Abstract. This paper evaluates the performance of a multicopter uncrewed aircraft and AirCore system (UAAS) for measuring vertical profiles of wind velocity (speed and direction) and the mole fractions of methane (CH₄) and carbon dioxide (CO₂), and presents a use case that combines UAAS measurements and dispersion modeling to quantify CH₄ emissions from a dairy farm. To evaluate the atmospheric sensing performance of the UAAS, four field deployments were performed at three locations in the San Joaquin Valley of California where CH₄ hotspots were observed downwind of dairy farms. A comparison of the observations collected on board the UAAS and an 11-m meteorological tower show that the UAAS can measure wind velocity trends with a root mean squared error varying between 0.4 and 1.1 m s⁻¹ when the wind magnitude is less than 3.5 m s⁻¹. Findings from UAAS flight deployments and a calibration experiment also show that the UAAS can reliably resolve temporal variations in the mole fractions of CH₄ and CO₂ occurring over 10 second periods or longer. Results from the UAAS and dispersion modeling use case further demonstrate that UAAS have great potential as a low-cost tool for detecting and quantifying CH₄ emissions in near real-time.

1 Introduction

Methane (CH₄) is a potent greenhouse gas responsible for a quarter of anthropogenic radiative forcing. Increases in agriculture, oil and gas, and waste management activities have contributed to the growth of atmospheric CH₄ levels and resultant climate warming. Due to its relatively short atmospheric lifetime of 10-12 years and high global warming potential of 84 on a 20-year timeframe (Myhre et al., 2013), CH₄ is an important target for climate mitigation. The Global Methane Pledge of 2021 (IEA, 2022) calls for reductions of CH₄ emissions, which will in turn require new measurements of baseline emissions and verification of CH₄ mitigation actions. The abatement of human-driven CH₄ emissions will take place at individual facilities, where local CH₄ hotspots have been observed and emissions can be quantified, requiring further measurements to verify the success of mitigation actions.

CH₄ emission estimates for individual facilities have been made through observations of wind velocity and CH₄ enhancements by mobile vehicle-mounted sensors, which provide the opportunity to survey a large number of facilities in urban or agricultural settings (Moore et al., 2022; Amini et al., 2022; Arndt et al., 2018). Facility-level measurements are particularly needed for dairy farms, which can have a large contribution to CH₄ budgets from wet manure management and enteric fermentation emissions, and are important for CH₄ mitigation plans in California (Marklein et al. 2021). Facilities with large emissions can be identified by atmospheric CH₄ enhancements adjacent to or downwind of the source observed from the ground (Hopkins et al., 2016), and then those enhancements can be converted to emission estimates with additional of local winds. However, vehicle-based studies have been limited by the requirements of site or public road access, and often cannot detect emissions from elevated infrastructure such as chimneys and flare stacks. Depending on the distance of the road from the source, the CH₄ plume may be lofted high above the mast of an on-road platform, particularly during daytime sampling when the planetary boundary layer height extends on the order of hundreds of meters above the surface.

While airborne platforms do not require road accessibility and are able to provide vertical profiles of CH₄, airborne mass balance techniques are limited to isolated facilities in open areas (Hajny et al., 2019; Karion et al., 2013; Kobayashi et al., 2016), and are costly, which limits the potential for repeated sampling to study time-varying emissions. Plume observations made by small uncrewed aircraft systems (sUAS) combine the flexibility of on-road measurements with the vertical profiling capabilities of aircraft. Particularly when used together with on-road sampling to identify hotspot locations, sUAS are a promising technology for facility-level methane emission estimation. Compared to light-crewed aircraft and sensor towers, small aircraft systems are low cost, portable, and can safely maneuver near emission sources at low altitudes in urban and rural environments. Such characteristics of sUAS are promising for improving the detection of CH₄ and CO₂ at sub-1km scales. Higher-resolution observations of CH₄ and CO₂ can in turn provide more reliable estimates of anthropogenic emission sources that are difficult or infeasible to measure directly as well as detect small plumes that are not resolved by existing remote sensing technologies.

Numerous studies have already explored the integration of low-cost sensors on board sUAS for measuring greenhouse gases. Small onboard sensors (Berman et al., 2012; Golston et al., 2017; Khan et al., 2012; Graf et al., 2018) have successfully

65 been used to measure multiple gas species including CH₄ and CO₂. However, low-cost CH₄ sensors are in an early stage of development and do not meet the part per million (ppm) or sub-ppm sensitivity required for environmental monitoring (Honeycutt et al., 2019).

70 Alternate atmospheric sampling methods have combined the capabilities of multirotor sUAS and higher-precision instruments to obtain more reliable measurements of local greenhouse gas levels. For example, multiple studies have used bag samplers for collecting lower-atmosphere air samples on board multirotor sUAS (Yuan et al., 2021; Nisbet et al., 2020; Shaw et al., 2021). Using this approach, an air volume is captured onboard the sUAS and then transported to a location where it can be analyzed using a higher-precision instrument, rendering a single point measurement for each sampling location. Other studies have aimed to obtain direct measurements of air composition by using a sUAS to tow the inlet of a high-precision instrument (Broisy et al., 2017). Although this method can increase the spatiotemporal resolution of measurements, the length and weight of the inlet can limit air sampling operations to a small domain. Therefore, the development of unconstrained air
75 sampling methods that can attain higher spatial and temporal resolution are necessary for accurate characterization of greenhouse gas emissions.

More practical and effective techniques for combining multirotor sUAS and high-precision air sampling instruments may be possible with AirCore technology. To date, passive and active AirCore systems have been developed and deployed on board aircraft (Tadić and Biraud, 2018; Karion et al., 2010), weather balloons (Tu et al., 2020; Sha et al., 2020; Li et al., 2023),
80 and sUAS (Andersen et al., 2018; Vinković et al., 2022). Passive AirCore systems rely on increases in ambient pressure for passive measurements of the atmosphere (Karion et al., 2010). Alternatively, active AirCore systems rely on a micropump and an orifice system to sample air both ascending and descending, as well as moving laterally, which provides an alternate method for increasing the spatial resolution of atmospheric measurements in the lower atmosphere. However, no study so far has explored the integration of multirotor sUAS and AirCore systems for measuring the vertical profiles of wind velocity (i.e.,
85 wind speed and wind direction) and air composition simultaneously.

