesoscale eddies are ubiquitous features  
540 in the Southern Ocean, yet their phenomenology is not well quantified. To tackle this task, we use satellite  
541 observations of sea level anomalies and sea surface temperature (SST) as well as in situ temperature and  
542 salinity measurements from profiling floats. Over the period 1997–2010, we identified over a million

543 mesoscale eddy instances and were able to track about 105 of them over 1 month or more. The Antarctic  
544 Circumpolar Current (ACC), the boundary current systems, and the regions where they interact are hot  
545 spots of eddy presence, representing also the birth places and graveyards of most eddies. These hot spots  
546 contrast strongly to areas shallower than about 2000 m, where mesoscale eddies are essentially absent,  
547 likely due to topographical steering. Anticyclones tend to dominate the southern subtropical gyres, and  
548 cyclones the northern flank of the ACC. Major causes of regional polarity dominance are larger formation  
549 numbers and lifespans, with a contribution of differential propagation pathways of long-lived eddies.  
550 Areas of dominance of one polarity are generally congruent with the same polarity being longer lived,  
551 bigger, of larger amplitude, and more intense. Eddies extend down to at least 2000 m. In the ACC, eddies  
552 show near surface temperature and salinity maxima, whereas eddies in the subtropical areas generally  
553 have deeper anomaly maxima, presumably inherited from their origin in the boundary currents. The  
554 temperature and salinity signatures of the average eddy suggest that their tracer anomalies are a result of  
555 both trapping in the eddy core and stirring.", "container-title": "Journal of Geophysical Research:

560 phenomenology", "URL": "https://onlinelibrary.wiley.com/doi/abs/10.1002/2015JC011047", "volume": "12  
561 0", "author": [{"family": "Frenger", "given": "I."}, {"family": "M\u00fcnich", "given": "M."}, {"family": "Gruber", "given": "N."}, {"family": "Knutti", "given": "R."}], "accessed": {"date-parts": [[2023, 5, 2]]}, "issued": {"date-parts": [[2015]]}}, "schema": "https://github.com/citation-style-language/schema/raw/master/csl-citation.json"} (Frenger et al., 2015) (Fox-Kemper et al., 2021). Performance evaluation relative to  
565 observations would undoubtedly point to the high-resolution simulation as superior due to the drastic  
566 underrepresentation of EKE in the eddy-permitting ensemble (Figure 1). Yet, the effects of climate  
567 change are still apparent in the AWI-CM-1 ensemble (Figure 1, 5), and the AWI-CM-1 dataset has been  
568 used to make similar projections of EKE already (Beech et al., 2022). Moreover, the eddy response to

569 forcing seems to be consistent between the model resolutions when expressed in relative (Figure 1g, h, i),  
570 rather than absolute terms (Figure 1a, b, c). While more verification of this result is necessary both  
571 regionally, and with other models, these results suggest that eddy-permitting resolutions can be  
572 interpreted with their shortcomings in mind in order to discern the real-world implications: as is often  
573 necessary with model data. Thus, based on the test case of the Southern Ocean, the usefulness of the  
574 AWI-CM-1 ensemble and the effectiveness of model simulations in identifying physically significant and  
575 reproducible impacts of climate change may be greater than would be identified using traditional  
576 methods and comes at a much lower cost relative to the eddy-resolving simulations.

577 This study has focused on EKE as an evaluation metric for the simulations since mesoscale  
578 activity is the primary motivation for increasing ocean model resolution. It has stopped short of assessing  
579 the improvements that resolving the mesoscale has on climate and ocean dynamics, many of which are  
580 discussed in detail elsewhere (eg. [Hewitt et al., 2017](#)). Rather than repeat an assessment of the benefits of  
581 resolving smaller scales, we assume that the accurate reproduction and evolution of eddy activity  
582 indicates that these improvements are transferred to broader processes. Certainly, inaccurate simulation of  
583 the mesoscale would raise questions regarding the improvements that this mesoscale activity should have  
584 on the simulations as a whole. Nonetheless, further evaluation of the modeling approaches employed in  
585 this study will be necessary to determine if these methods are appropriate for studying broader elements  
586 of the climate system. Since the high-resolution simulations derive their deep-ocean climate primarily  
587 from the medium-resolution spin-up simulation, improving the initialization process (Thiria et al., 2023)  
588 may be the critical barrier to extending these results from the mixed layer to the deeper ocean.

