Keywords: Petit-spot volcano, alkali basalt, carbonatite, asthenosphere

40

41 **Abstract**

42

43 Petit-spot volcanism, which occurs owing to the plate flexure, have been reported from around
44 the world. As the petit-spot melts ascent from the asthenosphere, they provide the essential information
45 of the lithosphere–asthenosphere boundary (LAB). Here, we observed the lava outcrops of six
46 monogenetic volcanoes formed by petit-spot volcanism in the western Pacific. Thereafter, we
47 determined the $^{40}\text{Ar}/^{39}\text{Ar}$ ages, major and trace element compositions, and Sr, Nd, and Pb isotopic
48 ratios of the petit-spot basalts. The $^{40}\text{Ar}/^{39}\text{Ar}$ ages of two monogenetic volcanoes were ca. 2.6 Ma
49 (million years ago) and ca. 0 Ma, respectively. The isotopic compositions of the western Pacific petit-
50 spot basalts suggest geochemically similar melting sources. They were likely derived from a mixture
51 of high- μ (HIMU) mantle-like and enriched mantle (EM)-1-like components related to
52 carbonatitic/carbonated materials and recycled crustal components. A mass balance-based melting
53 model implied that the characteristic trace element composition (i.e., Zr, Hf, and Ti depletions) of the
54 western Pacific petit-spot magmas could be explained by the partial melting of ~5% crust-bearing
55 garnet lherzolite with 10% carbonatite flux to a given mass of the source. This result confirms the
56 involvement of carbonatite melt and recycled crust in the source of petit-spot melts and provides an
57 implication for the genesis of tectonic-induced volcanoes including Hawaiian North Arch volcanics
58 and Samoan petit-spot like rejuvenated volcanoes having similar trace element composition to petit-
59 spot basalts.

60

61

62 **Short Summary**

63

64 Plate tectonics theory is understood as the motion of rocky plate (lithosphere) over ductile zone
65 (asthenosphere). The causes of lithosphere–asthenosphere boundary (LAB) is controversial, but petit-
66 spot volcanism supports the presence of melt at the LAB. We conducted geochemistry, geochronology,
67 and geochemical modeling for petit-spot volcanoes on the western Pacific Plate, and the results
68 suggested that carbonatite melt and recycled oceanic crust have induced the partial melting at the LAB.

69

70 **1 Introduction**

71

72 Among the upper mantle-derived alkali basaltic lavas in oceanic settings, those on thicker plates
73 away from the mid-ocean ridge, could be divided into plume-related and non-plume-related volcanoes.
74 For example, plume-related North Arch and post-erosional (rejuvenated-stage) volcanoes have been
75 reported in Hawaii and Samoa (Bianco et al., 2005; Bizimis et al., 2013; Clague and Frey, 1982; Clague

76 and Moore, 2002; Dixon et al., 2008; Frey et al., 2000; Garcia et al., 2016; Hart et al., 2004; Konter
77 and Jackson, 2012; Koppers et al., 2008; Reinhard et al., 2019; Yang et al., 2003). Non-plume related
78 intraoceanic alkali volcanoes, called as petit-spot volcanoes, probably originate where nearby plate
79 subduction causes plate flexures and upwelling of asthenospheric magma (Hirano et al., 2006; Hirano
80 and Machida, 2022; Machida et al., 2015, 2017; Yamamoto et al., 2014, 2018, 2020). Therefore, the
81 occurrence of petit-spot volcanisms supports the presence of melt at lithosphere–asthenosphere
82 boundary (LAB) below the area at least.

83 The presence of melt in the uppermost asthenosphere could be due to small-scale convection,
84 heating, or the presence of hydrous or carbonatitic components (Hua et al., 2023; Korenaga, 2020). In
85 particular, the presence of CO₂ and carbonated/carbonatitic materials is key in the formation of alkaline,
86 silica-undersaturated melt in the upper mantle (Dasgupta and Hirschmann, 2006; Dasgupta et al., 2007,
87 2013; Kiseeva et al., 2013; Novella et al., 2014). Experimental studies have shown that the solidus of
88 carbonate-bearing peridotite is lower than that of CO₂-free peridotite (Falloon and Green, 1989, 1990;
89 Foley et al., 2009; Ghosh et al., 2009). In addition, carbonatites and Si-undersaturated melts are
90 generated through the partial melting of CO₂-bearing or carbonated peridotite. The produced melts
91 could exhibit continuous chemical variations depending on pressure (i.e., depth). Namely, carbonatitic
92 melts are produced in the deep asthenosphere (300 km to 110 km), while carbonated or alkali silicate
93 melts are generated in the shallower upper mantle (~110 km to ~75 or 60 km) (Keshav and
94 Gudfinnsson, 2013; Massuyeau et al., 2015, 2021). Indeed, primary carbonated silicate magma and
95 evolved alkali basalts have been simultaneously observed at the post-spreading ridge in the South
96 China Sea (Zhang et al., 2017; Zhong et al., 2021). Hawaiian rejuvenated volcanoes were also
97 attributed to be explained by a carbonatite-metasomatized source with or without silicate
98 metasomatism (Borisova and Tilhac, 2021; Dixon et al., 2008; Zhang et al., 2022).

99 Submarine petit-spot volcanoes on the subducting northwestern (NW) Pacific Plate may
100 originate from carbonate-bearing materials and crustal components (pyroxenite/eclogite) based on the
101 characteristic trace element, enriched mantle (EM)-1-like Sr, Nd, and Pb isotopic, and relatively low
102 Mg isotopic compositions (Liu et al., 2020; Machida et al., 2009, 2015). In particular, the depletion of
103 specific high-field-strength elements (HFSEs) (i.e., Zr, Hf, and Ti) and the abundant CO₂ of petit-spot
104 basalts imply that their melting sources are related to carbonated materials (Hirano and Machida, 2022;
105 Okumura and Hirano, 2013). Here, the nature of the uppermost part of the asthenosphere beneath the
106 oldest Pacific Plate aged 160 Ma, was characterized using the eruptive ages and geochemical
107 properties of six newly observed petit-spot volcanoes and lava outcrops. We verified the contribution
108 of carbonatitic components and crustal materials to the melting source of petit-spot volcanoes to
109 understand the nature of the underlying lithosphere–asthenosphere system and model the geodynamic
110 evolution of the region.

111

112 **2 Background**

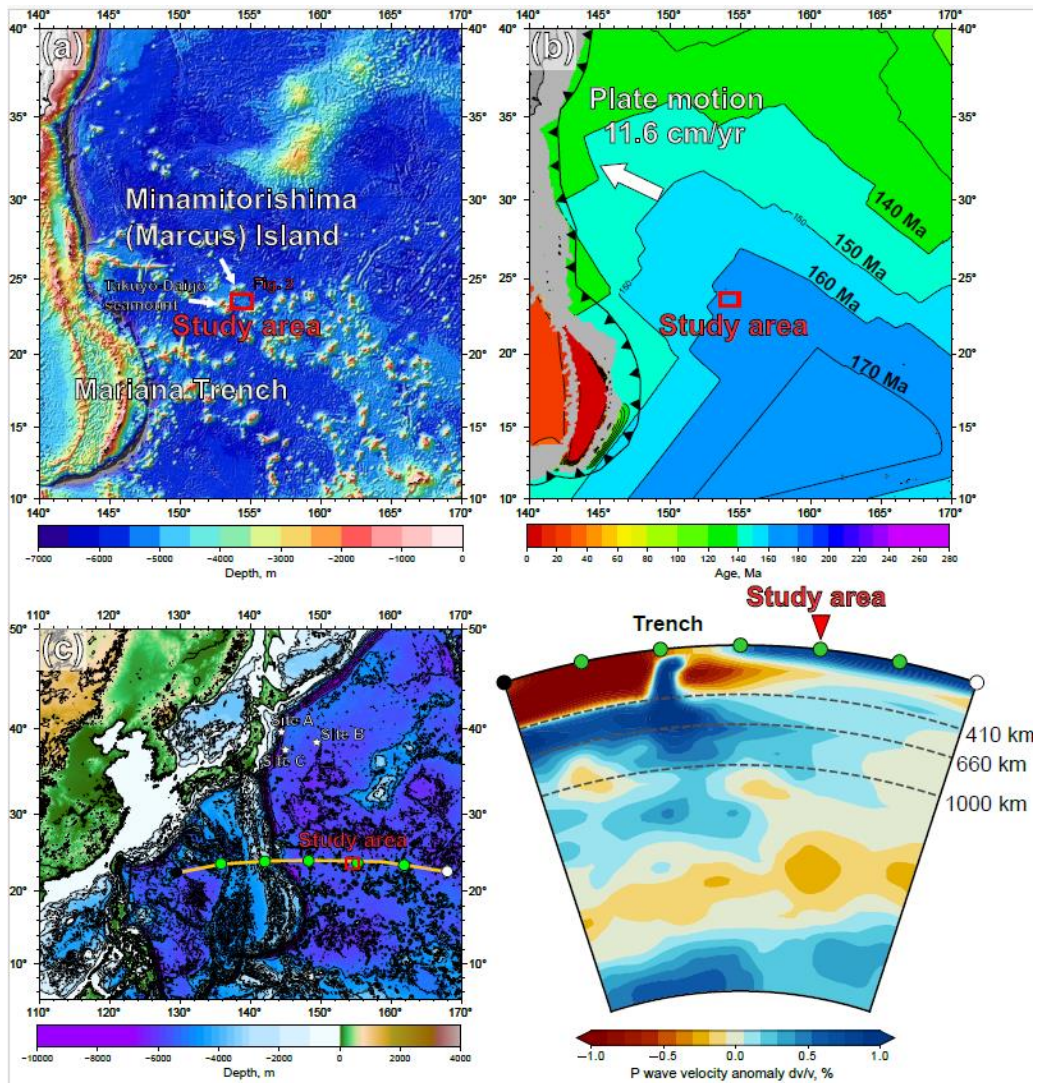

113

114 In the last 20 years, the increasing knowledge of petit-spot volcanic settings has provided useful
115 insights on the nature of the lithosphere-asthenosphere system, especially in the NW Pacific region
116 (Hirano et al., 2006; Hirano and Machida, 2022). As other implications, subducted petit-spot volcanic
117 fields with geological disturbances on the seafloor play a role in controlling the hypocentral regions
118 of megathrust earthquakes (Fujiwara et al., 2007; Fujie et al., 2020; Akizawa et al., 2022), and the
119 vestige of hydrothermal activity owing to petit-spot magmatism were recently reported (Azami et al.,
120 2023).

121 Petit-spot melts, which originated from the asthenosphere unrelated to mantle plume, could be
122 a key to elucidating the nature of the LAB (Hirano and Machida, 2022). Their asthenospheric origin
123 was supported by MORB-like noble gas isotopic ratios, multi-phase saturation experiment, and
124 geochemistry (Hirano et al., 2006; Hirano and Machida, 2022; Machida et al., 2015, 2017; Yamamoto
125 et al., 2018). The LAB is identified as a discontinuous transition in seismic velocities at the base of
126 the lithosphere, and its causes are attributed to hydration, melting, and mineral anisotropy with
127 considerations for the unique characteristics in each tectonic setting (e.g., Rychert and Shearer, 2009).
128 The occurrence of petit-spot volcanism substantiates the existence of melt at the LAB below the area
129 at least (Hirano et al., 2006). Recently, similar volcanic activities have been observed worldwide
130 including Java (Sunda) Trench, Tonga Trench, Chile Trench, Mariana Trench, Costa Rica, North
131 American Basin and Range, and southern offshore of Greenland, implying the universal occurrence
132 of petit-spot and similar magmatisms (Axen et al., 2018; Buchs et al., 2013; Falloon et al., 2022;
133 Hirano et al., 2013, 2016, 2019; Reinhard et al., 2019; Taneja et al., 2016; Uenzelmann-Neben et al.,
134 2012; Yamamoto et al., 2018, 2020; Zhang et al., 2019). Although there is still an open question of
135 whether the LAB discontinuity is due to the differences in the physical properties of minerals (e.g.,
136 Hirth and Kohlstedt, 1996; Kang and Karato, 2023; Karato and Jung, 1998; Katsura and Fei, 2021;
137 Stixrude and Lithgow-Bertelloni, 2005; Wang et al., 2006) or the presence of partial melts (e.g.,
138 Audhkhasi and Singh, 2022; Chantel et al., 2016; Conrad et al., 2011; Debayle et al., 2020; Herath et
139 al., 2022; Hua et al., 2023; Kawakatsu et al., 2009; Mierdel et al., 2007; Sakamaki et al., 2013; Yoshino
140 et al., 2006), the occurrence of petit-spot volcanism reveals the partial melting of the asthenospheric
141 mantle of the region because they erupted on the seafloor without hotspot and ridge activities (Hirano
142 et al., 2006; Hirano and Machida, 2022; Machida et al., 2015, 2017; Yamamoto et al., 2014, 2018,
143 2020).