Here we evaluate the performance of a multirotor uncrewed aircraft and AirCore system (UAAS) for measuring vertical profiles of the atmospheric wind velocity and the mole fractions of CH₄ and CO₂. The UAAS was designed to measure the mole fractions of CH₄ and CO₂ in the lower 120 m of atmosphere. The motion kinematics of the UAAS were also used to infer the wind speed and wind direction while steadily ascending and descending. The UAAS was deployed along with an on-
90 road mobile platform to measure the mole fractions of CH₄ and CO₂ downwind of dairy farm operations. Finally, the vertical profiles of wind velocity and the mole fractions of CH₄ and CO₂ were combined with a dispersion model to detect and quantify methane emissions from a dairy farm operation. The findings from field deployments and dispersion modeling are used to assess the effectiveness of the UAAS as a low-cost solution for detecting and quantifying greenhouse gas emission sources.

2 Methods and materials

95 2.1 Field operations

Four UAAS operations were performed from January 20th to 24th, 2020 in the San Joaquin Valley of California to measure CH₄ and CO₂ downwind of dairy farm operations (see Table 1). CH₄ and CO₂ surveys were first conducted downwind of dairy farm facilities before each deployment (see Figure 1a) by sampling through the inlet of a Picarro G1301 cavity ring-down spectrometer (CRDS) that was placed through the side window of a van driving at a speed of approximately 9 m s⁻¹. The four UAAS deployments were performed at three locations where hot spots of CH₄ or CO₂ from dairy farms were detected (see Figure 1a). Before each deployment, an ignited lighter was placed in front of the UAAS inlet to mark the starting point of the measurement interval. During each deployment, the UAAS profiled the wind velocity and the mole fractions of CH₄ and CO₂ steadily ascending up to a height of 120 m above ground level (AGL), and steadily descending along the same path (see Figure 1b). The mean speed of the ascent and descent flight operations was approximately 5 m s⁻¹. The air sample collected on board the UAAS was analyzed within a 5-minute period upon landing, also using the CRDS that was employed to conduct mobile surveys. The wind velocity profiles were estimated offline using the flight data collected onboard the UAAS autopilot and a kinematic vehicle motion model (González-Rocha et al., 2019a).

Table 1. Summary of UAAS flight operations conducted in the San Joaquin Valley of California.

2.2 Ground-based meteorological and gas analyzer instruments

110 2.2.1 Meteorological evaluation tower

Observations from an 11-m meteorological evaluation tower (MET) were used to assess the performance of the UAAS measuring wind velocity trends in the lower atmosphere. The MET was located within a radius of 8.3 km from all three UAAS operations. The surface topography between the MET and the locations of the three UAAS operations was relatively flat. As shown in Figures 2a and 2b, two Campbell Scientific CSAT-3 sonic anemometers were installed on top of the MET at heights of 3 m and 11 m AGL. A CR3000 data logger was used to collect and process 1-second and 5-minute sonic anemometer measurements. The sonic anemometers and data loggers were both powered using a 12V marine deep-cycle battery.

2.2.2. Gas Analyzer

The gas analyzer used during field experiments is the Picarro G1301 cavity ring-down spectrometer (CRD) shown in Figure 2c. The instrument measures CH₄, CO₂, and water vapor gas with a varying sampling rate ranging between 0.3 and 1 Hz. During field surveys, the gas analyzer was housed inside a passenger van and electrical power was supplied to the instrument using a standalone 12V marine deep cycle battery with a pure sine inverter. The instrument's precision, flow rate, and pressure while conducting CH₄ surveys were measured to be 10 ppb, 0.7 standard liters per minute, and 4.5 mbar, respectively.

2.3 Multirotor sUAS

The multirotor aircraft that was used to tow the AirCore system is a commercially available hexacopter Matrice 600 Pro (SZ DJI Technology, China). The Matrice 600 Pro airframe measures 1668 mm × 1518 mm × 727 mm and has a maximum take-off payload capacity of 6 kg. The AirCore system was attached to the bottom of the multirotor airframe using a 5-m long stainless-steel cable (see Figure 1b). Fully integrated, the UAAS has a maximum flight time of 13 minutes. The flight telemetry record is automatically logged on-board the autopilot of the UAAS. The control and retrieval of flight records were conducted using the DJI GO app (SZ DJI Technology, China).

2.4 AirCore system

2.4.1 Hardware description

The AirCore system consists of perfluoroalkoxy (PFA) coiled tubing that is approximately 60 m long. The coiled tubing has an outer diameter of 12.7 mm, an inner diameter of 9.53 mm, and can hold up to 4.3 liters of air. The inlet of the AirCore system is left open to collect ambient air. The outlet of the AirCore system is connected to a Karlsson Robotics D2028 micro diaphragm pump that weighs approximately 0.3 kg and has a vacuum range between 0 and 406 mm Hg. Airflow through the AirCore system was held constant at approximately 0.45 standard liters per minute using an O'Keefe Controls No. 9 (0.02286 cm diameter) metal orifice. The metal orifice is located 5 cm upstream of the micro diaphragm pump as shown in Figure 3b. The pump and a 12V lithium-ion battery pack were placed in a plastic enclosure that was positioned in the open area at the center of the AirCore coil. The activation of the AirCore was achieved using a remote relay connected to the pump's power cables. Fully assembled, the AirCore system weighs roughly 5 kg.

2.4.2 AirCore characterization experiments

Laboratory tests were conducted to evaluate the performance of the AirCore system for resolving variations in the mole fractions of CH₄. We first generated a CH₄ mixture by diluting a CH₄ standard of 500 ppm inside of a Teflon bag with room air. The Teflon bag was then connected to a three-way valve as shown in Figure 3a. The three-way valve of the calibration apparatus was controlled to switch between the intake of the CH₄ mixture and the ambient air. The AirCore system and the

CRDS used in field experiments were connected using a tee junction to pull air simultaneously from the Teflon bag. During the calibration experiment, spikes of CH₄ were generated for periods of 5 and 10 seconds to simulate the AirCore system passing through a CH₄ plume (see Figure 3b). The CRDS provided real-time and continuous measurements of CH₄ while the valve was opened and closed, and was used to analyze the air sample collected inside the AirCore system.

