**Abstract.** This study emulates dropsondes to elucidate how adequately sporadic airborne sondes represent divergence of moisture transport in arctic Atmospheric Rivers (ARs). The convergence of vertically integrated moisture transport (*IVT*) plays a crucial role as it favours precipitation that significantly affects arctic sea ice properties. Long-range research aircraft can transect ARs and drop sondes to determine their *IVT* divergence. In order to assess the representativeness of future sonde-based *IVT* divergence in arctic ARs, we disentangle errors arising from undersampling by discrete soundings and from the flight duration.

Our synthetic study uses CARRA reanalyses to set up an idealised scenario for airborne AR observations. For nine arctic spring ARs, we mimic flights transecting each AR in CARRA and emulate sonde-based *IVT* representation by picking single vertical profiles. The emulation quantifies *IVT* divergence observability by two approaches. First, sonde-based *IVT* and its divergence are compared to the continuous *IVT* interpolated onto the flight cross-section. The comparison specifies uncertainties of discrete sonde-based *IVT* variability and divergence. Second, we determine how temporal AR evolution affects *IVT* divergence values by contrasting time-propagating sonde-based values with the divergence based on instantaneous snapshots.

For our arctic AR cross-sections, we find that coherent wind and moisture variability contribute by less than 10 % to the total transport. Both quantities are uncorrelated to a great extent. Moisture turns out as the more variable quantity. We show that sounding spacing greater than 100 km results in errors greater than 10 % of the total *IVT* along AR cross-sections. For *IVT* divergence, the arctic ARs exhibit similar differences in moisture advection and mass convergence across the embedded front as mid-latitude ARs, but we identify moisture advection being dominant. Overall, we confirm their observability with an uncertainty of around 25–50 % using a sequence of at least seven sondes per cross-section. Rather than sonde undersampling, it is the temporal AR evolution over the flight duration that leads to high deviations in divergence components. Dedicated planning of sonde-based *IVT* divergence purposes should not only involve sonde positioning but rather pursue optimizing the flight duration. Our benchmarks quantify sonde-based uncertainties as a prerequisite to be used for future airborne moisture budget closure in arctic ARs.

## 1 Introduction

Atmospheric Rivers (ARs), which are elongated ( $> 2000$  km in length) but narrow ( $< 1000$  km in width) water vapour rich corridors with high moisture transport, occasionally enter the Arctic. Their occurrence accounts for roughly 70 % of poleward moisture transport (Nash et al., 2018). The presence of ARs can induce significant Arctic warming (e.g. Neff et al., 2014) causing substantial sea-ice retreat (Woods and Caballero, 2016) as well as Greenland ice sheet melt (Mattingly et al., 2018; Neff, 2018). In addition to near-surface heat fluxes (Woods and Caballero, 2016; You et al., 2022), the melting arises from AR-induced precipitation (Mattingly et al., 2018; Viceto et al., 2022). Lauer et al. (2023b) identified ARs as one of the main contributors to overall arctic precipitation. The moisture needed for this is mainly extracted more southern, with the North Atlantic being a dominant moisture uptake zone (Vázquez et al., 2018). In an interplay with poleward moving cyclones and warm conveyor belts (e.g. Dacre et al., 2019), the AR air masses can propagate meridionally towards the Arctic ocean and reach the sea-ice (Papritz et al., 2021), shaping the regional moisture patterns (Nygård et al., 2020). Along the long-distance displacement, the AR embedded moist and warm air masses are subject to substantial air mass transformation (You et al., 2022). Komatsu et al. (2018) discovered an amplification of air mass transformation after the ARs overpass the sea-ice edge. To illuminate moisture transformation processes occurring in arctic ARs, it is crucial to grasp characteristics of the moisture transport, i.e. the vertically Integrated Water Vapour Transport (*IVT*). Seager and Henderson (2013) point out that the divergence of *IVT* links the local temporal evolution of moisture amount to the efficiency of precipitation induction. In order to derive *IVT* divergence, the spatial variability of *IVT* in ARs needs to be resolved. Guan and Waliser (2015) considered global ECMWF Interim reanalysis (ERA-Interim, Dee et al., 2011) to specify strong moisture transport gradients that exist along AR cross-sections, perpendicular to the major *IVT* orientation. Along such lateral cross-sections through the AR center, a bell-shaped *IVT* distribution, having the strongest moisture transport in the AR core, is widely seen from airborne observations in mid-latitude ARs (e.g. Ralph et al., 2017; Demirdjian et al., 2020). Using ERA5, Cobb et al. (2021b) confirm this heterogeneous spatial variability of *IVT* for mid-latitude ARs. For arctic AR conditions with weaker moisture transport than in the mid-latitudes, we still lack quantitative knowledge of predominant *IVT* variability and how this reflects to *IVT* divergence. High-resolution observations of *IVT* variability to derive its divergence in ARs are missing for the Arctic. One reason is the remote and sporadic occurrence of arctic ARs over the ocean basins. Furthermore, the observation of moisture transport requires simultaneous measurements of winds and moisture for the entire troposphere. Radiosondes allow detailed insights of moisture transport profiles of arctic ARs at individual locations (e.g. Viceto et al., 2022), but their observation network in the Arctic is too sparse to obtain the divergence in single ARs (Dufour et al., 2016). Similarly, dropsondes released from research aircraft can provide vertical profiles of relative humidity and wind speed with an accuracy of 1 % and 0.1 m/s, respectively (e.g. George et al., 2021; Konow et al., 2021). The simultaneous measurements allow to derive moisture transport profiles and *IVT*. According to Zheng et al. (2021), dropsondes over ocean fill a data gap left by spaceborne remote sensing or ground-based observations. To derive the *IVT* divergence in ARs, it is necessary to release the sondes at close spacing but over horizontally extended areas above the AR which can only be achieved by long-range research aircraft (Neiman et al., 2014). The overall goal of this study is to assess the observability of moisture transport divergence in arctic ARs by dropsondes in

order to facilitate dedicated research flight campaigns and measurement strategies, as e.g. proposed by Wendisch et al. (2021). This assessment comprises the role of sounding frequency, the influence of correlated moisture and wind fields on moisture transport, the ability of dropsondes to reproduce *IVT* divergence in arctic ARs and the impact of extended flight duration. The following paragraphs set these aspects into context with recent findings based on mid-latitude ARs and unravel four research gaps for arctic ARs, summarised as guiding science questions.