144 The petit-spot volcanic province on the abyssal plain of the western Pacific is surrounded by
145 Cretaceous seamounts and oceanic islands of the Western Pacific Seamount Province (Koppers et al.,
146 2003) and located approximately 100 km southeast of the Minamitorishima (Marcus) Island (Fig. 1a).
147 The study area corresponds to the oldest portion of the Pacific Plate aged at 160 Ma and the foot of

148 the outer-rise bulge related to the Mariana subduction system (Hirano et al., 2019; Fig. 1b). Such a
149 subduction-related fore-bulge in front of the Mariana Trench has been numerically modeled and
150 detected in satellite gravity maps despite crosscutting by several seamounts (Bellas et al., 2022; Hirano
151 et al., 2019; Zhang et al., 2014, 2020). The petrography, geochemistry, and geochronology of petit-
152 spot basalts and zircons in peperites, which were collected from a knoll, suggested that petit-spot
153 magmas in this region ascend from the asthenosphere along the concavely flexed plate in response to
154 subduction into the Mariana Trench at younger than ~3 Ma (Yamamoto et al., 2018; Hirano et al.,
155 2019). Below the study area, low seismic velocity zone is observed under the lithosphere (Li et al.,
156 2019; Fig. 1c). Notwithstanding the low velocity anomalies crosscutting the lower mantle (Fig. 1c),
157 no active hotspots (i.e., heat supplies) have been reported around the western Pacific petit-spot
158 province surrounded by Cretaceous Wake seamount chains including Minamitorishima Island and
159 Paleogene intraplate volcanoes (Koppers et al., 2003; Aftabuzzaman et al., 2021; Hirano et al., 2021).
160 The other petit-spot lava outcrops were observed in a volcanic cluster during three research cruises
161 using the research vessel (RV) *Yokosuka* (YK16-01, YK18-08, and YK19-05S) with five dives using
162 the submersible, *Shinkai* 6500 (6K#1466, 6K#1521, 6K#1522, 6K#1542, and 6K#1544; Fig. 2), and
163 fresh basalts were collected. The information of sampling point, depth, thickness of palagonite rind
164 and manganese-crust, and age of the western Pacific petit-spot basalts are provided in Table 1.

Fig. 1. Geological and geophysical information of the study area. (a) Bathymetry of the western Pacific near the Mariana Trench. The red box shows the study area to the southeast of Minamitorishima (Marcus) Island (Fig. 2). The bathymetric data are adopted from ETOPO1 (NOAA National Geophysical Data Center; <http://www.ngdc.noaa.gov/>). (b) Seafloor age map of the same area as (a). This study area is on a 160–170 Ma Pacific Plate, called the Jurassic Quiet Zone (JQZ) (Tivey et al. 2006). The present absolute motion of the Pacific Plate and the seafloor age are derived from studies by Gripp and Gordon (1990) and Müller et al. (2008), respectively. (c) The cross-section P-wave tomography beneath the thick yellow line including the study area on the ETOPO1 bathymetry map (left). The tomographic image (right) was drawn using the SubMachine (Hosseini et al., 2018; <http://www.earth.ox.ac.uk/~smachine/cgi/index.php>) on applying the data of Lu et al. (2019).

Table. 1

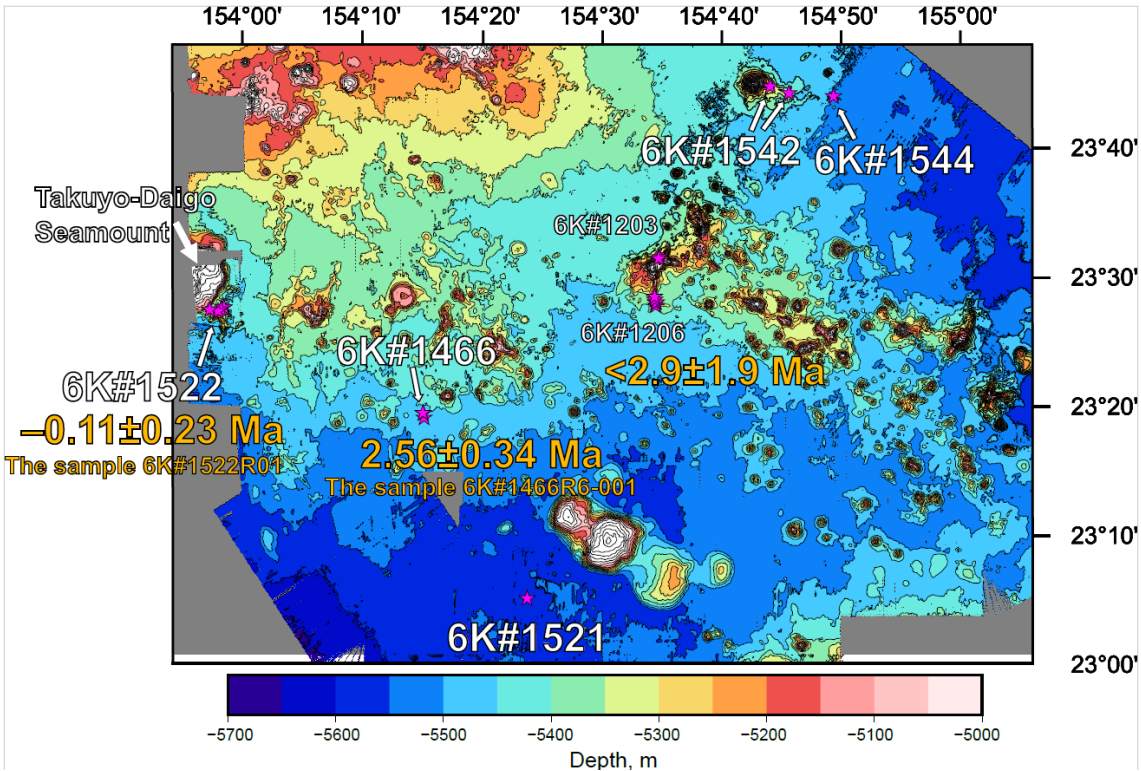

Information of the collected western Pacific petit-spot basalts

Fig. 2. Detailed bathymetry of the study area. The onboard multibeam data were surveyed during the YK10-05 and the YK18-08 cruises by the Japan Agency for Marine-Earth Science and Technology (JAMSTEC). The petit-spot knolls and outcrops were investigated during several dives as 6K#1466, 6K#1521, 6K#1522, 6K#1542, and 6K#1544. The pink-colored stars represent the sampling points. The age information was obtained in the present study and Hirano et al. (2019).

3 Field observations, sample locations, and petrography

186

187 Here, the eruptive sites of monogenetic volcanoes or lava outcrops are approximately along each
188 dive site numbered 6K#1466, #1521, #1522, #1542, and #1544 conducted using the *Shinkai* 6500.
189 Only the 6K#1466 dive was conducted at two types of monogenetic volcanoes, divided into the glassy
190 (R3) and crystalline, vesicular (R6 and R7) types based on the geochemical and petrographic
191 descriptions and occurrence of basaltic samples.

192

193 **3.1 YK16-01 cruise and 6K#1466 dive**

194

195 During the YK16-01 cruise, a small conical knoll (ca. 0.04 km³) was investigated by a
196 submersible dive, 6K#1466 (Figs. 2 and 3a). The lava flows, observed hollow lava tube resulting in
197 sediment-rolling/disturbing eruption, were located approximately 600 m south of the top of the knoll
198 (extremely fresh and glassy samples; 6K#1466R3-001 and R3-004 basalts) (Fig. 3a). Vesicular pillow
199 basalts were collected on the western slope of the knoll (samples 6K#1466R6-001, R7-001, and R7-
200 003; Fig. 3a). Although only the strong acoustic reflection could not completely distinguish the petit-
201 spot lava fields in ferromanganese nodule fields, this dive revealed lava outcrops using a sub bottom
202 profiler (SBP) and a multi narrow beam echo sounder (MBES). In detail, the petit-spot lava field, as
203 an acoustically opaque layer, was identified by a vigorous backscattering intensity in the MBES with
204 the distributions of the basement and sediment layers in the SBP.

205 The 6K#1466R3-001 and R3-004 samples were extremely fresh glassy basalts. The R3-001 and
206 R3-004 basalts exhibited similar petrographic features (Fig. 3a). These basalts were covered by 3.0–
207 4.5 mm-thick palagonite (hydrated quenched glass), and their outermost parts were surrounded by
208 5.8–7.2 mm-thick ferromanganese crust (Fig. 3a). They were less vesicular (<3 vol.%) and dominantly
209 basaltic glass with euhedral–subhedral olivine microphenocrysts (~100–500 μm in size), ferrotitanium
210 oxide (<50 μm in size), and minor plagioclase (~500 μm in size) (Fig. 3a). Secondary phases (e.g.,
211 clay minerals) were not observed.

212 The 6K#1466R6-001, R7-001, and R7-003 basalts, covered with 4.3–5.2 mm-thick
213 ferromanganese crust over 5.5–6.6 mm-thick palagonite rinds, exhibited high vesicularity (20–40
214 vol.%) (Fig. 3a). Certain pyroxene-dominated xenocrysts and peridotite xenoliths have been reported
215 by Mikuni et al. (2022). The basaltic groundmass comprised needle-shaped clinopyroxene (50–400
216 μm in size), subhedral olivine partly with aureoles of iddingsite (up to 100 μm in size), ferrotitanium
217 oxide, minor spinel (up to 10 μm in size), glass, and crystallite, notably without remarkable
218 phenocrysts (Fig. 3a). The photomicrograph of R6-001 is shown in Fig. 3a.

219

220 **3.2 YK18-08 cruise and 6K#1521 and #1522 dives**

221

222 Two submersible dives (6K#1521 and 1522) were conducted during the YK18-08 cruise to
223 investigate petit-spot volcanoes. During the 6K#1521 dive, a small lava outcrop was discovered in the
224 abyssal plain by tracing the strong acoustic reflection, which was expectedly derived from intrusive
225 rock bodies, in the sedimentary layer detected by deep-sea SBP equipped on the *Shinkai* 6500. We
226 observed that the strong reflective surface gradually became shallow during the navigation, revealing
227 the small lava outcrop (Figs. 2 and 3b). Fresh and massive (nonvesicular) basalts were collected from
228 this outcrop (samples 6K#1521R04 and R05; Fig. 3b). The samples from the 6K#1522 dive at a
229 seamount exhibited highly irregular shapes, and massive lava flows, pillows, and lava breccia were
230 observed (Fig. 3c). All the samples were fresh vesicular basalts (6K#1522R01, R02, R05, R12, R13,
231 R16, and R17; Fig. 3c).

232 The fresh, massive, and nonvesicular basalts were obtained by 6K#1521 dive (R04 and R05)
233 and comprised euhedral olivine microphenocrysts (150–400 μm in size), two types of ferrotitanium
234 oxide (50–150 μm in size), and crystallite (Fig. 2b). Secondary phases were not observed as well. They
235 were covered with 5.6–5.9 mm-thick ferromanganese crust and \sim 1.0 mm-thick palagonite rinds (Fig.
236 3b), but R05 did not have palagonite rinds. The photomicrograph of R04 is shown in Fig. 3b.

237 The seven fresh basalts collected during the 6K#1522 dive (6K#1522R01, R02, R05, R12, R13,
238 R16, and R17), exhibited high vesicularity (20–40 vol.%) with 2.9–6.0 mm-thick palagonite rinds
239 covered with 2.7–5.9 mm-thick ferromanganese crusts (Fig. 3c). Euhedral–subhedral olivine
240 microphenocrysts (glomeroporphyritic, 30–200 μm in size), radial–needle-shaped clinopyroxene,
241 iddingsite ($<$ 200 μm in size), spinel, and glass with minor xenocrystic olivines were observed (Fig.
242 3c). The photomicrograph of R01 is shown in Fig. 3c.