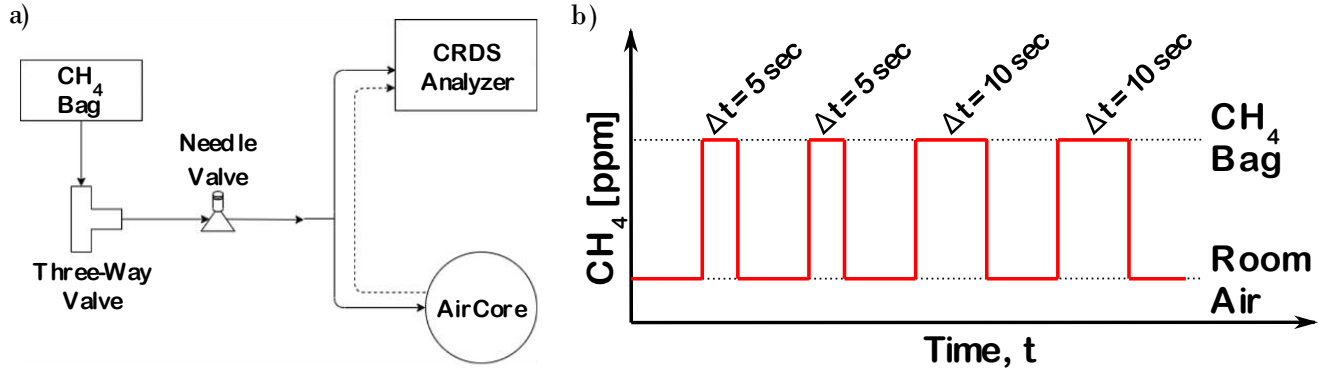

Figure 3. a) A schematic of the AirCore calibration experiment setup. The solid lines and arrows show the gas flow when the CRDS and AirCore sampled the CH₄ mixture simultaneously. The dashed lines and arrows show the gas flow when the CRDS pulls air from the AirCore system. b) A schematic showing the open and closed needle valve position during the AirCore calibration experiment.

2.5 Multirotor sUAS wind velocity sensing

2.5.1 Wind estimation method

Wind velocity profiles were estimated using a kinematic model of the UAAS and measurements of attitude and heading that were collected while steadily ascending and descending vertically using (Neumann and Bartholmai, 2015; González-Rocha et al., 2019b). The attitude and heading measurements were obtained from the attitude and heading reference system of the UAAS flight autopilot with a 20 Hz sampling rate. To develop the kinematic model, we first defined a body-fixed reference frame, $F_b = \{\mathbf{b}_1, \mathbf{b}_2, \mathbf{b}_3\}$ at the aircraft center of gravity such that the unit vectors \mathbf{b}_1 and \mathbf{b}_2 point along the front and lateral sides of the vehicle, respectively. The unit vector \mathbf{b}_3 is parallel to the propeller spin axis and points along the direction of the propulsive flow (see Figure 4a). We also defined an inertial reference frame $F_i = \{\mathbf{i}_1, \mathbf{i}_2, \mathbf{i}_3\}$, affixed to the Earth's surface such that the unit vectors \mathbf{i}_1 and \mathbf{i}_2 point in the north and east directions, respectively, and the \mathbf{i}_3 unit vector points towards the Earth's center. The orientation of the body-fixed reference frame is measured relative to the inertial reference frame using the roll-pitch-yaw Euler angles, $\theta = \{\phi, \theta, \psi\}$. After defining the body-fixed and inertial reference frames, two kinematic relationships were derived to infer wind speed and wind direction separately.

Wind speed estimates were inferred from the tilt of the aircraft that is realized in steady-ascending vertical flight to compensate for wind disturbances. The tilt of the multirotor sUAS was determined using the dot product rule:

$$\alpha = \cos^{-1}([\mathbf{R}(\phi, \theta, \psi) \cdot \mathbf{b}_3] \cdot \mathbf{i}_3) \quad (1)$$

where

$$\mathbf{R}(\phi, \theta, \psi) = \begin{pmatrix} \cos\theta\cos\psi & \cos\psi\sin\theta\sin\phi - \cos\phi\sin\psi & \cos\psi\sin\theta\cos\phi + \sin\phi\sin\psi \\ \cos\theta\sin\psi & \sin\psi\sin\theta\sin\phi + \cos\phi\cos\psi & \sin\psi\sin\theta\cos\phi - \sin\phi\cos\psi \\ -\sin\theta & \cos\theta\sin\phi & \cos\theta\cos\phi \end{pmatrix} \quad (2)$$

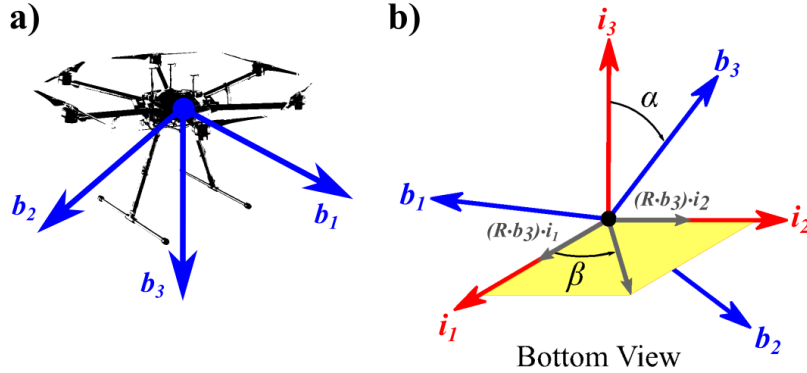

is the rotation matrix mapping \mathbf{b}_3 from F_b to F_i . In employing this approach, we assume there is a one-to-one relationship between the tilt angle α and the horizontal wind speed (i.e., $\alpha = \|\mathbf{u} + \mathbf{v}\|$).