## 589 **5 Conclusion**

590 Resolving the ocean mesoscale has become a focus for the climate and ocean modeling  
591 community as computational capabilities expand and models become increasingly complex. The benefits  
592 that explicitly resolved eddy activity can have on climate simulations are clear (Hewitt et al., 2017; Sein  
593 et al., 2017) along with the impact that mesoscale variability has on local (Lachkar et al., 2009; Wang et

594 al., 2017) and global environments (Falkowski et al., 1991; Sallée et al., 2012). However, state-of-the-art  
595 climate models will be unable to fully resolve the mesoscale for the foreseeable future, particularly in  
596 large-scale modeling endeavors such as CMIP (Hewitt et al., 2020). Thus, modelers must make informed  
597 choices regarding the explicit processes needed to answer research questions and where resources must be  
598 allocated to achieve specific goals. Existing analysis of resource allocation has typically addressed short-  
599 term weather forecasting or the ability to reproduce observations with low error (Ferro et al., 2012), but  
600 the question of how to best allocate resources for climate change impact assessment remains. This study  
601 has applied several cost-efficient modeling approaches to an analysis of the impacts of climate change on  
602 a key focus of high-resolution modeling: the mesoscale. Applying these results to broader climate change  
603 impact studies should improve the efficiency of resource allocation and focus modeling studies.  
604 Resolution can be dynamically adjusted both spatially, by focusing resources in study regions and where  
605 they are necessary to resolve local dynamics, and temporally, by allowing lower-resolution workhorse  
606 configurations to perform spin-up and transient runs. Limited simulation length and ensemble size can be  
607 sufficient for certain research questions and validation, but simulations must ultimately be designed to  
608 meet their specific goals. Where resources are limited, studies may best include a combination of eddy-  
609 resolving simulations able to fully capture the local eddy field, as well as eddy-permitting~~present~~  
610 simulations that can attest to the significance of results through consistency and repetition.

611 This work represents a contribution to the growing wealth of research that points to an  
612 intensification of eddy activity in the Southern Ocean (Hogg et al., 2015; Martínez-Moreno et al., 2021;  
613 Beech et al., 2022). The further conclusions that EKE variability may increase and that EKE  
614 intensification appears concentrated in key regions based on topography can both expand the present state  
615 of knowledge, as well as direct future research. The cost-efficient ~~modelling~~ approaches of regional grid  
616 refinement, reduced-resolution spin-up and transient runs, and limited simulation lengths distinguished by  
617 longer periods of change are demonstrated to be effective at reproducing change within a more traditional  
618 eddy-permitting ensemble. When resources are limited and resolution demands are high, these approaches

619 can be adapted to address specific research questions. Where assessing the robustness of change is  
620 critical, the complimentary eddy-permitting ensemble represents an effective, low-cost supplement to the  
621 high-resolution simulations.

624

625 **Data Availability**

626 Geostrophic velocities derived from satellite altimetry data are publicly available at  
627 <https://doi.org/10.48670/moi-00148>. Daily sea surface height data from AWI-CM-1-1-MR in CMIP6  
628 used to compute geostrophic velocities in this study is archived at the World Data Center for Climate at  
629 the DKRZ (<https://doi.org/10.26050/WDCC/C6sCMAWAWM>,  
630 <https://doi.org/10.26050/WDCC/C6sSPAIAWM>) (Semmler et al., 2022a, b). Model output from AWI-  
631 CM-1-1-MR in the CMIP6 framework, including all variables used to force the standalone ocean  
632 simulations conducted for this study, is publicly available at <https://doi.org/10.22033/ESGF/CMIP6.359>  
633 (Semmler et al., 2018). Eddy kinetic energy datasets calculated from FESOM output velocities are  
634 available at <https://doi.org/10.5281/zenodo.8046792> (<https://doi.org/10.5281/zenodo.8046792>) (Beech,  
635 2023b).

636 **Code Availability**

637 Source code for the ocean model FESOM2 is available at (<https://doi.org/10.5281/zenodo.7737061>) (patrickscholz et al., 2023). Code used for data analysis and visualization in  
638 this study is publicly available at  
639 <https://doi.org/10.5281/zenodo.10025361> (<https://doi.org/10.5281/zenodo.8046783>) (Beech, 2023a).  
640 Code used to calculate geostrophic velocities from sea surface height data from AWI-CM-1-1-MR is  
641 available from <https://doi.org/10.5281/zenodo.7050573>.

643 **Author Contributions**

644 NB, TJ, TR, and TS conceived of the study. NB carried out the simulations, analyzed the data, and drafted  
645 the manuscript. All authors reviewed the manuscript.

646 **Competing Interests**

647 The authors declare no competing interests.