243

244 **3.3 YK19-05S cruise and 6K#1542 and #1544 dives**

245

246 A petit-spot knoll and related lava flows were surveyed by the 6K#1542 and #1544 dives,
247 respectively, during the YK19-05S cruise (Fig. 2). During the 6K#1542 dive, geological survey and
248 rock sampling were conducted from two points on the eastern slope of the knoll (Figs. 2 and 3d). Here,
249 the 6K#1542R03 and R05 basalts were collected from the lava-breccia field covered with thin
250 ferromanganese crust (Fig. 3d). Samples R06 and R09 were obtained from the lobate-surface lava
251 between tubular lavas closer to the summit than R03 and R05 (Fig. 3d).

252 High-resolution (one-meter scale) bathymetric mapping was successfully conducted during the
253 6K#1544 dive, and this can contribute to future oceanographic investigations using the Human
254 Occupied Vehicle (Kaneko et al., 2022). During this acoustic survey, several mounds, 10–20 m in
255 height and a few hundred meters in diameter, were recognized (Fig. 3d). We observed these mounds
256 and collected samples from outcrops during the second half of the dive. Pillow lavas, tumuli, and lava
257 breccias were observed, and basaltic samples (6K#1544R04, R05, and R06) were collected (Fig. 3d).

258 Four vesicular basalts (10–30 vol.% vesicularity; 6K#1542R03, R05, R06, and R09) were
 259 covered with 4.3–4.4 mm-thick ferromanganese crust. The outer palagonitic rinds were 3.2–3.4 mm-
 260 thick (Fig. 3d). A few to 300- μ m-sized euhedral–subhedral olivine microlites and microphenocrysts
 261 were glomeroporphyritic (Fig. 3d). The groundmass was dominated by needled dendritic
 262 clinopyroxenes (\sim 100 μ m in size). The others were olivine, spinel, glass, and xenocrystic olivine
 263 megacrysts. The photomicrograph of R06 is shown in Fig. 3d.

264 The basaltic samples from the 6K#1544 dive (6K#1544R04, R05, and R06) were covered with
 265 ferromanganese crust (5.0–5.8 mm-thick) over palagonitic rinds (3.4–4.4 mm-thick). All the samples
 266 exhibited high vesicularity in the range of 20–35 vol.% (Fig. 3d). They comprised olivine
 267 microphenocrysts (30–250 μ m in size, euhedral–subhedral or columnar), clinopyroxene (<100 μ m,
 268 needled, columnar, radial or dendritic shape), spinel, and glass without secondary phases (Fig. 3d).

269 The photomicrograph of R04 is shown in Fig. 3d. During macroscopic observations, practically
 270 all the basalts from the 6K#1542 and 6K#1544 dives exhibited similar vesicularity and freshness.
 271 Their geochemical features were also similar to each other and are described in Sect. 5-1 and 5-2.

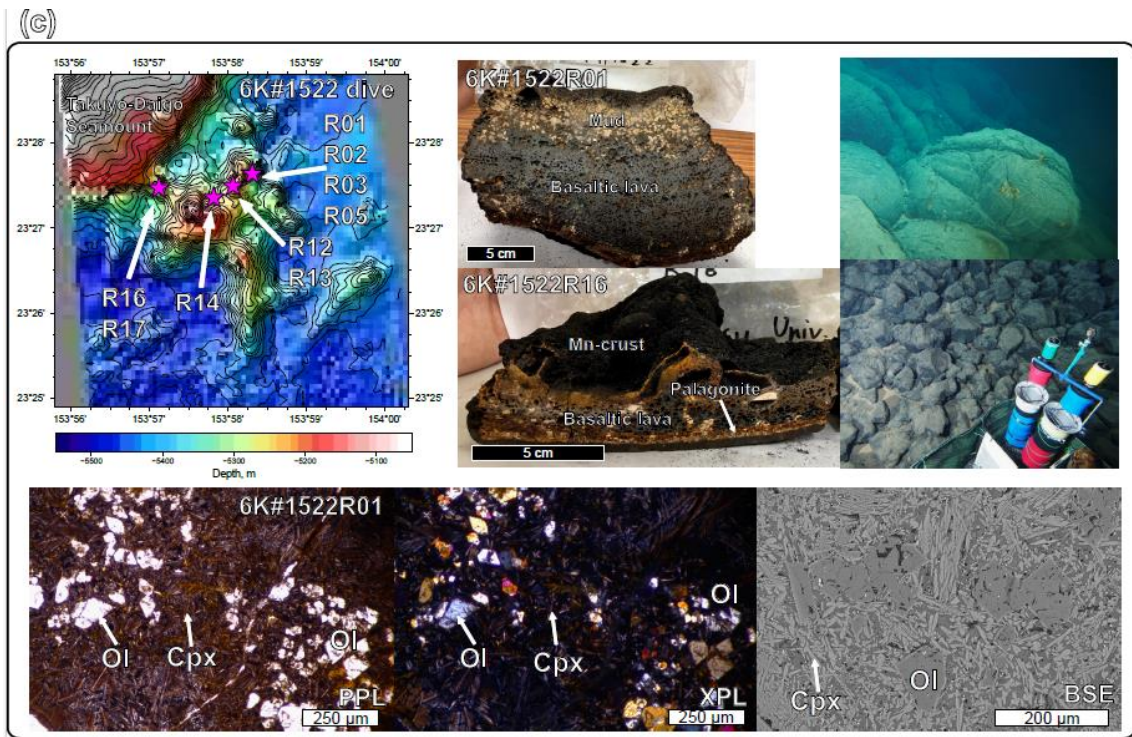

272

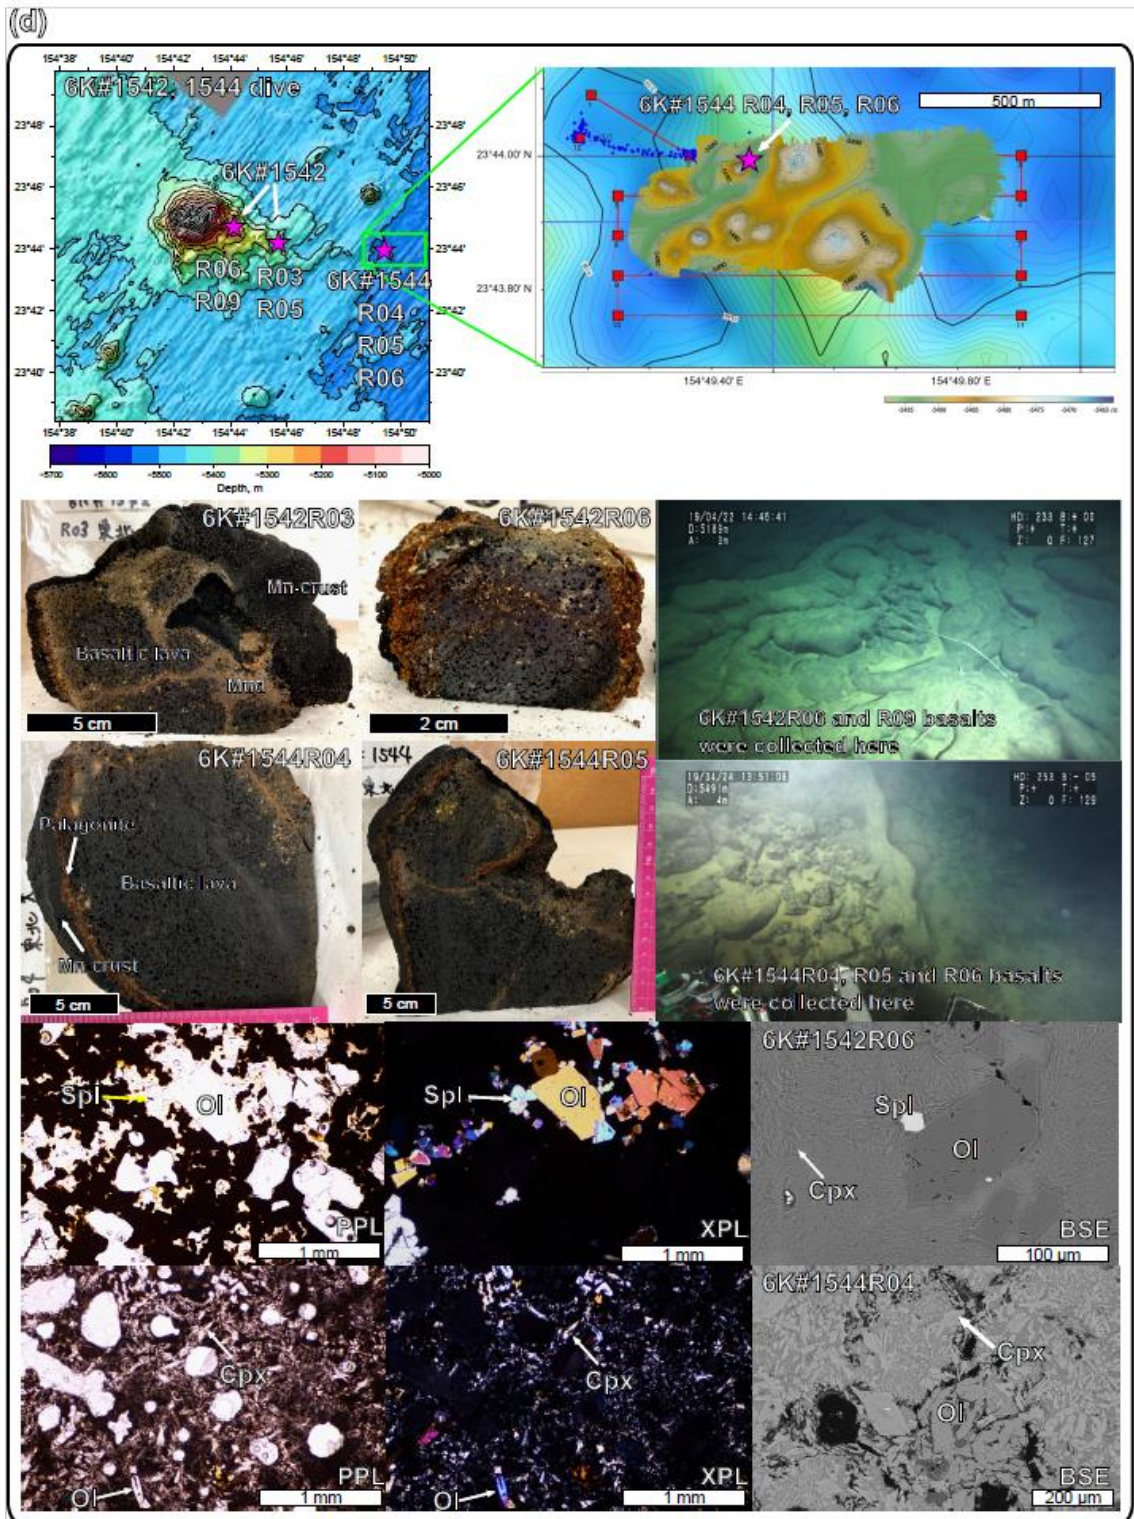

273

274

275

276
 277 Fig. 3. Bathymetric map with photos of the outcrop, the collected samples, and their photomicrographs with detailed
 278 bathymetry of the sampling points. (a) The GK#1466, (b) GK#1521, (c) GK#1522, and (d) GK#1542 and
 279 GK#1544 dives using the *Shinkai 6500* by JAMSTEC. The 1-m gridded bathymetry of the GK#1544 dive
 280 is shown in (d), obtained using an MBES equipped with the *Shinkai 6500* over a 100-m resolution map

281 obtained using the surface ship, R/V *Yokosuka* (Kaneko et al., 2022). The photomicrographs of
282 representative samples are shown for plane-polarized light (PPL), cross-polarized light (XPL), and
283 backscatter electron (BSE). Ol, olivine; Cpx, clinopyroxene; Mgt, magnetite; Spl, spinel.