180 The wind direction was inferred from the projection of the \mathbf{b}_3 unit vector onto the $\mathbf{i}_1 - \mathbf{i}_2$ plane shown in Figure 4b during steady-ascending flight. If the aircraft heading is pointing north, wind direction is expressed in the inertial reference frame by computing the four-quadrant tangent inverse of the components of the \mathbf{b}_3 unit vector projected onto the \mathbf{i}_1 and \mathbf{i}_2 unit vectors

$$\beta = \tan_4^{-1} \left(\frac{[\mathbf{R}^T(\phi, \theta, \psi) \cdot \mathbf{b}_3] \cdot \mathbf{i}_2}{[\mathbf{R}^T(\phi, \theta, \psi) \cdot \mathbf{b}_3] \cdot \mathbf{i}_1} \right) \quad (3)$$

Otherwise, wind direction is expressed in the Earth-fixed reference frame by making the following correction:

$$\text{Wind Direction} = \begin{cases} \beta - \psi, & \text{if } \beta > \psi \\ \beta - \psi + 360, & \text{if } \beta < \psi \end{cases} \quad (4)$$

185 **Figure 4.** a) A schematic of the sUAS body-fixed reference frame. b) A schematic showing how the tilt angle, α , and wind direction, β , are computed from the orientation of the sUAS body-fixed frame relative to the inertial reference frame.

2.5.2 Evaluation of multirotor sUAS wind velocity estimates

UAAS wind velocity estimates were validated employing two methods. First, we compared UAAS wind velocity estimates to wind velocity observations collected from the 11-m MET tower described in Sect. 2.2.1. The difference between UAAS and MET tower wind observations was quantified using the root mean squared error (RMSE) metric. Second, we compared UAAS wind speed estimates to wind speed profiles obtained from the wind profile power law (WPPL) described in Eq. (5)

$$U(Z_2) = U(Z_1) * \left(\frac{Z_2}{Z_1} \right)^\alpha \quad (5)$$

where $U(z_1)$ and $U(z_2)$ are the wind speeds at heights z_1 and z_2 , respectively, and α is the wind shear exponent value obtained from the MET tower at $Z_1 = 3$ m and $Z_2 = 11$ m using Eq. (6)

$$\alpha = \frac{\ln U(z_2) - \ln U(z_1)}{\ln z_2 - \ln z_1} \quad (6)$$

195 Results from the two assessments were used to characterize the UAAS wind estimation performance.

2.6 Methane emissions estimates

2.6.1 Dairy farm description

The vertical profiles of wind velocity and CH₄ collected during the first flight were used as inputs for a dispersion model to quantify CH₄ emissions from a dairy farm. As shown in Figure 5a, the UAAS vertical profiles were measured at a location that is 1,645 m north and 802 m west from the dairy farm, which itself is ~800 m wide. During the first UAAS operation the wind direction changed from north to south, allowing the downwind and upwind profiles to be collected from a single flight. The methane emission sources on this dairy farm consists of wet manure management in five manure lagoons, and enteric fermentation from 3115 milk cows and associated support stock housed in three freestall barns and three cattle corrals (Figure 5b; Table 2). Surface area estimates derived from Figure 5b, and estimates of number of animal units derived from permit data (Table 3) were used along with the UAAS vertical profiles to evaluate the effectiveness of the UAAS for estimating methane emissions.

Figure 5. a) A satellite image from Google Earth showing the location of the first UAAS operation downwind of a dairy farm. b) A close-up of a) showing the potential emission sources of CH₄ within the farm.

210 **Table 2.** Dairy farm sections likely to produce CH₄ emissions from the enteric fermentation or manure management of approximately 3115 milk cows (Marklein et al., 2021).

**1 AU = 1,000 lbs. live weight.

2.6.2 Dispersion model

220 The unknown emission rate from the dairy can be estimated from atmospheric observations of CH₄ through the following relationship:

$$C_i = \sum_{j=1}^N T_{ij} E_j + C_b + \varepsilon_i \quad (7)$$

where T_{ij} is the transport matrix of an area source estimated by Eq. (7) with unit emission rate on data point i and at source j , C_b is the lowest mole fraction of CH₄ measured from the UAAS, and E_j is the inferred emission rate obtained by minimizing the residual square $\sum_i^N \varepsilon_i^2$ with the constraint that their values are greater than or equal to zero. To achieve this, we use the

225 MATLAB function *lsqnonneg* described by Lawson and Hanson (1974). The 95% confidence intervals for the emission rate

can be determined by a bootstrapping method which generates a distribution of emission rates by fitting the pseudo-observations to the model estimates.

In the numerical model, the dairy farm can be treated as an area source, which consists of a set of line sources perpendicular to the wind direction. For the contribution from each line source to the receptor, we use an analytical approximation to the integral along the source (Venkatram and Horst, 2006), which gives the concentration as

$$C(x, y, z) = q[erf(t_1) - erf(t_2)]F_z(x, z) \quad (8)$$

where

$$t_i = \frac{y - y_i}{\sqrt{2}\sigma_y x} \quad (9)$$

and q is the line source emission rate per unit length, x is the downwind distance of the receptor from the source, $y - y_i$ is the distance of the receptor from two end points of the line along the direction parallel to the source, σ_y is the horizontal plume spread, erf is the error function, and $F_z(x, z)$ is the vertical distribution function, which is applied the numerical solution of the mass conservation equation (Akula Venkatram and Nico Schulte, 2018)

$$U(z) \frac{\partial C}{\partial x} = \frac{\partial}{\partial z} \left(K(z) \frac{\partial C}{\partial z} \right) \quad (10)$$

where C denotes the crosswind-integrated concentration \underline{C}^y for convenience, $K(z)$ is the vertical eddy diffusivity, and $U(z)$ is the horizontal velocity. The boundary conditions are

$$K(z) \frac{\partial C}{\partial z} = 0 \text{ at } z = z_0 \text{ and } \frac{\partial C}{\partial z} = 0 \text{ at } z = H$$

where z_0 is the roughness length, which is computed to be 0.005 m (Qian et al., 2010) and H is the boundary layer height. The numerical method initializes a Gaussian concentration distribution at $x = 0$, which is centered at source height $z_s = 0.1$ m and with an initial vertical spread $\sigma_z = 0.1$ m. Van Ulden, (1978) shows that the analytical solution of Eq. (8) provides an excellent description of concentrations measured during the Prairie Grass Project (Barad, 1958). Venkatram (2018) evaluates the usefulness of the analytical formulas through the numerical solution using the Businger-Dyer expressions for eddy diffusivity of heat $K_H(z)$, and the wind profile $U(z)$.