Deteriorations in the airborne representation of AR moisture transport variability can result from a limited number of sondes if the sounding spacing becomes too coarse to reflect the spatial variability of *IVT*. The sondes may misinterpret *IVT* divergence. For mid-latitude ARs, Guan et al. (2018) compared sonde-based Total Integrated Water Vapour Transport (*TIVT*), being the integral of *IVT* along an AR cross-section, with reanalysis-based *TIVT* and found an agreement up to 3% for airborne results based on a mean sounding spacing of 80 km. Contrasting the airborne *TIVT* in two separate AR cross-section legs can serve as an initial estimate of *IVT* divergence in between both legs. However, Ralph et al. (2017) found considerable sensitivity of sonde-based *TIVT* to sonde spacing. Enlarging the initial spacing between the sondes by reducing the number of included sondes, they found a mean deviation of at least 5% for *TIVT* when doubling the spacing. Since given sensitivity studies refer purely to mid-latitude cases where we do expect higher *TIVT* (Guan et al., 2018), it remains as open question: *What is the maximum distance between sondes to determine the total moisture transport in arctic AR cross-sections (Q1)?*

When assessing spatial *IVT* variability in arctic ARs, it becomes crucial how moisture and wind fields coincide in the AR cross-section or whether they contribute independently to the *IVT* variability. For instance, in a polar AR case study, Terpstra et al. (2021) identified incoherent patterns of moisture and wind that form the moisture transport patterns but are less aligned than in mid-latitude ARs. The disentanglement of both quantities facilitates flight strategies in the observation of moisture transport divergence in arctic ARs. If the moisture transport variability (and divergence) were e.g. mainly controlled by the moisture field, more investment should be spent on the airborne representation of AR moisture by supplementary measurements. For this reason, it is important to determine whether moisture and wind are aligned in AR cross-sections and to ascertain: *How correlated are moisture and winds in arctic ARs and do coherent patterns contribute significantly to IVT (Q2)?*

Knowing the spatial structure of *IVT* is an essential prerequisite for flight planning and reveals insights into the moisture transport divergence pattern in arctic AR cross-sections. Since ARs primarily occur in conjunction with a cold front, different dynamic and thermodynamic processes act on the moisture transport and its divergence across the embedded front (Cobb et al., 2021a). For mid-latitude ARs, Cobb et al. (2021a) found significant differences of vertical moisture and wind domains for different sectors across the front which transfer to frontal gradients in divergence characteristics (Guan et al., 2020). Using reanalysis data, Guan et al. (2020) specified lateral differences of moisture transport divergence across centers of ARs. In the AR center with maximum *IVT*, they identified the dynamical convergence of moisture as the most prominent component regulating moisture amount and precipitation. The Arctic is more affected by exit regions of ARs rather than over-passed by AR centres and exhibits weaker *IVT* from ARs compared to the mid-latitudes (Guan and Waliser, 2019). ARs here commonly start dissipating and terminating (Guan et al., 2023). For such conditions, we lack knowledge of predominant *IVT* divergence.

Thus, we examine: *How can the divergence of moisture transport be characterised along cross-sections of arctic ARs (Q3)?* Norris et al. (2020) conducted airborne studies to determine *IVT* divergence in mid-latitude ARs from dropsondes. Such

research flights allow to interpret the discrepancies that Guan et al. (2020) found between reanalyses in representing *IVT* divergence in ARs. In contrast, Norris et al. (2020) point to the large variability of *IVT* divergence at spatial scales of 50 km which has implications for sonde-based results. For arctic AR conditions, we lack equivalent estimates. Moreover, besides  
 95 sonde-based under-sampling of *IVT* variability and divergence, we hypothesise that airborne results are also impaired by a time component. Over the flight duration required to enclose an AR corridor, the temporal evolution of the AR (its life cycle and spatial displacement) can affect the sonde-based results significantly. Before dropsondes are used to interpret the actual *IVT* divergence in arctic ARs, we have to disentangle sonde-based errors that arise from undersampling by discrete sounding and from non-instantaneous sampling over the flight duration. We quantify: *To what extent do non-instantaneous sondes re-*  
 100 *produce IVT divergence in the light of the AR evolution during flight (Q4)?*

To pursue Q1-Q4, we focus on ARs occurring over the Arctic ocean (i.e. Fram Strait and Greenland Sea) in the vicinity of the sea-ice edge due to the above-mentioned AR impacts on the sea-ice. We constrain on ARs during spring, when maximum sea-ice extent starts melting. We look at arctic ARs within the novel C3S Arctic Regional Reanalysis (CARRA). Introducing a flight strategy to analyse moisture transport divergence in arctic AR corridors, we consider arctic AR events along synthetic  
 105 flight tracks that transect an AR corridor. We emulate synthetic dropsondes along the tracks by depicting single vertical profiles. This study compares actual *IVT* variability and divergence along the flight tracks with the emulated sonde-based representation of *IVT* in order to assess how adequately such airborne perspectives reproduce predominant AR-*IVT* characteristics. In a nutshell, our synthetic assessment provides benchmarks of sonde-based uncertainties in their representation of *IVT* divergence in arctic ARs to facilitate future mission planning.