284
285

286 **4. Analytical methods**

287

288 **4.1 Major and trace element analysis of volcanic glass, mineral, and whole-rock**

289

290 Major element compositions of glasses and minerals were determined using an electron probe
291 micro analyzer (EPMA). JXA-8900R at Atmosphere and Ocean Research Institute (AORI), the
292 University of Tokyo was used for glass analysis and JXA-iHP200F at GSJ, AIST was used for mineral
293 analysis. The analyses were performed using an accelerating voltage of 15 kV, a beam current of 12
294 nA, and a beam diameter of 10 μm for glass and 2 μm for mineral. A peak counting time of 20 s and
295 a background counting time of 10 s were used, except for Ni, for which a peak counting time of 30 s
296 and a background counting time of 15 s. For Na analysis of glass, the peak counting time was 5 s and
297 the background counting time was 2 s. Natural and synthetic minerals were used as standards, and data
298 were corrected using a ZAF online correction program (Akizawa et al., 2021). Major element
299 composition of glass was determined by the mean value of 10 analytical points.

300 Trace element compositions of minerals were determined using a laser ablation-inductively
301 coupled plasma-mass spectrometry (LA-ICP-MS; New Wave Research UP-213 and Agilent 7500s)
302 at Kanazawa University. The Nd: YAG deep UV (ultraviolet) laser's wavelength is 213 nm. The
303 analyses were conducted with 100 μm spot size. A repetition frequency of 6 Hz and a laser energy
304 density of 8 J cm^{-2} were used. NIST612 glass (distributed by National Institute of Standards and
305 Technology) was employed for calibration, using the preferred values of Pearce et al. (1997). Data
306 reduction was undertaken with ^{29}Si as the initial standard, and SiO_2 concentrations were obtained by
307 an electron microprobe analysis (Longerich et al., 1996). BCR-2G (distributed by the United States
308 Geological Survey) was used as a secondary standard to assess the precision of each analytical
309 session (Jochum and Nohl, 2008).

310 Whole-rock major and trace element compositions of rock samples were analyzed by Activation
311 Laboratories Ltd., Canada, using Code 4Lithoresearch Litho geochemistry and ultratrace5 Exploration
312 Geochemistry Package. The former package uses lithium metaborate/tetraborate fusion with
313 inductively coupled plasma optical emission spectrometry (FUS-ICP-OES) and inductively coupled
314 plasma mass spectroscopy (FUS-ICP-MS) for the major and trace element analyses, respectively. The
315 latter package uses inductively coupled plasma optical emission spectrometry (ICP-OES) and
316 inductively coupled plasma mass spectroscopy (ICP-MS) for the major and trace element analyses,

317 respectively.

318

319 **4.2 Sr, Nd, and Pb isotope analysis**

320

321 **4.2.1 Acid leaching**

322

323 Acid leaching was conducted for the selected basaltic samples on the basis of the procedure of
324 Weis and Frey (1991, 1996) as follows: [1] About 0.3–0.4 or 0.6 g of rock powder is weighed into an
325 acid-washed 15 mL Teflon vial (Savilex®). [2] 10 or 12 mL of 6N (N: normality) HCl were added, and
326 then heated at 80°C for 20–30 min. [3] After heating, the suspension is ultra-sonicated in 60°C water
327 for 20 min. [4] The supernatant is decanted. Steps [2] to [4] were repeated more than 4 times (up to 6
328 times) until the supernatant become clear or pale yellow to colorless. [5] TAMAPURE-AA Ultrapure
329 water (Tama Chemicals; Co., Ltd.), which includes a lower Pb blank than milli-Q H₂O, were added
330 instead of 6N HCl, and the suspension is ultra-sonicated for 20 min. This step is conducted twice. [6]
331 The leached rock powder is dried on a hot plate at 120°C. [7] After cooling, the powder is weighed.

332

333 **4.2.2 Extraction of Pb, Sr, and Nd**

334

335 The extraction of Pb, Sr, and Nd was performed following the procedures of Tanimizu and
336 Ishikawa (2006) and Machida et al. (2009). First, from ~50 to ~100 mg of rock powder was weighted
337 in a 7 mL Teflon vial (designated as “vial A”), and digested using mixed acid composed of HF and
338 HBr. The separation was conducted by cation exchange resin (AG-1X8; Bio-Rad Laboratories Inc.)
339 on the basis of procedures described in Tanimizu and ishikawa (2006). All fractions from the first and
340 second supernatant loading (0.5 M HBr) to the elution of other elements (mixed acid composed of
341 0.25 M HBr and 0.5 M HNO₃) were collected in another 7 mL Teflon vial (designated as “vial B”) for
342 Sr and Nd separation. Finally, Pb was extracted by 1 mL of 1M HNO₃ in another 7 mL Teflon vial
343 (designated as “vial C”). The procedural blanks for Pb totaled less than 23 pg.

344 The Sr and Nd-bearing solution in the vial B was transferred into the vial A containing residues
345 of digested samples. 2 mL of HClO₄ and 2 mL HNO₃ was further added to the vial A, and the residue
346 was dissolved at 110 °C. Both Sr and Nd were separated by column with a cation exchange resin
347 (AG50W-8X; Bio-Rad Laboratories Inc.) and a Ln resin (Eichrom Tech- nologies Inc.) on the basis of
348 procedures described in Machida et al. (2009). The separated Sr and Nd were further purified by
349 column separation with a cation exchange resin. The total procedural blanks for Sr and Nd were less
350 than 100 pg.

351

352 **4.2.3 Analytical procedure**

353

354 Pb isotopic ratios were obtained using the multi-collector ICP-MS (MC-ICP-MS; Neptune plus,
355 Thermo Fisher Scientific), with nine Faraday collectors, at Chiba Institute of Technology (CIT), Japan.
356 The NIST SRM-981 Pb standard was also analyzed and yielded the average values of $^{206}\text{Pb}/^{204}\text{Pb} =$
357 16.9303 ± 0.0005 , $^{207}\text{Pb}/^{204}\text{Pb} = 15.4828 \pm 0.0006$, and $^{208}\text{Pb}/^{204}\text{Pb} = 36.6710 \pm 0.0016$. These
358 correspond to previous values determined using MC-ICP-MS with Tl normalization, but they were
359 slightly lower than values determined by TIMS in Tanimizu and Ishikawa (2006) from the ^{207}Pb – ^{204}Pb
360 double-spike. Reproducibility was monitored by an analyses of the JB-2 GSJ standard, and the
361 obtained values were $^{206}\text{Pb}/^{204}\text{Pb} = 18.3326 \pm 0.0005$, $^{207}\text{Pb}/^{204}\text{Pb} = 15.5453 \pm 0.0006$, and $^{208}\text{Pb}/^{204}\text{Pb}$
362 $= 38.2240 \pm 0.0017$.

363 Sr and Nd isotopic analyses for powdered rocks and glasses were conducted using the thermal
364 ionization mass spectrometry (TIMS; Triton XT, Thermo Fisher Scientific) with nine Faraday
365 collectors, at CIT. 1.5 μL of 2.5M HCl and 0.5M HNO₃ was used for loading of separated Sr and Nd
366 of sample on the single and double Re-filament, respectively. The measured isotopic ratios were
367 corrected for instrumental fractionation by adopting the $^{86}\text{Sr}/^{85}\text{Sr}$ value to be 0.1194 and that of
368 $^{146}\text{Nd}/^{144}\text{Nd}$ to be 0.7219. The average value for the NIST SRM-987 Sr standard was 0.710239
369 ± 0.000005 (2σ , $n = 2$), and that for the GSJ JNdi-1 Nd standard was 0.512103 ± 0.000005 (2σ , $n = 2$).
370 They agree well with values from the literature for the NIST SRM-987 ($^{87}\text{Sr}/^{86}\text{Sr} = 0.710252$ –
371 0.710256 ; Weis et al., 2006) and JNdi-1 ($^{143}\text{Nd}/^{144}\text{Nd} = 0.512101$; Wakaki et al., 2007). Consequently,
372 we did not correct the values of the unknowns for offsets between the measurements and the values
373 for the Sr and Nd standards.

374

375 **4.3 $^{40}\text{Ar}/^{39}\text{Ar}$ dating**

376

377 Samples for $^{40}\text{Ar}/^{39}\text{Ar}$ dating were prepared by separating crystalline groundmass after crushing
378 them to sizes between 100 and 500 μm . The separated groundmass samples were leached by HNO₃ (1
379 mol/L) for one hour to remove clays and altered materials. All samples were wrapped in aluminum
380 foil along with JG-1 biotite (Iwata, 1998), K₂SO₄, and CaF₂ flux monitors. Any amorphous (e.g.,
381 quenched glass) was removed because ^{39}Ar may move from one phase to another in a process known
382 as “recoil.” This can create a disturbed age spectrum when ^{39}Ar is produced from ^{39}K in amorphous
383 material through interaction with fast neutrons during irradiation of the sample. Samples were
384 irradiated for 6.6 days in the Kyoto University Research Reactor (KUR), Kyoto University. Argon
385 extraction and isotopic analyses were undertaken at the Graduate School of Arts and Sciences, the
386 University of Tokyo. The sample gases were extracted by incremental heating of 10 or 11 steps
387 between 600°C and 1500°C. The analytical methods used are the same as those used by Ebisawa et al.
388 (2004) and Kobayashi et al. (2021).

389

390 **5 Results**

391

392 To describe the geochemical and chronological results, each sample group was denoted by its
393 dive number, e.g., the sample group obtained from the 6K#1521 dive was labeled “1521 samples”.
394 The basalts from the 6K#1466 dive were divided into two groups for R3 (collected from the seafloor
395 south of the knoll) and R6–R7 (sampled on the knoll) based on their geographical, petrological, and
396 compositional differences. The mineral compositions of each petit-spot basalt are shown in Fig. S1
397 and Table S1, S2 and S3.

398

399 **5.1 Major and trace element compositions**

400

401 The major and trace element compositions for the whole rock and glass of the petit-spot basalts
402 are listed in Table 2 and 3, respectively. The basalt compositions for a petit-spot knoll were reported
403 by Hirano et al. (2019) (expressed as “1203, 1206” in each figure). The data are discussed along with
404 the reported NW Pacific petit-spots (Hirano and Machida, 2022). Using a total alkali vs. silica (TAS)
405 diagram, virtually all the samples were classified as alkalic rocks, but the 1542 and 1544 basalts were
406 plotted near the boundary between alkalic and non-alkalic (Fig. 4a). Two petit-spot basalts (1466R7-
407 001 and R7-003) from the petit-spot knoll were notably silica-undersaturated (i.e., $\text{SiO}_2 = 39.3\text{--}39.4$
408 wt%) and classified as foidite (Mikuni et al., 2022). All the western Pacific petit-spot basalts, except
409 for the 6K#1466R7 basalts, were sodic ($\text{K}_2\text{O}/\text{Na}_2\text{O} = 0.24\text{--}0.58$) and were notably discriminated to
410 the potassic NW Pacific petit-spots (Fig. 4b).

411 Selected major element oxides and trace element ratios vs. MgO plots for the petit-spot basalts
412 are shown in Figs. 5 and 6, respectively. The MgO concentrations of the 1466R3 and 1521 samples
413 each exhibiting similar petrographic features (i.e., nonvesicular, and glassy) were characterized by
414 values (4.0–4.4 wt%) lower than those of other vesicular samples (6.6–9.3 wt%). The K_2O , Na_2O ,
415 Al_2O_3 , and SiO_2 contents negatively correlated with MgO (Figs. 5a–d). The CaO, FeO_T , and
416 $\text{CaO}/\text{Al}_2\text{O}_3$ abundances exhibited positive correlations with MgO (Figs. 5e–g). The TiO_2
417 concentrations exhibited no correlations with MgO (Fig. 5h), as well as the selected trace element
418 ratios (Figs. 6a–g) except for the Sm/Hf ratio with positive correlations (Fig. 6h). The Sm/Hf ratio also
419 negatively correlated with SiO_2 (Fig. S2). The study samples exhibited whole-rock loss on ignition
420 (LOI) in the range of 0.67–1.72 wt%, excluding two relatively altered samples, 6K#1466R7-001 (LOI
421 = 2.68 wt%) and R7-003 (LOI = 6.29 wt%).