245 3 Results

Four UAAS deployments were performed at three locations in the San Joaquin Valley where CH₄ hotspots from dairy farms were detected. During each deployment, the UAAS measured vertical profiles of wind velocity and the mole fractions of CH₄ and CO₂ while ascending and descending during periods of both variable and relatively-stable wind conditions (each deployment lasting approximately 9 minutes). All four sets of wind velocity and air composition profiles were evaluated using ground-based measurements. The UAAS measurements and dispersion modeling were combined to estimate the methane emissions from one of the dairy farms.

3.1 Wind velocity profiles

255 The UAAS was found to reliably measure wind velocity trends while vertically ascending and descending in both variable and relatively-stable wind conditions. The comparison of UAAS and MET wind speed observations during variable wind conditions resulted in an RMSE of 1.1 m s^{-1} , with the smallest error being observed while the UAAS ascended and descended near the surface (see Figure 6a). The corresponding measurements of wind direction from the UAAS and MET were in close agreement near the surface as well. In relatively-stable wind condition, the RMSE between UAAS and MET tower wind speed observations was equal to or less than 0.5 m s^{-1} (see Figure 6b, 6c, and 6d). Notable differences between UAAS and MET observations of wind direction were observed only at the start of the third flight.

260 The UAAS may also have good performance measuring wind speed while ascending vertically based on the evaluation of UAAS and power law wind speed profiles. As shown in Figure 7a, the uncertainty bands of the wind speed profiles that were obtained from the ascent and descent UAAS operations and the power law overlapped up to 120 m AGL and 80 m AGL, respectively, in variable winds. In relatively-stable wind conditions, the uncertainty bands of the wind speed profiles obtained from ascent and descent operation and the power law overlapped up to 110 m AGL and 60 m AGL, respectively, as shown in Figure 7b.

	CH ₄ signal	
	5 seconds	10 seconds
CRDS [ppm]	1,015	845
AirCore system [ppm]	810	980
Percent difference	20.2	16.2

270

Figure 7. A comparison of UAAS and power law wind speed profiles measured during a) variable and b) relatively-stable wind conditions. The dashed blue lines show the uncertainty of the power law wind speed profiles.

3.2 CH₄ and CO₂ profiles

In addition to measuring wind velocity trends, the UAAS measured the mole fractions of CH₄ and CO₂ during both variable and relatively-stable wind conditions. As shown in Figure 8, the CH₄ and CO₂ measurements from the UAAS and those from the CRDS when sampling ambient air were in close agreement at both the start and end of the first, second, and fourth UAAS flights, which is when the UAAS and CRDS were closest to each other. During the third flight, as shown in Figure 8c, only the UAAS and CRDS measurements of CO₂ were found to overlap at both the start and end of the UAAS operation. The UAAS and CRDS measurements of CH₄ differed by 0.5 ppm at the start of the UAAS flight, which may be due to the separation between the CRDS and UAAS during deployment. Despite the measurement anomaly observed at the start, the UAAS and CRDS measurements of CH₄ were found to follow more consistent trends throughout the remaining period of operation.

280

3.3 AirCore characterization experiments

The UAAS was found to accurately resolve two spikes in CH₄ that were 10 seconds long based on results obtained from the characterization experiments performed in a laboratory. On the other hand, the UAAS was significantly less accurate measuring two CH₄ spikes that were only 5 seconds long, which is likely due to the UAAS having a slower time response. However, the lower performance of the UAAS for measuring the spikes in CH₄ that were 5 seconds long may have an insignificant effect on the overall reliability of CH₄ and CO₂ measurements. As shown in Table 4, the percent differences between the area under the curve of UAAS and CRD signals were found to be 20.2 and 16.2 when measuring CH₄ spikes that were 5 and 10 seconds long, respectively. From these results we conclude that the UAAS has a spatial resolution of 5 m while flying at a steady rate of 0.5 m s⁻¹.