110 The remainder of the manuscript is structured as follows: After introducing our AR cases, Section 2 describes the methods emulating dedicated flight patterns and synthetic soundings, and how we derive moisture transport divergence. For this framework, Section 3 deals with the *IVT* variability. This entails total moisture transport and the *IVT* variability along cross-sections in arctic ARs, their sonde-based representation (Q1) and the coherence of moisture and winds (Q2). Section 4 specifies the moisture transport divergence in arctic ARs (Q3) and compares its continuous representation to that by sporadic sondes. Section 5  
 115 quantifies airborne deviations arising from AR evolution over flight duration that is mostly idealised as stationary (Q4).

## 2 Airborne derivation of moisture transport divergence in arctic ARs

The central quantity of our study is the Integrated Water Vapour Transport (*IVT*) that represents the AR intensity as:

$$IVT = -\frac{1}{g} \cdot \int_{p_{sfc}}^{p_{top}} q \mathbf{V} dp \quad (1)$$

where  $\mathbf{V}$  is the horizontal wind vector and  $q$  the specific humidity. The divergence of *IVT* represents a key component contributing to the overall atmospheric moisture budget. Following Seager and Henderson (2013), the vertically integrated moisture  
 120

**Table 1.** Specifications of used reanalyses for AR analysis

Reanalysis Dataset	Horizontal Resolution	Vertical resolution up to 10 km ( $\approx$ 250 hPa)	Time resolution
ERA5	0.25 x 0.25 deg	21 levels	hourly
CARRA	2.5 x 2.5 km	15 levels	hourly

budget components consist of:

$$\underbrace{\frac{\delta I WV}{\delta t}}_{\text{local change in Integrated Water Vapour}} = \underbrace{E}_{\text{Evaporation}} - \underbrace{P}_{\text{Precipitation}} - \underbrace{\nabla I VT}_{\text{Divergence of Integrated Water Vapour Transport}}, \quad (2)$$

with all components in kilogram per metre squared per second. Precipitation and evaporation refer to surface values, while the integrated water vapour  $I WV$  and  $I VT$  (Eq. 1) represent the vertically integrated quantities of moisture and moisture transport. Note that Eq. 2 neglects the moisture flux through a tilted bottom pressure surface that is included in Seager and Henderson (2013).

Given the relevance of  $I VT$  to the AR moisture budget, this feasibility study targets the overall observability of  $I VT$  and its divergence ( $\nabla I VT$ ) in arctic ARs by airborne sondes in a synthetic way. For this purpose, this section introduces the reanalysis framework we use to investigate a presented selection of arctic ARs. In addition, our airborne flight strategy to derive  $\nabla I VT$  in arctic ARs is specified and how we emulate the synthetic sondes in the reanalyses. Lastly, we describe the sonde-based derivation of  $\nabla I VT$  and how we categorise different sectors across the AR front to examine the divergence.

## 2.1 Reanalysis framework

This study investigates arctic ARs in a reanalysis framework (Tab. 1). We use ECMWF Reanalysis v5 (ERA5) (Hersbach et al., 2020) to identify the AR events of our interest. ERA5 outperforms other global reanalyses with respect to AR characteristics (Graham et al., 2019; Cobb et al., 2021b). Thus, recent studies consider ERA5 to investigate AR conditions specifically in the Arctic (e.g. Fearon et al., 2021; Zhang et al., 2022). At the Fram Strait and Greenland Sea, the lat-lon grid from ERA5 yields approximately 30 km distances. Given the flight performance of long-range research aircraft (see Stevens et al., 2019), the spacing of airborne soundings in such a resolution would require releases every 2 minutes, which are more frequent than conducted in recent campaigns (e.g. Ralph et al., 2017). Still, Skamarock et al. (2014) emphasise that the effective resolution of processes in simulations is much greater than the model grid spacing. However, if our study aims to assess the sub-grid scale variability of moisture transport between sonde releases from reanalyses, the effective resolution should be of the order of  $\sim$  10 km rather than of  $\sim$  100 km.

Therefore, we further include the C3S Arctic Regional Reanalysis (CARRA). CARRA has a 2.5 km horizontal resolution over the entire domain and is accessible by Schyberg et al. (2021). Driven by lateral boundary conditions from ERA5, CARRA includes more observations and hourly forecasts by the HARMONIE-AROME model (Bengtsson et al., 2017). Kølitzow et al.

(2022) verified the improved representation of arctic surface-near meteorological conditions in CARRA, with decorrelation lengths of wind speed in better agreement to reference observations than ERA5.