422 The PM-normalized (Sun and McDonough, 1989) trace element patterns for the petit-spot
423 basalts, including those reported by a previous study (Hirano et al., 2019), were shown for each dive
424 compared to the representative ocean island basalt (OIB) in Figs. 7a–f. The petit-spot basalts generally

425 showed high light rare earth element (LREE)/heavy REE (HREE) ratios. Negative Zr, Hf, Ti, and Y
 426 anomalies were commonly observed in these western Pacific petit-spots as well as those of the NW
 427 Pacific petit-spots (Fig. 7g). The 1466 basalts collected on the seafloor south of the knoll (6K#1466R3-
 428 001 and R3-004) were compositionally different from those obtained on the knoll (6K#1466R7-001,
 429 R7-003). The basalts from the 6K#1542 and 1544 dives, collected from nearby locations, had the same
 430 compositions in major and trace element ratios in both whole rock and glass, respectively (Figs. 4, 5,
 431 6, 7e, and f). These samples in the Ba/Nb and Sm/Hf diagrams were plotted in the range of “Group 3”
 432 in the discrimination of the NW Pacific petit-spot basalts (Machida et al., 2015), indicating their
 433 negative Zr and Hf anomalies without notable U, Th, Nb, and Ta anomalies in the PM-normalized
 434 trace element patterns (Fig. 7h). The Sm/Hf ratio of the differentiated 1466R3 samples was lower than
 435 that of other samples. A positive correlation between fluid mobile and immobile elements, Ba vs. Nb
 436 (Fig. 8a) and U vs. Th (Fig. 8b), respectively, was observed, excluding the Ba of the 1466R7 samples
 437 (Fig. 8a).
 438

Fig. 4. Relationships between the SiO₂ and alkali contents. (a) Total alkali vs. silica diagram using the platform of Le

445

Bas et al. (1986). The dividing line of alkaline and sub-alkaline is from Irvine and Baragar (1971). The

446

data are plotted as the total 100 wt%. The triangles and circles show the whole-rock and quenched-glass

447

compositions, respectively. The compositions of the NW Pacific petit-spots are represented by gray

448

triangles (Hirano and Machida, 2022). The data of the 6K#1203 and 1206 basalts are from Hirano et al.

449

(2019), and those of the 6K#1466R7 basalts are from Mikuni et al. (2022). (b) K₂O vs. Na₂O diagram.

450

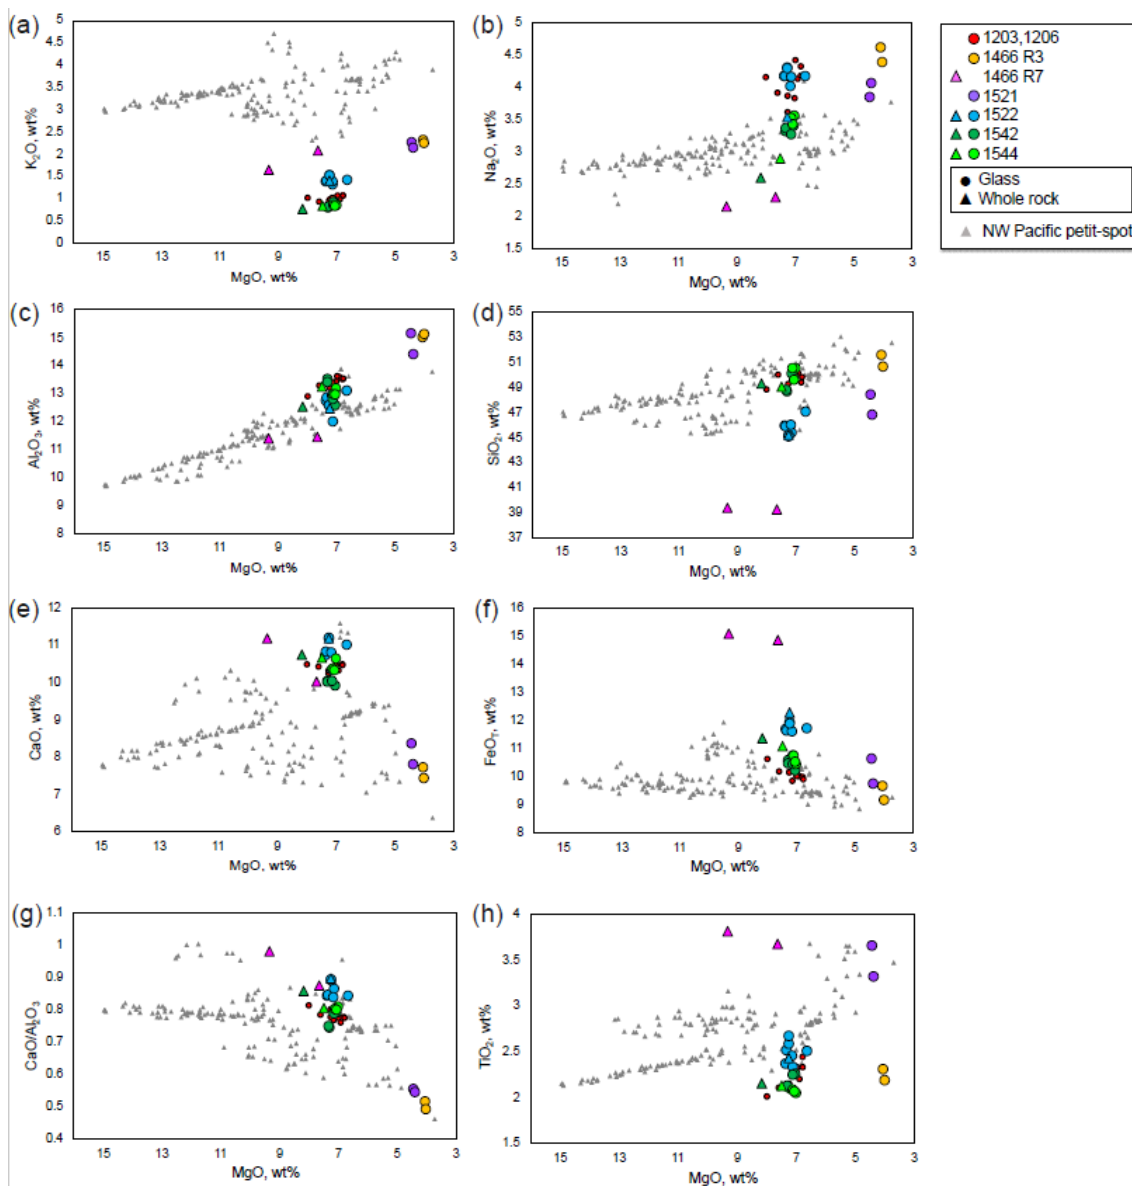

The maximum K₂O/Na₂O value of kimberlite is from PetDB database (<https://search.earthchem.org/>).

451

The data of OIB and MORB are compiled from Stracke et al. (2022) as “Expert datasets” in GEOROC

452

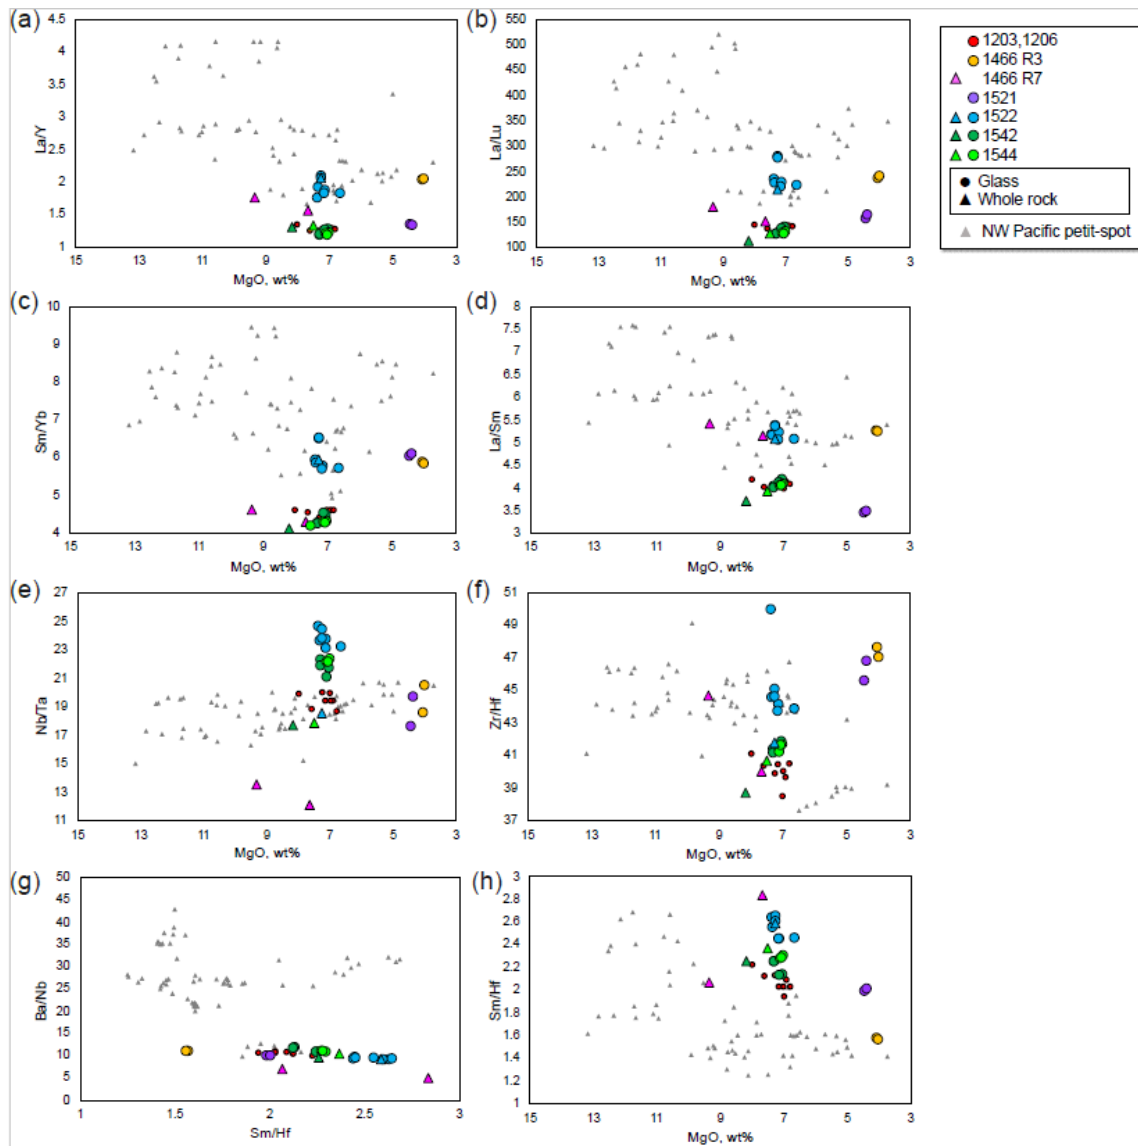

database (<https://georoc.eu/georoc/new-start.asp>).

5.2 Sr–Nd–Pb isotopic composition

The Sr, Nd, and Pb isotopic compositions of the leached, unleached whole rock, and fresh glasses

475 in this study (presented in Table 4) were in practically identical ranges of $^{87}\text{Sr}/^{86}\text{Sr}$ (0.703412–
 476 0.704424), $^{143}\text{Nd}/^{144}\text{Nd}$ (0.512694–0.512890), $^{206}\text{Pb}/^{204}\text{Pb}$ (18.6582–18.7778), $^{207}\text{Pb}/^{204}\text{Pb}$ (15.5086–
 477 15.5749), and $^{208}\text{Pb}/^{204}\text{Pb}$ (38.6506–38.8041) despite their different locations (Figs. 9a–d, Table 4).
 478 The isotopic compositions of the quenched glass and whole rock were identical, indicating that the
 479 characteristics of the melting source could be obtained through the geochemistry of the young and
 480 fresh volcanic quenched glass. The leached and unleached materials of the same sample also had
 481 similar isotopic ratios, except for the 1466R7-003 basalt, which had a relatively high LOI (6.29 wt%)
 482 (Figs. 9a–d). The Sr–Nd–Pb isotopic three-dimensional (3D) plot is shown in Fig. 9e.
 483

484
 485 Fig. 9. Sr–Nd–Pb isotopic variations of the petit-spot basalts. The mantle endmembers are derived from a study by
 486 Zindler and Hart (1986). The open triangles in (a)–(d) represent the acid-leached samples. Carbonatite
 487 data were compiled from GEOROC (<https://georoc.eu/georoc/new-start.asp>) with Bizimis et al. (2003).
 488 Carbonatite data with $^{87}\text{Sr}/^{86}\text{Sr} > 0.706$ by GEOROC were eliminated. The northwestern (NW) Pacific
 489 petit-spots and petit-spots off the Tonga Trench are from Hirano and Machida (2022) and Reinhard et al.