290

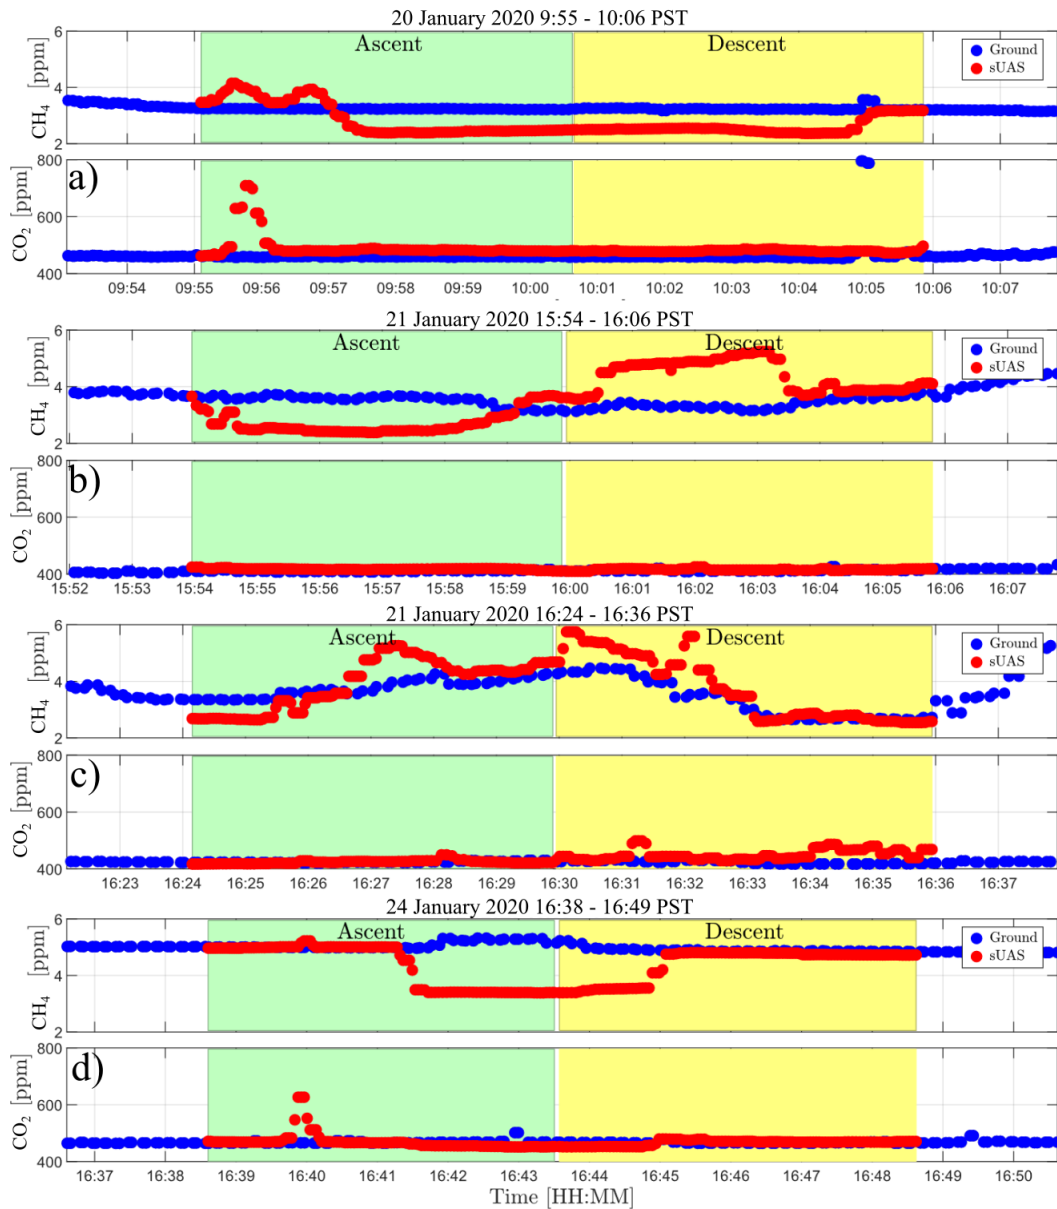

Figure 8. Comparison of UAAS (red) and ground-level (blue) observations of CH₄ and CO₂.

3.4 Wind velocity and air composition profiles

295

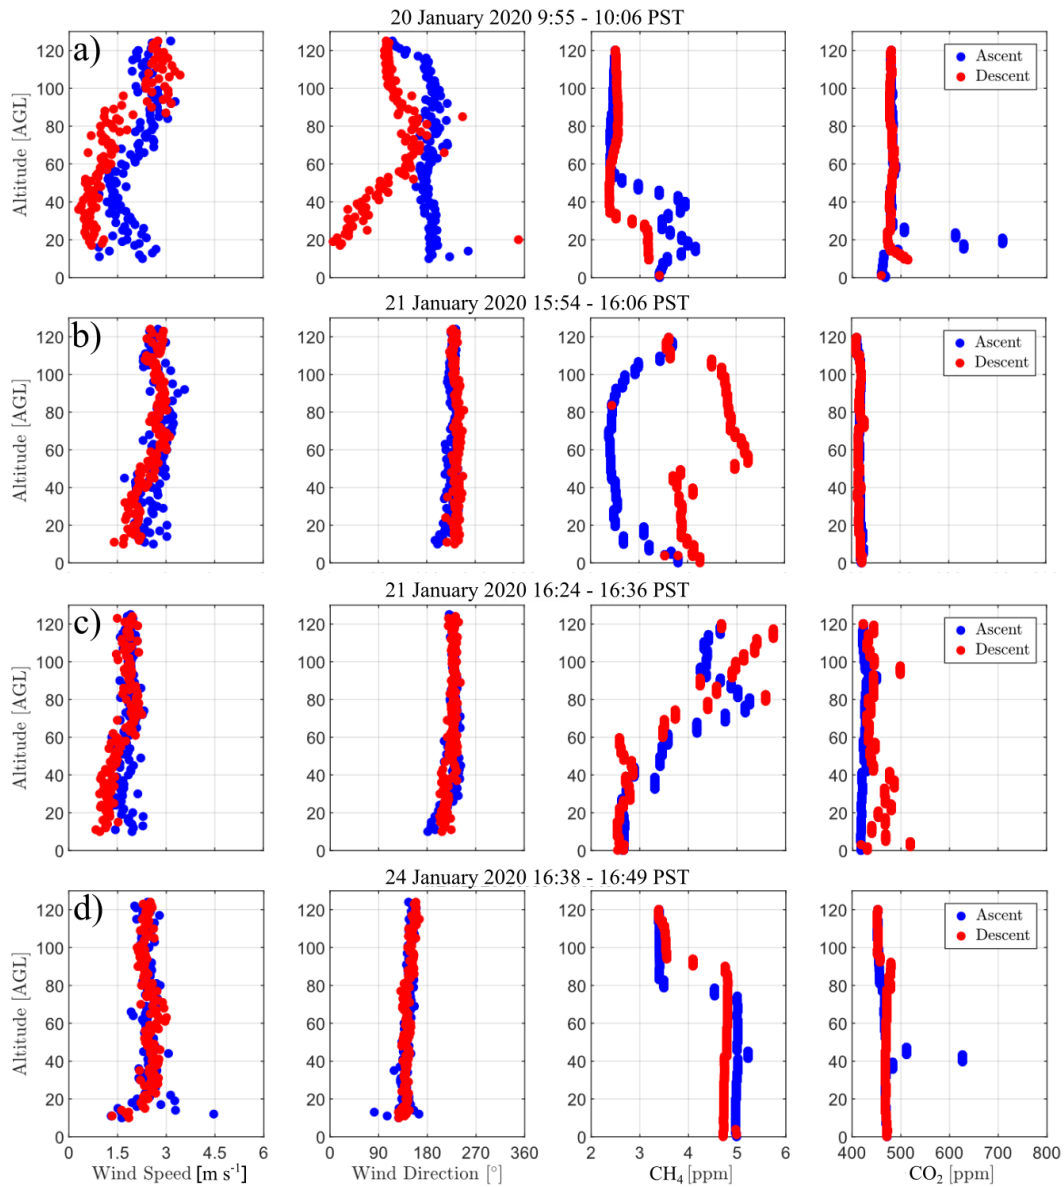

As shown in Figure 9, the UAAS profiles of wind velocity and air composition were found to capture the vertical and temporal variations of CH₄ and CO₂ plumes that were measured downwind of dairy farm operations. These observations were useful for understanding how the enhancements of CH₄ and CO₂ varied in the lower atmosphere during periods of both variable and relatively-stable wind conditions.