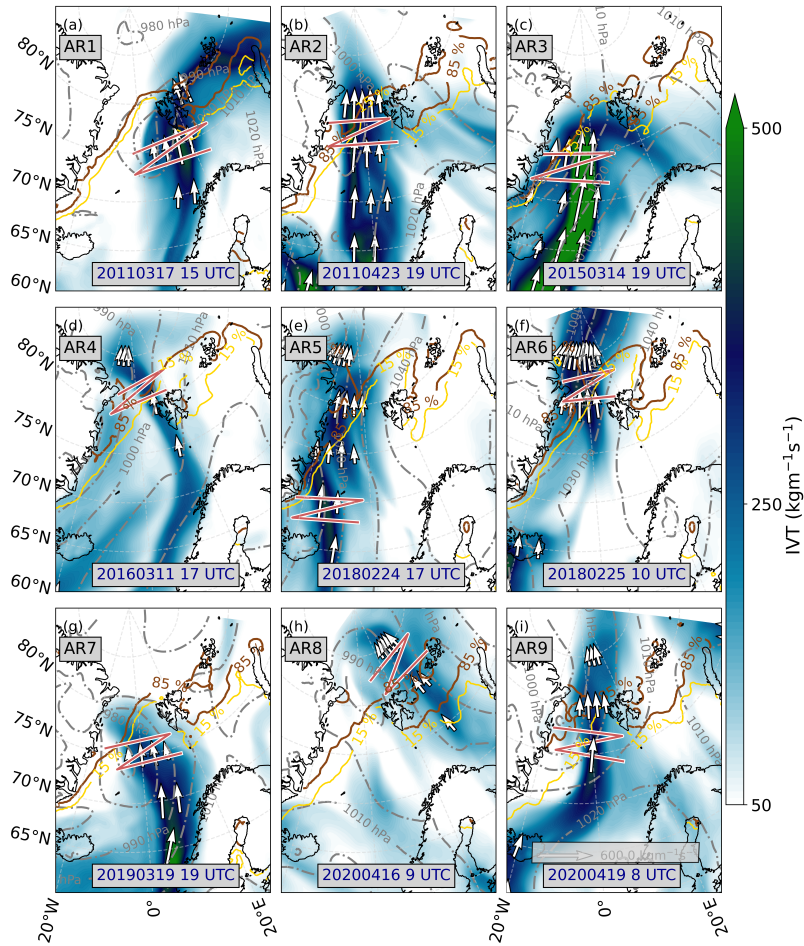

Both reanalyses are provided on pressure levels by the Copernicus Climate Data Store (CDS). While ERA5 contains *IVT* as  
150 output, we calculate *IVT* in CARRA by the trapezoidal integral of moisture transport along the pressure levels (Tab. 1). In the following, we declare the high spatial resolution representation in CARRA as our idealised background reality of AR features.

## 2.2 Selection of Atmospheric River cases

The transformation of arctic air masses over changing surface types (open ocean and sea-ice) along large-scale meridional circulations is part of current research and investigated by research aircraft over the Arctic ocean (Wendisch et al., 2021). For  
155 this reason, our study selects ARs causing air masses to overshoot the sea ice edge in this region. The principle identification of arctic AR events is based on the *IVT*-based AR detection catalogue by Guan (2022) applied to ERA5 (Lauer et al., 2023a). Among these ARs, we focus on the spring season, when maximum sea-ice extent in the Arctic ocean starts to break-up and reacts very prone to the intrusion of warm and moist air (Rostosky and Spreen, 2023). We restrict to conditions and events only from last decade, as the arctic climate has witnessed rapid and intense changes over the last decades (Wendisch et al., 2023).  
160 Our AR pathways originate from the North Atlantic and Barents Sea that Papritz et al. (2021) spot as dominant regions for arctic moisture intrusions. The selection constrains on ARs whose lateral width is purely situated over open ocean or sea-ice. This ensures that we do not encounter orographic induced effects on  $\nabla IVT$  which are out of the scope of this study. Moreover, airborne sonde releases over land are more complicated to be conducted. Given the criteria above, we selected ARs from nine spring days between 2011 and 2020, presented in Fig. 1.

165 In the synoptic composition of a Greenland trough, low-pressure systems force large-scale meridional transport where ARs can commonly evolve on the eastern cyclone flank and reach into the Arctic (Papritz and Dunn-Sigouin, 2020). Similarly, blocking situations over Eurasia can favor meridional circulation. For our nine ARs (Fig. 1), we confirm a large case-to-case variability regarding the synoptic situation. While some ARs (AR2, AR3, AR4, AR9) have evolved along the eastern flank of large-scale troughs over Greenland, AR5 and AR6 are more steered by blocking high pressure over the Barents Sea. AR1 and  
170 AR7 are, in turn, reinforced by a mesoscale cyclone situated over the Fram Strait and reach very close into the cyclone center. The synoptic compositions lead to AR dispersions over the North Atlantic and Arctic Ocean (Fig. 1), which correspond to the typical arctic moisture transport pathways identified in Papritz et al. (2021). Some ARs exhibit straight meridional moisture transport north of Iceland and approach or exceed Svalbard (AR1, AR2, AR3 in Fig. 1). AR4 and AR7 show more elongated filaments along the Norwegian coast but still reach far north. We consider eight independent AR events wherein AR5 is also  
175 considered for the consecutive day (AR6). At this stage, the centre of AR6 reaches close to the North Pole. AR8 originates from Siberia that, according to Komatsu et al. (2018), represents another significant roadway for arctic moisture intrusions favoring ARs. The last events in 2020 (AR8, AR9) are accompanied by a warm air intrusion period observed by the Multidisciplinary drifting Observatory for the Study of Arctic Climate (MOSAiC) expedition (Shupe et al., 2022), studied in Kirbus et al. (2023).

A caveat of our selection for making general statements about *IVT* variability in arctic ARs is the small sample size (nine  
180 AR events). Therefore, we place our events in the climatology for arctic ARs in spring. Using the entirety of spring ARs along

**Figure 1.** *IVT* contours of investigated AR events from ERA5. Grey lines indicate surface isobars, while brown (orange) contour lines specify sea ice cover thresholds given in %. The arrows depict the magnitude and orientation of *IVT*. Red lines represent the zig-zag flight pattern to investigate the moisture budget in AR corridors. Background maps were made with Natural Earth.

the Atlantic pathway from the catalogue of Guan (2022), we compare the latitude of the AR centres and mean *IVT* of our ARs with the long-term distribution (1979–2019) for spring ARs (Fig. 2). The climatological distribution in Fig. 2 indicates the decrease of mean *IVT* with meridional location of the AR centre. Further towards the Arctic, ARs become weaker and when centered north of 65°N, the mean *IVT* remains below  $300\text{ kg m}^{-1}\text{ s}^{-1}$ . This is also the case for our AR events but they, in turn, are characterized by a higher intensity relative to the long-term mean (Fig. 2). Only AR3 and AR7 are centred below 60°N, aligned with mean *IVT* values around  $350\text{ kg m}^{-1}\text{ s}^{-1}$ . However, despite their southern centre, they reach far north with *IVT*  $> 250\text{ kg m}^{-1}\text{ s}^{-1}$  inside the Fram Strait (Fig. 1), so that we declare them as arctic ARs. We conclude from Fig. 2 that our cases represent the stronger AR events occurring in the Arctic.