490 (2019), respectively. The petit-spots off the Java trench are from Taneja et al. (2016) and Falloon et al.
 491 (2022). The data of the Wake seamounts are from studies by Konovalov and Martynov (1992), Koppers et
 492 al. (2003), Konter et al. (2008), Natland (1976), Smith et al. (1989), and Staudigel et al. (1991). The
 493 northern hemisphere reference line (NHRL) and Low Nd (LoNd) arrays are from studies by Hart (1984)
 494 and Hart et al. (1986), respectively. (e) The three-dimensional (3D) plot of the Sr–Nd–Pb isotopic
 495 compositions. The compilation and mantle endmembers correspond to (a)–(d). The color usages of the
 496 plots were the same as (a)–(d).
 497

Table 4
 Sr, Nd, and Pb isotopic compositions of western Pacific petit-spot basalts and measured standards.

500 5.3 Age determination and estimation

501

502 The $^{40}\text{Ar}/^{39}\text{Ar}$ ages were determined for two samples (1466R6-001 and 1522R01) (Fig. 10a,
 503 Table S4). The secondary material (e.g., alteration products) plausibly causes the recoil loss and
 504 redistribution of Ar during irradiation of samples, particularly fine-grained groundmass separates of
 505 submarine basalt (Koppers et al., 2000). This effect is negligible for $^{40}\text{Ar}/^{39}\text{Ar}$ dating samples in this
 506 study because the total K/Ca ratios estimated using the irradiated $^{39}\text{Ar}_K/^{37}\text{Ar}_{Ca}$ ratio (0.089 for
 507 6K#1466R6, 0.080 for 6K#1522R01; Table S4) are mostly correspond to the bulk K/Ca ratios
 508 calculated using the major element compositions of Table 2 (0.088 for 6K#1466R7-001, 0.076 for
 509 6K#1522R01). This is supported by the rock descriptions recognized no secondary materials of

510 crystalline $^{40}\text{Ar}/^{39}\text{Ar}$ specimens. Sample 1466R6-001 had a plateau age of 3.03 ± 0.18 Ma in seven
 511 fractions comprising 94.1% released ^{39}Ar . However, the plateau age was recognized as apparently old,
 512 owing to excess ^{40}Ar , as indicated by the initial $^{40}\text{Ar}/^{36}\text{Ar}$ ratio of 325 ± 15 , which exceeded the
 513 atmospheric ratio (296.0; Nier, 1950) in the inverse isochron. The inverse isochron age of 2.56 ± 0.34
 514 Ma showed the best age estimate for the 1466R6-001 basalt (Fig. 10a). The 1522R01 sample released
 515 almost no radiogenic daughter nuclide of ^{40}Ar in the K–Ar age system (Fig. 10a).

516 The ranges of eruption age were estimated for all the samples using the average thickness ($n =$
 517 20) of ferromanganese crust and palagonite rind (hydrated quenched glass) with their
 518 deposition/formation rates on the seafloor (ferromanganese crust, 1–10 mm/Myr; Hein et al., 1999;
 519 palagonite, 0.03–0.3 mm/Myr; Moore et al., 1985) (Fig. 10b). Using this approach, the western Pacific
 520 petit-spots were expected to have erupted later than ca. 9 Ma. The ranges of eruption age estimated
 521 from palagonite rind did not overlap with those from ferromanganese crust showing older durations,
 522 although they had general correlations (Fig. 10b). The $^{40}\text{Ar}/^{39}\text{Ar}$ ages of two samples and the U–Pb
 523 age of zircon in the 1203 and 1206 peperites (Hirano et al., 2019) were overlaid within these ranges.
 524

525
 526 Fig. 10. Geochronological data. (a) The $^{40}\text{Ar}/^{39}\text{Ar}$ ages of the 6K#1466R6-001 and 6K#1522R01 basalts. The errors
 527 show a 2-sigma confidence level. (b) Estimated relative ages using the thickness of ferromanganese crust
 528 (green bands) and palagonite (hydrated quenched-glass rind; red bands) covered with petit-spot basalts.
 529 These values were estimated using the average for each sample ($n = 20$). The U–Pb age of zircon in the
 530 6K#1203 and 1206 peperites are from Hirano et al. (2019).

531

532 6 Discussion

533

534 6.1 Eruptive setting of western Pacific petit-spots

535

536 Here, two crystalline petit-spot basalts were subjected to $^{40}\text{Ar}/^{39}\text{Ar}$ dating. A previously reported
 537 petit-spot knoll in this region (examined during the 6K#1203 and 1206 dives) aged “younger than 3
 538 Ma” was investigated using the U–Pb dating of eight zircons in peperites (Fig. 10b) (Hirano et al.,

2019). The results showed that the silica-undersaturated vesicular basalt of 6K#1466R6-001, as a host of ultramafic xenoliths (Mikuni et al., 2022), exhibited a $^{40}\text{Ar}/^{39}\text{Ar}$ age of 2.56 ± 0.34 Ma (Fig. 10). Oppositely, the fresh vesicular basalt of 6K#1522R01, which erupted at the foot of the 100-Ma Takuyo-Daigo seamount (Fig. 2) (Nozaki et al., 2016), did not exhibit radiogenic ^{40}Ar highlighting that this sample is quite young (approximately 0 Ma) (Fig. 10). The ranges of eruption ages were estimated using the average thickness of ferromanganese crust and palagonite rind (seawater-hydrated quenched glass) with their deposition/formation rates on the seafloor. The $^{40}\text{Ar}/^{39}\text{Ar}$ and zircon U–Pb ages were within these ranges (Fig. 10). Here, the petit-spot volcanic field is surrounded by Cretaceous seamounts (Koppers et al., 2003) and irregular Paleogene volcanoes (Aftabuzzaman et al., 2021; Hirano et al., 2021). However, no zero-aged hotspots were observed in this region, and the P-wave tomographic image of the surface to the core–mantle boundary of the study area did not exhibit a plume-like low-velocity zone (Fig. 1c; Lu et al., 2019). Furthermore, the MORB-like to more depleted noble-gas isotopic compositions of the petit-spot knoll (6K#1203, 1206) suggested its upper mantle origin (Yamamoto et al., 2018). Along with the outer-rise bulge in front of the Mariana Trench detected through a positive gravitational anomaly (Hirano et al., 2019), these data suggest that the western Pacific petit-spot volcanoes could have erupted at $\sim 0\text{--}3$ Ma owing to the flexure of the subducting Pacific Plate into the Mariana and Ogasawara Trenches.

The petit-spot basalts from the 6K#1542 and 1544 dives could have originated from the same eruptive source based on their similar petrographic and geochemical features despite a distance of approximately 6.8 km between both (Figs. 3d, 4, 5, 6, 7, 8, and 9). Contrarily, in terms of their petrography and geochemistry, the basalts from the 6K#1466 dive are discriminated between the samples from the lava flows on the abyssal plain (R3-001 and R3-004) and the samples from the knoll site (R6-001, R7-001, and R7-003). The R3 basalts were collected at a lava outcrop 600 m south of the knoll, and the R6 and R7 samples were collected on the western slope of the knoll (Fig. 3a). The 6K#1466R3 series are glassy with a high SiO_2 content (50.6–51.6 wt%), including minor plagioclase and less vesicles (Figs. 3a and 4a). However, the 6K#1466R6 and R7 series exhibited silica-undersaturated compositions ($\text{SiO}_2 = 39.3\text{--}39.4$ wt%) and high vesicularities (20–40 vol.%) (Figs. 3b and 4a). Combining these observations with the differences in MgO contents and trace element compositions, the R3 and R6–R7 basalts are implied to have different parental magmas (Figs. 6 and 7b). Generally, vesicular samples (6K#1203, 1206, 1466R7, 1522, 1542, and 1544 basalts) are relatively primary (i.e., $\text{MgO} > 6.63$ wt%), whereas nonvesicular samples (6K#1466R3 and 1521 basalts) are evolved (i.e., $\text{MgO} < 4.43$ wt%). This correlates with the compositions of olivine microphenocrysts in the low forsterite content ($\text{Fo}\# = 100 \times \text{Mg}/[\text{Mg} + \text{Fe}^{2+}]_{\text{cation}}$) of olivine in evolved basalts and the high Fo# of olivine in the relatively primary basalts (Figs. S1a–c).

The CI chondrite-normalized REE ratios of these samples are within those of OIBs, and the REE patterns exhibit HREE-depleted patterns (Fig. S3). However, among the western Pacific petit-

575 spots, the REE and trace element ratios differ for each volcano (i.e., parental magmas) (Figs. 6 and
576 S3). Given the lack of correlation between MgO and the trace element ratios, each volcano could have
577 originated from isolated sources (i.e., melt ponds) with different chemical compositions and degrees
578 of melting (Fig.6). Oppositely, the radiogenic Sr, Nd, and Pb isotopic ratios of the samples are nearly
579 identical, and the components in the source are probably equivalent (Fig. 9).

580 Summarily, (1) the western Pacific petit-spot volcanoes erupted at ~0–3 Ma owing to the plate
581 flexure related to the subduction of the Pacific Plate into the Mariana Trench (Figs. 1 and 2). (2) The
582 6K#1542 and 1544 samples originated during the same magmatic event (Fig. 3d). However, the basalts
583 from the 6K#1466 dive are subdivided into two parental magmas (R3 and R6–R7 basalts) (Fig. 3a).
584 (3) Each volcano originated from isolated source and/or ascending processes based on the independent
585 trace element ratios. The geochemical components involved in the source, however, were similar
586 among the western Pacific petit-spot volcanoes because of the nearly identical Sr, Nd, and Pb isotopic
587 compositions (Figs. 6 and 9). A variation in the trace element compositions among the volcanoes is
588 plausibly due to the degree of contribution of carbonatite flux and/or the recycled crustal component
589 to the source, as discussed below.

590

591 **6.2 Petit-spot magma composition and its evaluation**

592

593 Post-eruption seawater alteration might have affected the chemical composition of oceanic
594 basalts. Thus, various approaches, including petrographic observation, geochemical investigation, and
595 acid leaching, have been employed to evaluate the primary features and the removal of this effect for
596 isotopic analysis (Hanano et al., 2009; Melson et al., 1968; Miyashiro et al., 1971; Nobre Silva et al.,
597 2009; Resing and Sansone, 1999; Staudigel and Hart, 1983; Zakharov et al., 2021). The study samples
598 exhibit whole-rock LOI <1.72 wt%, excluding two relatively altered samples, 6K#1466R7-001 (LOI
599 = 2.68 wt%) and R7-003 (LOI = 6.29 wt%). Pristine quenched glasses are preserved in most of the
600 samples, excluding three exceptional samples (the 6K#1466R6-001, R7-001, and R7-003 basalts).
601 Positive correlations are observed between the alteration-insensitive (e.g., Nb, Th) and -sensitive (e.g.,
602 Ba, U) incompatible elements. This indicates that the effect of seawater alteration was not extensive,
603 excluding the 6K#1466R7-001 and R7-003 basalts (Fig. 8). Although each sample was derived from
604 different volcanic edifices, the positive correlation of all the study samples is due to the chemical
605 similarity of the source compositions for certain elements (i.e., Ba/Nb and U/Th ratios are nearly
606 constant among the samples), as well as the Sr, Nd, and Pb isotopic compositions (Fig. 9). These
607 observations showed that most of the petit-spot basalts were unaffected by seawater alteration with a
608 few exceptions (i.e., 1466R7-001 and R7-003 basalts).