During the first UAAS deployment, CH₄ and CO₂ plumes were observed close to the ground under variable wind
300 conditions. The observed enhancements of CH₄ and CO₂ at low altitude are likely due to UAAS operations taking place in the
morning when the boundary layer was shallow and there was minimal vertical mixing. As shown in Figure 9a, the UAAS
ascent measurements captured a 1.5 ppm CH₄ enhancement near the ground and up to 60 m AGL. A CO₂ enhancement of
approximately 220 ppm was observed to extend from 15 m AGL to 25 m AGL. The winds during the ascent fluctuated between
1 and 3 m s⁻¹ from the south, shifting eastward above a height of 117 m AGL. The descent measurements captured a 0.7 ppm
305 enhancement of CH₄ extending from the ground up to 30 m AGL. The winds during the UAAS descent varied between 0.5
and 3 m s⁻¹ while the wind direction rotated from the east to the south and from the south to the north. CH₄ and CO₂ mole
fractions were relatively constant at heights greater than 60 m AGL during the ascent and descent, indicating local background
levels above the height of the dairy farm's emission plume.

The second UAAS deployment captured a methane plume moving upward during a period of turbulent conditions
310 and relatively constant winds. As shown in Figure 9b, CH₄ mole fraction enhancements greater than 1 ppm were observed
both at the start and end of the UAAS ascent. South-southwesterly winds were observed to gradually increase from 1.5 to 3 m
s⁻¹ during this period. UAAS descent measurements show the mole fraction enhancement of CH₄ to gradually double from 1.4
to 2.8 ppm before decreasing again as south-southwesterly winds persisted. The enhancements of CO₂, on the other hand, were
insignificant during the UAAS ascent and descent. The observed differences between the ascent and descent measurements of
315 CH₄ provide insight into the dynamic nature of plumes in well mixed afternoon conditions driven by atmospheric turbulence,
which is difficult to obtain using ground-based sensing techniques alone.

The third deployment showed an elevated CH₄ plume under constant wind conditions. As shown in Figure 9c, the
CH₄ mole fraction was observed to increase from approximately 2.6 to 6 ppm both during the ascent and descent, showing the
CH₄ plume to vary less significantly with time. The mole fraction enhancements of CO₂ were greater than 50 ppm only below
320 40 m AGL during the descent. Southwesterly winds were observed to gradually increase with height from 1 to 2.5 m s⁻¹ both
during the ascent and descent.

The fourth deployment captured consistent CH₄ enhancements downwind of a dairy farm extending from the surface
up to 80 m AGL, with a marked drop in enhancements above 100 m. CH₄ mole fraction enhancements of 1.7 and 1.5 ppm
were observed up to heights of 75 and 80 m AGL during the ascent and descent, respectively. The mole fraction of CO₂ was
325 observed to increase briefly from 480 to 620 ppm at a height of 40 m AGL before returning to a constant value of 480 ppm for
the remainder of the UAAS operation. Southeasterly winds varying between 1.5 and 3 m s⁻¹ persisted during both the ascent
and descent. The similarity between the ascent and descent profiles measured during the fourth deployment are not surprising
for the stable atmospheric conditions expected an hour before sunset.

330 **Figure 9.** Vertical profiles of wind velocity, CH₄, and CO₂ measured using the UAAS.

3.5 CH₄ detection and quantification

The vertical profiles of wind velocity and CH₄ that were collected from the UAAS operation performed on January 20th, 2020 were used as inputs for the dispersion model described in Section 2.6.2 to quantify CH₄ emissions from an isolated dairy farm. We selected this set of measurements for two key reasons: 1) the wind conditions during the UAAS operation

335 shifted from south to north, making it possible to obtain upwind and downwind CH₄ measurements from a single flight, and

2) the UAAS was able to fly high enough to measure the height of the CH₄ plume and the CH₄ background (the latter was determined from the air sample collected 120 m AGL).

To detect CH₄ emissions from the nearby dairy farm, UAAS measurements of wind speed and wind direction were used with the dispersion model to generate a footprint map of CH₄ emissions. As shown in Figure 10, the dairy farm operation, which is denoted by a white rectangle, is well within the area having the highest contribution to the CH₄ mole fraction measured at the receptor (i.e., the UAAS). After generating a footprint map, UAAS profiles of wind velocity and CH₄ were used as dispersion modeling inputs to compute dairy farm emission estimates. Results from this analysis show that whole-farm emissions for this dairy were on average 226 kg hr⁻¹ with a lower limit of 140 kg hr⁻¹ and an upper limit of 277 kg hr⁻¹.

345 **Figure 10.** A satellite image from MathWorks overlaid with the footprint map obtained from the dispersion model. The white star shows the location of the UAAS operations, and the white rectangle shows the location of the upwind dairy farm. The color bar units are in ppm per unit of emission.