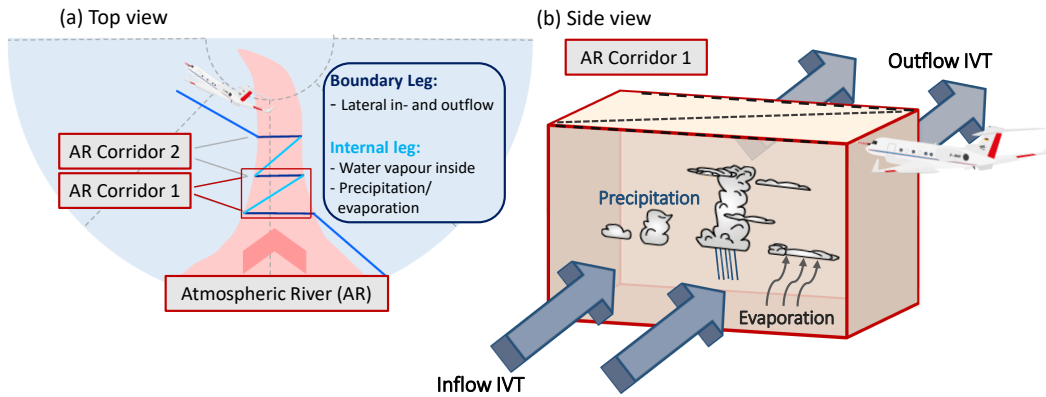

**Figure 2.** Comparison of selected AR events to long-term statistics (1979–2019) regarding mean IVT and AR centre latitude at given reanalysis time step (ERA-Interim) based on the AR catalogue of Guan (2022). Isolines represent 25th and 75th percentiles of the kernel density estimate. Coloured lines on the right indicate the centre of the respective flight pattern.

### 2.3 Flight pattern and emulated observations

190 Having introduced our AR cases, this subsection returns to the perspective of the airborne observability of  $\nabla IVT$  inside arctic ARs. We describe the emulation of real observations by mimicking dedicated flight patterns and creating synthetic soundings.

#### 2.3.1 Zig-zag flight tracks observing AR corridors

For the airborne derivation of moisture transport divergence, flight patterns have to well sample specific corridors of the AR. In general, flight tracks enclosing corridors, e.g. circles, allow divergence calculations best and are frequently applied for  
 195 such purposes (e.g. Bony and Stevens, 2019). However, ARs exhibit cross-frontal heterogeneity in moisture and wind fields (Cobb et al., 2021a) that would smooth out in single circles. Instead, the high lateral variability in AR moisture transport characteristics requires long flight legs across the AR front to better capture divergence heterogeneity. Two parallel cross-sections can be connected via an internal flight leg resulting in a zig-zag flight pattern (Fig. 3). The zig-zag pattern observes corridors of the AR across its transport direction. The boundary cross-section legs perpendicular to the major flow quantify  
 200 the corridor in- and outflow, i.e. in- and outgoing  $IVT$  over the entire lateral AR extension and enable simplified divergence calculations. Note that the diagonal internal legs can assess precipitation rate, evaporation or water load inside the AR corridor so that this pattern additionally allows to quantify the remaining moisture budget components. According to Fig. 1, we place such zig-zag flight patterns over AR corridors at the sea ice edge. The cross-section legs orientate orthogonal to the major  $IVT$  direction and extend such that they cross the entire AR as long as the legs remain over open ocean and sea ice and disregard

**Figure 3.** Top (a) and side (b) view on envisioned zig-zag flight pattern to derive the moisture budget components inside AR corridors.

205 land. As depicted in Fig. 2, the flights transecting the AR corridors close to the sea-ice are mainly located north of AR centres. For the airborne representation, we mimic the flight performance of state-of-the-art long-range research aircraft. We refer to the High Altitude and LOng Range Research Aircraft (HALO), equipped with dropsondes and a remote sensing configuration (Stevens et al., 2019; Konow et al., 2021); a similar aircraft like the one examining pacific ARs, specified in Cobb et al. (2022). Both aircraft allow along-track observations during flight at common cruising levels above 10 km and a ground speed of around 250 m/s. Accordingly, we idealize flights with a constant ground speed of  $250 \text{ m s}^{-1}$  but neglect the duration for turns and choose a constant flight altitude of 10 km. From this, we represent the aircraft location in a 1 Hz resolution, in line with the operational resolution of common airborne remote-sensing products (e.g. Mech et al., 2014; Konow et al., 2019) that can support dropsonde data. The zig-zag patterns, shown in Fig. 1, require roughly 2–3 h to be flown, and up to 1 h for single AR cross-sections.

215 Using this idealised flight performance, up to three reanalysis time steps represent atmospheric conditions during the flights. We upsample the reanalysis data to minutely frequency by linear time interpolation. For our 1 Hz representation of flight location, we depict the reanalysis values from the nearest minute and spatially interpolate them along the flight using haversine distances. This evolving representation of meteorological values and AR characteristics will from now on be referred to as "continuous AR representation". Admittedly, the upsampling leaves the model physics at intermediate time steps. However, we declare the interpolation as a suitable estimate of airborne atmospheric observations in dynamic systems like ARs that are subject to significant spatial displacement.

### 2.3.2 Synthetic dropsondes

We synthetically refer to the measurement principle of dropsondes (Sect. 1). Along the continuous airborne AR representation (Sect. 2.3.1), we depict profiles as synthetic soundings for which we neglect any vertical drift or fall time. We also neglect any measurement uncertainties. Such effects are out of the scope of this study. Our sondes observe exact *IVT* values at their release position. Accordingly, we focus on the spatial representativeness of sporadic sonde-based *IVT* and evaluate the uncertainties

in the lateral variability of moisture transport, and how these uncertainties affect the airborne perspective on  $IVT$  divergence in arctic ARs.