609 The variable MgO (4–9 wt%), Ni (<263 ppm), and Cr (<350 ppm) contents in the samples are
610 lower than the expected values of primary mantle-derived melt (MgO >10 wt%, Ni >400 ppm, Cr

611 >1000 ppm; Frey et al., 1978). Similarly, the Mg# ($100 \times \text{Mg}/[\text{Fe}^{2+} + \text{Mg}]_{\text{molar}}$) values are differentiated
612 in the range of 41–57 (Table 2) against the primary basaltic melt, which is equilibrated with the upper
613 mantle (Mg# = 66–75; Irving and Green, 1976). No phenocrysts were observed (only
614 microphenocryst), despite such differentiated compositions as well as most of the NW Pacific petit-
615 spot basalts. This suggests that the western Pacific petit-spots experienced crystal fractionation in the
616 lithosphere as well as the case of NW Pacific petit-spot (Machida et al., 2017; Valentine and Hirano,
617 2010; Hirano, 2011; Yamamoto et al., 2014). Therefore, the calculation of primary composition of the
618 petit-spot basalts using the mineral modal composition on the thin section could not be performed.
619 However, the trends of the major elements of the samples imply the crystal fractionation of the same
620 phases. The negative trends of the Al₂O₃ content and the positive trends of the CaO and CaO/Al₂O₃
621 content with a decrease in MgO indicate the occurrence of olivine, spinel, and clinopyroxene
622 fractionation (Figs. 5c, e, and g). The absence of visible correlations of the K₂O, Na₂O, SiO₂, and TiO₂
623 contents against MgO suggests that the fractionation of plagioclase and the Fe–Ti oxides was
624 insignificant. The Fe–Ti oxides as minor phases in the groundmasses and plagioclases were only
625 observed in the most differentiated 1466R3-001 and R3-004 basalts (Figs. 3, 5a, b, d, and h). However,
626 these major elemental trends should be interpreted as apparent trends because each petit-spot volcano
627 originated from an isolated parental magma with different chemical composition or degree of partial
628 melting as discussed above.

629 The trace element composition of alkali basalts can be used to determine the melting source
630 rather than major elements (Hofmann, 2003; Machida et al., 2014, 2015). Trace element composition
631 of magma, however, could be modified by crustal and/or mantle assimilation and fractionation of
632 certain minerals. The relatively primitive basalts (6K#1203, 1206, 1466R6, R7, 1522, 1542, and 1544)
633 included xenocrystic olivines and partly ultramafic xenoliths, indicating a rapid magma ascent (Hirano
634 et al., 2019; Mikuni et al., 2022; Fig. S4). However, since the stagnation of ascending petit-spot magma
635 could occur to create fertile peridotite and pyroxene-rich veins from the middle to lower depths of the
636 lithosphere (Mikuni et al., 2022; Pilet et al., 2016), the chemical composition of the petit-spot magma
637 could be modified because of assimilation with the ambient lithospheric peridotite. According to
638 Hirano and Machida (2022), ascending silica-undersaturated melt would mainly consume
639 orthopyroxene (\pm spinel) and become a more silicic composition with Zr and Hf depletion. This is
640 because of the relatively higher Zr–Hf partition of orthopyroxene than those of other trace elements
641 (Pilet et al., 2008; Shaw, 1999; Tamura et al., 2019). The orthopyroxenes of fertile pyroxenites and
642 lherzolite xenoliths metasomatized by petit-spot melts exhibit Zr and Hf enrichment (Mikuni et al.,
643 2022; Fig. S5). If this silica-enrichment (i.e., melt–rock interaction) was significant, a positive
644 correlation between SiO₂ and Sm/Hf is expected as a mantle assimilation trend. However, the samples
645 exhibit a negative correlation, similar to those of the NW Pacific petit-spots (Hirano and Machida,
646 2022) (Fig. S2). Considering the relationship between the Sm and Hf partition coefficients of

647 clinopyroxene (i.e., $D^{Hf} < D^{Sm}$; McKenzie and O’Nions, 1991; Kelemen et al., 2003), we suggest that
648 the negative correlation between the Sm/Hf and SiO₂ of the petit-spot basalts probably reflects the
649 crystal fractionation of clinopyroxene rather than mantle assimilation. The Ba/Nb ratios of the samples
650 are nearly constant and do not correlate with the MgO and SiO₂ contents (Figs. 6g and S2g). The lack
651 of correlation between the other trace element ratios, excluding Sm/Hf and Ba/Nb (i.e., La/Y, La/Lu,
652 Sm/Yb, La/Sm, Nb/Ta, Zr/Hf), and the MgO concentration imply that crystal fractionation may not
653 have been involved with those of the incipient melt (Fig. 6). However, it is difficult to independently
654 follow the evolution of the trace element composition for each volcano since each volcano originated
655 from isolated sources. Thus, considering the observations above, the fresh and zero-aged 6K#1522
656 basalts (the highest Sm/Hf ratios and lowest SiO₂ contents among the fresh samples and higher MgO
657 contents) were selected for further analysis with geochemical modeling. Considering that the 6K#1522
658 samples had MgO in the range of 6.63–7.36 wt%, olivine was expectedly the dominant phase of crystal
659 fractionation (Asimow and Langmuir, 2003; Helz and Thornber, 1987; Herzberg, 2006). When the
660 olivine maximum fractionation model (Takahashi et al., 1986; Tatsumi et al., 1983) was applied to test
661 two samples, the calculated primary trace element contents did not significantly differ from those of
662 the analytical compositions (Table S5 and Fig. S6). Thus, the 6K#1522 basalts were assumed to be the
663 most primary petit-spot basalt samples and were used to evaluate the geochemical modeling results.

664

665 **6.3 Melting source of western Pacific petit-spots**

666

667 The depletions of specific elements (e.g., Ta, Zr, Hf, and Ti) of petit-spot basalts potentially
668 demonstrate the involvement of carbonatitic materials in conjunction with a large amount of CO₂ and
669 lower Mg isotopic ratio than that of the normal mantle (Bizimis et al., 2003; Dasgupta et al., 2009;
670 Hirano and Machida, 2022; Hoernle et al., 2002; Liu et al., 2020; Okumura and Hirano, 2013). Other
671 oceanic lavas originating from the asthenosphere (e.g., Hawaiian rejuvenated lavas and North Arch
672 volcanoes) exhibited characteristic trace element signatures (i.e., Zr and Hf depletion) similar to those
673 of petit-spot lavas. This implies that their melting sources were involved with carbonatitic materials
674 with or without plume-derived components (Fig. S7; Borisova and Tilhac, 2021; Clague and Frey,
675 1982; Clague et al., 1990; Dixon et al., 2008; Yang et al., 2003). In addition, the involvement of
676 recycled crustal components was inferred from the geochemical features of the petit-spot basalts, and
677 the upper mantle was revealed to be heterogeneous (Liu et al., 2020; Machida et al., 2009, 2015). Such
678 scenario of the source on petit-spot magma is consistent with the previously suggested petrogenesis
679 of alkaline rocks explained by the addition of CO₂-rich components and/or recycled crustal materials
680 with or without sediment to the mantle (e.g., Dasgupta et al. 2007; Hofmann, 1997). Conversely, the
681 melting of an amphibole-rich metasomatic vein explains the major and trace element composition of
682 alkali basalts (Pilet et al., 2008; Pilet, 2015). However, the experimentally produced melts exhibit Pb

683 depletion and a positive Nb-Ti anomaly in the PM-normalized trace element patterns (Fig. S8)
684 inconsistent with the petit-spot basalts (Fig. 7). In addition, Juriček and Keppler (2023) demonstrated
685 that amphibole dehydration is not the cause for the oceanic LAB by high-pressure experiment on the
686 realistic condition. The fertile pyroxenitic xenoliths and pyroxene xenocrysts occurring in the 1466R6
687 and R7 basalts, which originated from the metasomatic vein related to prior petit-spot magmatism,
688 had neither amphiboles nor other hydrous minerals (Mikuni et al., 2022).

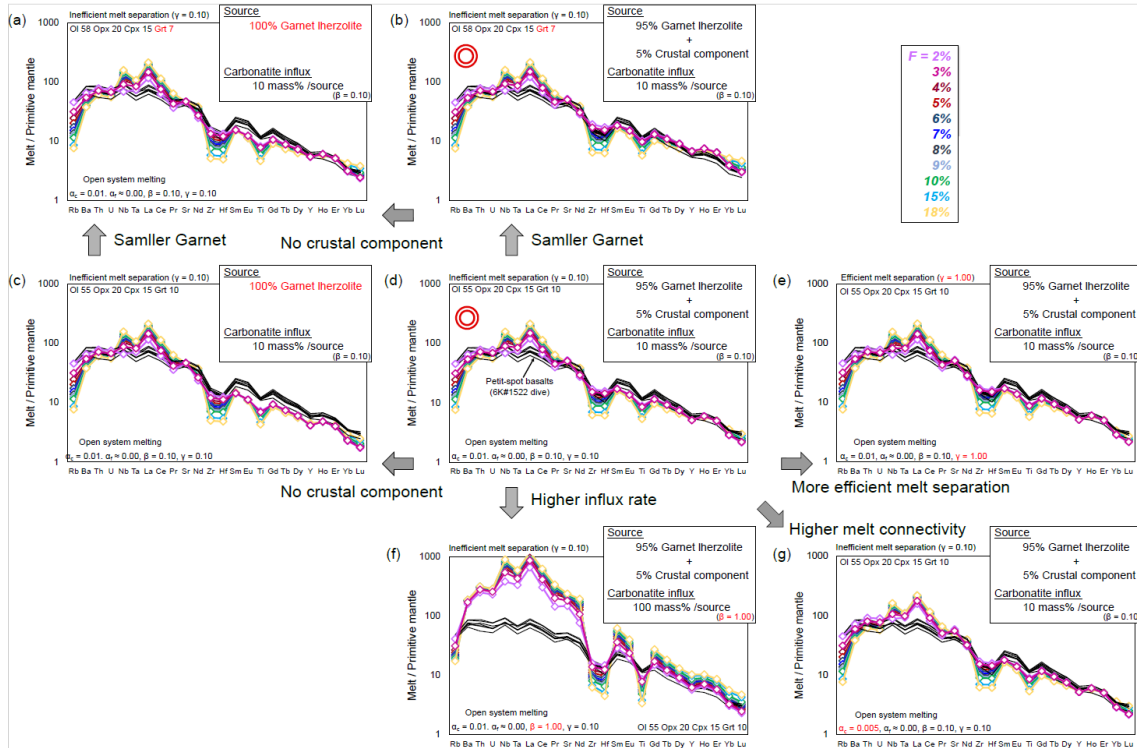

689 To discuss the involvement of carbonatitic and crustal components in petit-spot melts, a partial
690 melting model of the heterogeneous mantle is provided. The involvement of carbonatitic fluids and
691 recycled materials in the genesis of petit-spot melts has been suggested, and the open-system model
692 with carbonatite influx from the outer system was employed using “OSM-4” of Ozawa (2001),
693 referring the parameters of Borisova and Tilhac (2021). This model is based on the mass conservation
694 equations of one-dimensional steady-state melting. In this present study, the model uses a critical melt
695 fraction (α_c ; mass fraction of melt when melt separation begins = melt connectivity threshold) at 0.005
696 or 0.01. The system is opened to fluxing at a constant melt-separation rate (γ) when the system reaches
697 the α_c . The final trapped melt fraction (α_f ; mass fraction of melt trapped in the residue) was fixed at ~ 0
698 (it was calculated as 10^{-6} owing to mass balance). We calculated the trace element composition of
699 partial melts at various degree of melting (F), a few rates of influx (β) and melt separation (γ). We
700 assumed a primitive mantle (PM) source as a lherzolite with or without a normal (N)-MORB source
701 as the recycled oceanic crust (Sun and McDonough, 1989), such as pyroxenite and eclogite. The
702 recycled crust (N-MORB component) was mixed in the source as compositional heterogeneity
703 calculated as “0.05N-MORB + 0.95PM” for the trace element concentration, and the considered
704 mineral phases and their proportions were derived only from garnet lherzolite (i.e., olivine,
705 orthopyroxene, clinopyroxene, and garnet). The mineral mode of garnet lherzolite (olivine 55%,
706 orthopyroxene 20%, clinopyroxene 15%, and garnet 10%) and the melting reaction mode (olivine 8%,
707 orthopyroxene -19%, clinopyroxene 81%, and garnet 30%) are based on studies by Johnson et al.
708 (1990) and Walter (1998), respectively. The proportion of olivine and garnet was also changed to
709 evaluate the effect of garnet modal ratio to the produced melt composition. In this situation, the
710 clinopyroxene is consumed at an F (degree of partial melting) of $\sim 19\%$; therefore, the system was
711 calculated up to 18% partial melting. The carbonatite melt, as an influx, in this model is “average
712 carbonatite” from a study by Bizimis et al. (2003). The partition coefficient of trace elements is
713 generally based on a study by McKenzie and O’Nions (1991, 1995) excluding Ti for clinopyroxene
714 and garnet (Kelemen et al., 2003). The variables of β (influx rate) and γ (melt-separation rate) were
715 changed during the modeling within the mass balance ($\gamma \leq \beta + 1$). The modeled melts were outputted
716 as “total melt,” considering the instantaneous and accumulated melts. For the carbonatite composition,
717 the value of “average carbonatite” of Bizimis et al. (2003) is applied because the chemical composition
718 of carbonatite is largely diverse, and this value is recommended for geochemical modeling (Bizimis