4 Discussion

Four UAAS deployments were successfully performed in the San Joaquin Valley to measure vertical profiles of wind velocity and the mole fractions of CH₄ and CO₂ downwind of dairy farm operations. We evaluated the reliability of the UAAS measurements using ground-based MET and CRDS observations. We also used the UAAS measurements of wind velocity and air composition to evaluate the enhancements of CH₄ and CO₂ during periods of variable and relatively-steady wind conditions. Lastly, we combined UAAS measurements and dispersion modeling as part of a use case study to determine the utility of UAAS datasets for detecting and quantifying CH₄ emissions from a dairy farm operation. From this single use case

355 that met the requirements of emission estimation (i.e., observation of an isolated plume downwind of a nearby dairy farm
where the farm falls entirely within the footprint of the observation and background CH₄ levels are also measured), we
estimated facility emissions of 5430 kg d⁻¹ (with a range of 3370-6660 kg d⁻¹). This range overlaps with the yearly estimated
methane emissions for this particular farm of 3950 kg d⁻¹, assuming emissions are evenly spaced over the course of a year,
from a model that accounts for the number of cows and manure management practices (Marklein et al. 2021). After normalizing
360 for herd size, our estimated emissions of 714 g/AU/d (range of 444-876) are similar to those measured in wintertime at another
California dairy with comparable management practices, 752 g/AU/day (range of 700-803) (Arndt et al. 2018).

We found the UAAS to provide reliable measurements of wind speed and wind direction in both variable and
relatively-steady wind conditions. During variable wind conditions, the UAAS and MET observations of wind speed and wind
direction were consistent when the height difference between the two systems was less than 50 m. More significant differences
365 observed aloft between the UAAS and wind speeds derived from power law analysis of MET observations were likely due to
wind shear. During periods of relatively-stable wind conditions, the UAAS and MET observations of wind speed and wind
direction were consistent up to heights of 60-80 m AGL. However, a more thorough comparison of UAAS and ground-based
wind observations is required to assess if the wind speed errors observed aloft are the result of extrapolation errors associated
with the wind profile power law, and to determine the full range of wind conditions for which the wind estimation scheme
370 used to infer wind velocity is reliable. Overall, we expect the wind speed estimation errors to increase as wind conditions
intensify since the tilt range of the aircraft is reduced by the added payload weight.

In addition to providing observations of wind velocity, the UAAS was effective measuring the mole fractions of CH₄
and CO₂ in the lower atmosphere. UAAS and ground-level CRDS measurements of CH₄ and CO₂ were in close agreement
when the UAAS operated near the surface while both ascending and descending in variable and relative-steady wind
375 conditions. Results from the laboratory AirCore characterization experiment also demonstrated that the UAAS can accurately
resolve CH₄ variations occurring over a period of 10 seconds or longer. Resolving variations at the 10-second scale is important
for both reducing the uncertainty of CH₄ and CO₂ emission estimates and extending the spatial coverage of UAAS operations.
Furthermore, we found that the smearing effects produced by fast CH₄ variations led only to a 5 percent difference in the area
under the curve of the 5- and 10-second long CH₄ signals. The latter finding suggests that smearing effects may only have a
380 small impact in the accuracy of CH₄ and CO₂ column measurements.

Future work will address a number of limitations that were encountered while validating UAAS wind velocity
measurements. First, UAAS flight operations will be conducted next to conventional *in-situ* and remote wind sensors (e.g.,
mast towers and LiDAR instruments) to better characterize the uncertainty of UAAS wind estimates. Additionally, more
385 sophisticated dynamic models will be explored as a means to increase the accuracy of wind estimates, both ascending vertically
and moving laterally. Previous studies have shown that dynamic models can render higher-fidelity wind estimates from the
motion of sUAS (Gonzalez-Rocha, 2019; 2020). Higher-fidelity measurements of wind velocity and mole fraction
measurements obtained from both lateral and vertical profiles will likely lead to improved emission estimates. Combined with

vertical profiles, lateral measurements of wind velocity and the CH₄ mole fraction can help determine the horizontal spread of CH₄ plumes.

390 Findings from the use case study show that combining UAAS measurements and dispersion modeling can help to detect and quantify CH₄ emission from large source areas. The region of the footprint map with the highest CH₄ sensitivity was found to overlap with the location of the downwind dairy farm. In addition to aiding the detection of large emission sources, UAAS measurements and dispersion modeling can provide emission estimates in just hours. In addition to the system design issues that can be improved, these flights provide guidance for the meteorological conditions and spatial considerations
395 for CH₄ emission estimation. For example, the comparison of all four sets of profiles shown in Figure 9 suggests that measurement conditions are most favorable in the morning when the UAAS can fly well above the height of the planetary boundary layer and before the regional signals get mixed.

Overall, we found the UAAS to be a promising low-cost solution for detecting and quantifying greenhouse gas emissions from dairy farm operations. Leveraged with a ground-based mobile laboratory, the UAAS can be deployed at sites
400 where greenhouse gas hotspots are prevalent provided that airspace access is available. The UAAS measurements of wind velocity and air composition are useful for understanding how CH₄ and CO₂ enhancements vary with height and time, providing higher resolution observations for monitoring lofted plumes. Combined with dispersion modeling, UAAS measurements are also useful for detecting and quantifying greenhouse gas emissions from dairy farms. Furthermore, the extension of UAAS capabilities to measure horizontal transects of wind velocity and air composition can help characterize the
405 spatial heterogeneity of large emission sources. This capability can provide a new paradigm for improving bottom-up estimates of greenhouse gas emissions from dairy farm operations and other important sources such as waste landfills, gas and oil fields, and wetlands. Ultimately, more reliable bottom-up estimates of greenhouse gases will lead to more effective mitigation strategies.

Conclusion

410 We developed and deployed a multirotor uncrewed aircraft and AirCore system to measure vertical profiles of wind velocity and the mole fractions of CH₄ and CO₂ downwind of dairy farm operations in the San Joaquin Valley of California. Results from field and laboratory performance evaluations show that the UAAS can reliably measure vertical profiles of wind velocity and the mole fractions of CH₄ and CO₂. Integrated with ground-based mobile sampling strategies, UAAS measurement capabilities can increase the vertical resolution of wind velocity and air composition observations in the lower atmosphere,
415 especially in areas where it is difficult to utilize conventional in-situ and remote sensing technologies. Leveraging UAAS and dispersion modeling capabilities can also help detect and quantify greenhouse gas emissions from large area sources. Overall, our findings support further development of UAAS as a low-cost solution to detect and quantify greenhouse gas emissions.