## 2.4 Sonde-based divergence derivation

230 To derive  $\nabla IVT$  in AR corridors from sondes, a simplified approximation relies on deriving the Total Integrated Water Vapour Transport ( $TIVT$ ) of both cross-section legs in Fig. 3. Following Ralph et al. (2017),  $TIVT$  of a cross-section is defined as:

$$TIVT = \int IVT dx, \quad (3)$$

representing the lateral integral of  $IVT$  over the flight distance  $x$  in a respective cross-section flight leg. Neglecting the moisture flux that exists apart from perpendicular to the flight track, we can approximate  $\nabla IVT$  in an AR corridor by the difference  
235 of out- minus ingoing  $TIVT$  of the cross-sections. However, this excludes any divergence of the flow perpendicular to the cross-section.

The Gaussian Theorem sets the moisture flux over the perimeter of a closed surface equal to its divergence. However, our flight pattern (Fig. 3) has open boundaries at the outer sides. Only if lateral flow can be neglected, we can obtain the divergence by subtracting the inflow in the entrance leg from the streamward outflow. Given this limitation, Lenschow et al. (2007)  
240 alternatively suggests the regression method. Under linear variations, a meteorological quantity  $\Phi$  (e.g. wind speed) that is stationary in time can be inferred as:

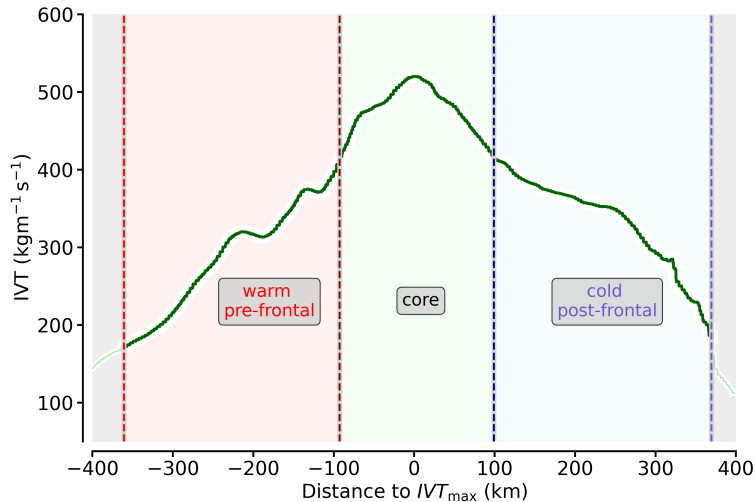

$$\Phi = \Phi_o + \frac{\delta\Phi}{\delta x} \cdot \Delta x + \frac{\delta\Phi}{\delta y} \cdot \Delta y, \quad (4)$$

with the area mean value  $\Phi_o$  and  $\Delta x$  and  $\Delta y$  being zonal, meridional displacements from the area centre point. Using the values of  $\Phi$  at sounding locations and minimising the least-squared errors in the linear regression fit of Eq. 4, we obtain a linear  
245 estimate of zonal (x) and meridional (y) gradients, along with the mean mesoscale value for  $\Phi$ . Adding up both gradients, we calculate the divergence. Bony and Stevens (2019) and George et al. (2021) proved the feasibility of this method by comparing its divergence values with the Gaussian-based line integral over flown circles.

Having the mathematical expression, we view on the impact of  $IVT$  divergence. The divergence of moisture transport can be split up into two components:

$$250 \quad \nabla IVT = -\frac{1}{g \cdot \rho_w} \cdot \int_{p_{sfc}}^{p_{top}} \nabla (q\mathbf{V}) dp = \underbrace{\frac{1}{g \cdot \rho_w} \cdot \int_{p_{sfc}}^{p_{top}} q (-\nabla \mathbf{V}) dp}_{\text{dynamical mass convergence (CONV)}} + \underbrace{\frac{1}{g \cdot \rho_w} \cdot \int_{p_{sfc}}^{p_{top}} \mathbf{V} (-\nabla q) dp}_{\text{integral of horizontal moisture advection (ADV)}}. \quad (5)$$

The first term represents the dynamical mass convergence being the product of the moisture mass and divergence. The mass convergence term can be related to vertical velocity via the continuity equation and itself is closely linked to precipitation (Wong et al., 2016; Norris et al., 2020). The second term represents the horizontal advection of moisture that Guan et al. (2020) shows to be little correlated to precipitation formation. Instead, it locally affects the amount of water vapour. To calculate  $ADV$

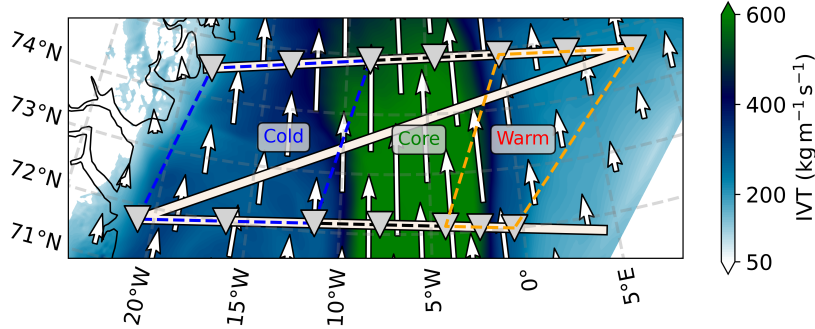

**Figure 4.** Frontal sector decomposition for an exemplary  $IVT$  cross-section (AR1) using the criteria described in Sect. 2.5. The colored shadings and text boxes indicate each frontal sector. The grey shading on the left represents moisture transport (i.e.  $IVT$ ) that is not considered as AR because it is too weak.

255 and  $CONV$ , we use the regression method. Finally, all terms in Eq. 5 are divided by the density of water  $\rho_w$  to provide their contributions to the moisture budget (Eq. 2) in  $\text{mm d}^{-1}$ .