719 et al., 2003). The parameters are listed in Table S6. As a result, partial melting of garnet lherzolite with
720 10% carbonatite influx to a given mass of source (i.e., garnet lherzolite) can roughly explain the trace
721 element pattern of petit spot basalts (Figs. 11a–e), and the presence of 5% crustal component in the
722 source is the most plausible model of petit-spot magma generation (Figs. 11b and d). In addition,
723 slightly less garnet in the lherzolite source than the modal ratio of Johnson et al. (1990) fits the petit-
724 spot better (Fig. 11b). In both cases, the presence of a crustal component in the source yields more
725 plausible results (Figs. 11a–d). The higher carbonatite influx ($\beta = 1.0$) could not explain the trace
726 element composition of the petit-spot basalts (Fig. 11f). The melt connectivity threshold (α_c) of 0.01
727 is plausible because higher connectivity of melt (i.e., lower α_c value) leads to enrichment of LILEs and
728 LREEs (Fig. 11g). The results also showed that the melt-separation ratio is insignificant to the trace
729 element composition of the calculated melts (Figs. 11d and e). Thereafter, we concluded that the partial
730 melting of ~5% crustal component-bearing garnet lherzolite with ~10% carbonatite flux to a given
731 mass of the source plausibly explains the melting source of petit-spot volcanoes (Figs. 11b and d).
732 Assuming that the trace element composition of 6K#1203, 1206, 1542, and 1544 basalts are also
733 primitive, they may be explained by a partial melting of garnet lherzolite with 5% crustal component
734 and lower carbonatite influx rate ($\beta = 0.03$) (Fig. S9). Actually, the 6K#1203, 1206, 1542, and 1544
735 basalts exhibited the similar MgO contents and Mg# to those of 6K#1522 basalts (Fig. 4 and Table 2).
736 These results provide quantitative evidence on the petrogenesis of petit-spots, i.e., the contribution of
737 carbonatite melt and recycled oceanic crust.

738 Although the melting source contained small proportions of carbonatite melt and crustal
739 components, these components could have contributed to the isotopic composition because of their
740 abundant incompatible elements rather than the ambient mantle. The determination of the Sr, Nd, and
741 Pb isotopic compositions revealed that they had geochemically identical prevalent mantle (PREMA)-
742 like sources (Fig. 9). They do not belong to any mantle isotopic endmembers (i.e., depleted MORB
743 mantle (DMM); EM-1, -2; and HIMU; Fig. 9) contrary to those of NW Pacific petit-spots toward the
744 EM-1 isotopic composition (Machida et al., 2009; Liu et al., 2020). In the Pb isotopic space, the present
745 samples do not correlate with those of the neighboring HIMU-like Cretaceous seamounts (Fig. 9a) (N-
746 Wake, S-Wake seamounts; Konter et al., 2008; Koppers et al., 2003; Natland, 1976; Smith et al., 1989;
747 Staudigel et al., 1991). For the melting source of the NW Pacific petit-spot basalts, the contributions
748 of the eclogite/pyroxenite endmember as recycled oceanic crust and the carbonated endmember were
749 suggested based on the major and trace elements and the Mg, Sr, Nd, and Pb isotopic compositions
750 with the Mg diffusion modeling (Liu et al., 2020). The higher FeO/MnO ratios of the present melts
751 (65.9–78.0), compared with those of partial melts originating from peridotite (50–60), are attributed
752 to the presence of recycled pyroxenite (Herzberg, 2011). This could have contributed to the crustal
753 components in the melting source. However, the western Pacific petit-spots in this study identically
754 exhibited a PREMA-like isotopic signature without extreme endmember contributions as described

755 above (Fig. 9). Such isotopic compositions with the world's petit-spots can be possibly explained by
756 the diverse mixing proportion of HIMU and EM-1 components (Fig. 9e). The isotopic compositions
757 of the NW Pacific petit-spots (off the Japan Trench), Samoan petit-spots (off the Tonga Trench), petit-
758 spot dikes in Christmas Island (off the Java trench), and western Pacific petit-spots (off the Mariana
759 Trench in this study) are roughly along the HIMU–EM-1 mixing line (Fig. 9e). Furthermore, the
760 isotopic compositions of global carbonatites can be generally explained by the mixing of HIMU and
761 EM-1 (Bell and Tilton, 2002; Hoernle et al., 2002; Hulett et al., 2016). The contributions of the
762 carbonated material/carbonatite and crustal components to the melting source were suggested in terms
763 of the origin of HIMU and EM-1 (Collerson et al., 2010; Hanyu et al., 2011; Wang et al., 2018; Weiss
764 et al., 2016; Workman et al., 2004; Zindler and Hart, 1986). However, the EM-1 and HIMU
765 components could not be determined to be carbonated component and recycled crust, respectively,
766 owing to the various views on each tectonic setting for the mantle endmember. The variability of global
767 carbonatite isotopic compositions also makes it difficult to determine their representative isotope ratios
768 (Fig. 9). Although such issues make a quantitative isotopic mixing model challenging, the HIMU-EM-
769 1 like trend of the global petit-spot volcanoes may reflect the involvement of carbonatitic and recycled
770 crustal materials. Conclusively, the mass balance models on the trace elements and the isotopic
771 variations in the petit-spot volcanoes confirmed the contribution of carbonatite melt and the recycled
772 oceanic crust to the melting source of the western Pacific petit-spots (Fig. 12). Experimental studies
773 have revealed the various petrogenesis of carbonatite and carbonatitic alkali-rich magma under high
774 pressures (Dasgupta et al., 2006; Ghosh et al., 2009). The geochemistry of petit-spot basalts including
775 Mg isotopes suggested that the conceivable origin of carbonatite related to the petit-spot melt is
776 subducted “carbonated” pelite, pyroxenite/eclogite, or peridotite stored as diamond or metal carbide
777 in the reduced lower portion of the upper mantle (Liu et al., 2020; Rohrbach et al., 2007). Subducted
778 carbonated pelite, for example, would melt under high pressure (>8 GPa) through the oxidation at the
779 redox boundary where the the iron-wüstite (IW) buffer changes to the quartz–fayalite–magnetite
780 (QFM) buffer (i.e., redox melting; Grassi and Schmidt, 2011). Chen et al. (2022) demonstrated that
781 the alkali-rich carbonatite melt could occur under a pressure higher than 6 GPa, particularly exhibiting
782 K-rich and Na-rich carbonatites under 6–12 and >12 GPa, respectively. This pressure-dependent
783 alkalinity of the produced carbonatite melts might explain the variation between potassic NW Pacific
784 petit-spot lavas and present sodic petit-spot lavas (Fig. 4b). On the other hand, an experimental study
785 pointed out the existence of carbonate-rich layer in the LAB owing to the horizontally spread carbonate
786 from around the wedge mantle rather than upwelling from the deep mantle (Hammouda et al., 2020).
787 Several high pressure–temperature experiments and modeling revealed that the chemical composition
788 of intraplate magmas from upper mantle depends on their original depth; carbonatitic melt can be
789 generated beneath thick cratonic lithosphere (~250–200 km), kimberlitic melt would be produced at
790 >120 km in depth, and alkali basalt would occur at 100–60 km in depth by partial melting of “original”

791 CO₂ and H₂O-bearing mantle (Massuyeau et al., 2021). These depth-dependent compositional
 792 variation, that is, K-rich kimberlite to alkali basalt may also explain the geochemical gap between K-
 793 rich NW Pacific petit-spots and K-poor western Pacific petit-spots (Fig. 4b). Although the multiple
 794 origins of carbonatite are merely suggested and remain unclear, carbon-rich components play a key
 795 role in the partial melting of mantle at the LAB (Sifré et al., 2014), that is, the source of petit-spot
 796 magma.

797
 798 Fig. 11. Geochemical modeling for the primitive mantle (PM)-normalized trace-element pattern. The calculated
 799 hypothetical melts are a production of carbonatite influx melting of garnet lherzolite with or without 5%
 800 crustal component. Detailed information of the parameters is described in Section 6-3 and Table S6. F is
 801 the degree of melting (%). The trace-element composition of the western Pacific petit-spot basalts from
 802 the 6K#1522 dive is shown as black lines for comparison. The PM composition of lherzolite and the N-
 803 MORB composition of recycled crust were based on a study by Sun and McDonough (1989). The influx
 804 carbonatite is the “average carbonatite” of a study by Bizimis et al. (2003). The parameters used in the
 805 open-system melting models were as follows: a_c is a critical melt fraction, a_f is a final trapped melt
 806 fraction, β is a melt influx rate, and γ is a melt-separation rate. Model results are compared by varying
 807 each parameter, i.e., garnet modal ratio and presence of crustal material (a–d), melt-separation rate (d and
 808 e), carbonatite influx rate (d and f), and critical melt fraction (d and g). Each figure is expressed based on
 809 the difference from the condition in (d).

Authorship contributions

835

836

837

838

K. Mikuni and N. Hirano conceived the project and performed all experiments. S. Machida and Y. Kato contributed the Sr, Nd, and Pb isotopic analysis using TIMS and MC-ICP-MS. H. Sumino contributed the $^{40}\text{Ar}/^{39}\text{Ar}$ dating. N. Akizawa, A. Tamura, and T. Morishita helped and performed

839 EPMA and LA-ICP-MS analyses. S. Machida and N. Hirano conducted the research cruises to gain
840 the rock samples. All authors interpreted the data and wrote the manuscript with comments and
841 improvements.

842

843 **Competing Interest**

844

845 The authors declare that they have no conflict of interest.

846

847 **Data availability**

848

849 The data newly analyzed in this study and results of geochemical modeling are included in
850 digital format in the online data repository of this paper (Tables 1, 2, 3 and 4, and Supplementary
851 Tables S1 to S6) and the EarthChem online database (DOI will be obtained when it is accepted).

852

853 **Acknowledgement**

854

855 We would like to thank the captains, crews, and shipboard scientific parties of the R/V *Yokosuka*
856 and the operating team of the submersible *Shinkai 6500* for their great work during the YK16-01,
857 YK18-08, and YK19-05S cruises. The Kyoto University Research Reactor Institute is gratefully
858 acknowledged in their assistance of undertaking the radiometric dating. We would like to express our
859 great appreciation to Prof. T. Tsujimori (ORCID: 0000-0001-9202-7312) for his effort in management
860 of the laboratory at Tohoku University. We also thank R. Fukushima (ORCID: 0000-0003-2683-6757)
861 for improving the wording in the manuscript. We are really grateful Y. Matamura, Y. Shimbo, and Y.
862 Jindo for their help and discussion on scientific matters. The authors would like to thank Enago
863 (www.enago.jp) for the English language review. This research was supported by the Cooperative
864 Program (No. 106, 202) of Atmosphere and Ocean Research Institute, The University of Tokyo. The
865 Japan Society for the Promotion of Science (Grant Numbers 17K05715, 18H03733, 20K04098) also
866 supported this research.