## 2.5 Decomposition in AR frontal sectors

Current research considering  $IVT$  divergence in ARs suggests to distinguish between different sectors along the lateral AR cross-sections. Guan et al. (2020) highlight the cold-frontal structures that are commonly embedded in the AR, where different dynamics take place. Hence, Guan et al. (2020) separate  $IVT$  divergence calculations across the major AR axis and the AR embedded front. Similarly, using airborne observations of a large set of pacific AR cross-sections, Cobb et al. (2021a) classified different sectors in ARs based on the position of the AR embedded cold front and  $IVT$  shape. Both approaches distinguish between a pre-frontal (warm) sector, the AR core with highest  $IVT$  and the post-frontal (cold) sector behind the cold front. 265 Since there exist significant frontal differences in moisture transport divergence between the sectors (Guan et al., 2020), a lot of variability is smoothed out when calculating  $IVT$  divergence for entire cross-sections.

Therefore, we conduct a similar sector-based decomposition of  $IVT$  divergence for our arctic AR events in CARRA. As in Guan et al. (2020) and Cobb et al. (2021a), our decomposition relies on the  $IVT$  characteristics along the cross-section, which we depict for an exemplary AR cross-section in Fig. 4. The central AR core represents the region of strongest  $IVT$ , which is 270 more than 80% of maximum  $IVT$  ( $IVT_{\max}$ ). East of the core we situate the pre-frontal sector and west the post-frontal sector. Yet, the outer edges of the frontal sectors are less trivial as ARs basically have no clear outer boundaries. To account for case-specific relative values, we assign both frontal edges where  $IVT \leq 0.33 \cdot IVT_{\max}$  (Fig. 4). As a secondary absolute threshold,

**Figure 5.** Illustration of AR cross-section sectors and placed sondes to calculate the divergence for AR3. *IVT* contours refer to CARRA at the hour mid of the flight corridor. Dashed lines connect the sonde sectors. Background map made with Natural Earth.

we declare a moisture transport with  $IVT \leq 100 \text{ kg m}^{-1} \text{ s}^{-1}$  as too weak to be assigned as AR. Both conditions form the outer edges of the AR where the pre- and post-frontal sectors end. Note that the latter threshold to define the AR edges follows the  
 275 approach of Cobb et al. (2021a). However, we lower their mid-latitude based *IVT* threshold from 250 to  $100 \text{ kg m}^{-1} \text{ s}^{-1}$ . By this, we refer to common polar moisture transport magnitudes that exceed the 95th percentile of climatology and are declared as ARs in the detection of Guan and Waliser (2015). Otherwise, we would either exclude most ARs north of  $70^\circ\text{N}$  or would shrink the AR cross-section so much that most transport is ignored, as the statistics in Fig. 2 indicate.

Applying the frontal classification to both cross-sections, we obtain three sectors. For the cross-sections of the AR, we locate  
 280 the sondes so that six synthetic sondes (three each from the in- and outflow cross-section) span each frontal sector and calculate its *IVT* divergence, respectively (Fig. 5). Inspecting the sonde positions in Fig. 5, we emphasise that our *IVT*-determined frontal AR sectors along the flight track tilt while the internal *IVT* has a straight northward orientation. This arises from the north-eastward displacement of the AR filament over the course of the 2.5 h synthetic flight section (Sect. 2.3). Accordingly, Sect. 5 examines the extent to which sonde-based *IVT* divergence is affected by flight duration, as opposed to actually looking  
 285 at the AR in an instantaneous snapshot.

### 3 Moisture transport in Arctic AR cross-sections and its variability

This section examines the *IVT* variability in our arctic ARs (Sect. 2.2) using the high-resolution CARRA (Sect. 2.1). First, we analyse the shape of *IVT* (and document the larger *IVT* variability compared to forcing ERA5). Next, we focus on the observability of prevailing AR moisture transport variability by discrete soundings, using the synthetic sondes (Sect. 2.3.2). We  
 290 determine the maximum distance between sondes needed to derive the total moisture transport in AR cross-sections accurately (Q1). Finally, we describe how coherence in moisture and wind speed contributes to moisture transport and its variability (Q2).

**Figure 6.** Inflow IVT cross-section from AR1 (2011-03-17) with six synthetic soundings placed along the track. A gaussian fit based on the sounding  $IVT$  representation is calculated (grey).

### 3.1 Shape of $IVT$ across arctic ARs

We investigate whether arctic ARs feature the same bell-shaped structure of  $IVT$  along their cross-sections as observed in mid-latitudes (Ralph et al., 2017), and to what extent sondes can reproduce the  $IVT$  cross-section. For AR1, Figure 6 illustrates the cross-section  $IVT$  along the inflow flight leg. We recognise the bell-shaped  $IVT$  from both, CARRA and forcing ERA5. Within the cross-section centre which we declare as the AR core in Sect. 2.5, CARRA, however, shows stronger moisture transport with a more pronounced  $IVT$  maximum  $> 500 \text{ kg m}^{-1} \text{ s}^{-1}$ . Moreover, CARRA resolves more small-scale structures of the AR moisture transport. In particular, CARRA increases the cross-section variability for this case.

Summarising all cross-sections of our ARs from Sect. 2.2, most arctic AR cross-sections show this typical bell-shaped  $IVT$  curve over widths of roughly 400–800 km and indicate pronounced  $IVT$  maxima in the core of  $300\text{--}600 \text{ kg m}^{-1} \text{ s}^{-1}$  (not shown). Only for the weak AR8, this structure is less pronounced. We find that the arctic ARs are not substantially narrower than the AR widths of global climatology (Guan and Waliser, 2015) and observed mid-latitudes events (Cobb et al., 2021a). Flight planning should therefore consider cross-section distances of about 500-1000 km, similar to mid-latitude ARs. However, this only applies if the legs are not restricted to regions with  $IVT > 250 \text{ kg m}^{-1} \text{ s}^{-1}$  which is a widely used threshold for mid-latitude ARs (e. g. Ralph et al., 2019). In contrast, the maximum  $IVT$  for the arctic events is roughly half as high as the majority of mid-latitude ARs from airborne studies in Cobb et al. (2021a). Moreover, the  $IVT$  magnitudes strongly differ between our cases and synoptic conditions. The strongest ARs, with  $IVT_{\text{max}}$  exceeding  $500 \text{ kg m}^{-1} \text{ s}^{-1}$  are found for intense Greenland troughs, while the ARs are weaker along the Siberian pathway (see also Fig. 1). If we compare our ARs with those of other arctic case studies (e. g. Viceto et al., 2022), we are looking at rather strong ARs.

Viceto et al. (2022) documented the improved representation of arctic AR characteristics in ERA5 against coarser reanalysis data. In our comparison of CARRA with ERA5, the location and horizontal patterns of the ARs agree quite well (not shown). For all cross-sections, we ascertain plausible  $IVT$  values from CARRA with respect to ERA5. In particular, we highlight that

maximum (mean) values of  $IVT$  per cross-section increase by roughly 9 % (8 %) from ERA5 to CARRA on average. CARRA further increases the  $IVT$  variability by roughly 11 %. We attribute this to the higher horizontal resolution than in ERA5.

315 Using a set of six synthetic sondes, a gaussian fit of  $IVT$  can reproduce the bell-shaped AR- $IVT$  cross-section (Fig. 6). This gaussian fit is very sensitive to the actual positions of dropsonde releases. While the centred sonde in Fig. 6 is positioned close to  $IVT_{\max}$ , a slight shift of this sounding, which easily occurs in real observations, can quickly lead to an underestimation of the moisture transport in the AR core. Flight planning should thus imply a sonde release in the vicinity of the predicted  $IVT$  maximum and place additional sondes symmetrically around the core. While sonde positions in Fig. 6 are suitable to represent

320 the cross-section  $IVT$ , other AR cross-sections evince more complexity in being accurately represented by this number of soundings. We need further inspections on how sounding intervals deteriorate the AR moisture transport observability.

### 3.2 Sonde-based total cross-section moisture transport

As stated in Sect. 2.5, the determination of  $TIVT$  in two AR cross-sections can provide first estimates on the prevailing  $IVT$  divergence. However, the accuracy in sonde-based  $TIVT$  of an AR cross-section depends on the number of sondes across the

325 AR, i.e. their spacing (Ralph et al., 2017). For AR1, one of the stronger events with  $IVT_{\max} \approx 500 \text{ kg m}^{-1} \text{ s}^{-1}$  (presented in Fig. 6), we find that from the release of six sondes we underestimate  $TIVT$  by roughly 10 % against the continuous  $IVT$  representation in CARRA (defined in Sect. 2.3.1). In contrast,  $TIVT$  estimates based on ten sondes differ by less than 1 % (not shown).

For all of our AR events, we assess the required sounding spacing to gain adequate  $TIVT$  estimates by varying the frequency

330 between synthetic sondes and by comparing their values with  $TIVT$  of the continuous representation in CARRA. When increasing the spacing between soundings, their location becomes more essential and strongly affects the derived moisture transport variability. To account for this dependency, Figure 7 illustrates the outcome of a bootstrapping approach in which we sample the cross-sections with varying release intervals and varying positions and derive  $TIVT$  therefrom. The distributions of the relative error of  $TIVT$  against the continuous AR representation (the grey box-whiskers in Fig. 7) reveal how dense

335 sonde releases need to be performed in order to derive  $TIVT$  in the AR cross-sections precisely. Correspondingly, the relative error of  $TIVT$  against the continuous AR representation increases significantly for sounding spacing  $\geq 150 \text{ km}$  (roughly five sondes for the given cross-section lengths, corresponding to release intervals above 10 min at a cruising speed of  $250 \text{ m s}^{-1}$ ). For sonde spacing  $\geq 200 \text{ km}$ , sonde-based  $TIVT$  can substantially deviate.

The  $TIVT$  uncertainty in Fig. 7 increases less rapidly with larger sonde spacing than derived for mid-latitude AR cases (see

340 Ralph et al., 2017 and Guan et al., 2018). Total moisture transport in the arctic cases is, in turn, much smaller than in mid-latitude cases. The arctic  $TIVT$  values are roughly half as high as the sonde-based mean  $TIVT$  of  $5 \cdot 10^8 \text{ kg s}^{-1}$  ascertained by Ralph et al. (2017) from 21 mid-latitude ARs. The ARs we consider have, in turn, roughly two third the width of the ARs in Ralph et al. (2017) and Guan et al. (2018). Here, we remind that our threshold to define the outer AR edges is much lower to encounter for arctic AR conditions. Applying the mid-latitude thresholds (given in Sect. 2.5), mean AR widths would be in

345 range of a few hundred kilometer and  $TIVT$  values much lower than in mid-latitude ARs.

With increasing spacing, the spread in  $TIVT$  errors in Fig. 7 increases. One reason is the rising relevance of the sonde position.

**Figure 7.** Relative error in  $TIVT$  as a function of sounding spacing in km for all AR cross-section representations (grey) and those including highest (75th percentile) IVT maxima (coloured). Statistics rely on the boots-trapping approach containing of 100 cross-section sonde representations per AR. The boxes show the quartiles while whiskers show the rest of the distribution, except for outliers (markers). For an assumed aircraft speed of  $250 \text{ m s}^{-1}$ , equivalent release intervals are given on the top x-axis.

Too large sonde spacing enhances the probability to miss  $IVT$  dominating regions. Especially with the occurrence of a low-level jet (LLJ), Guan and Waliser (2017) confirm that the AR core alone accounts for  $\approx 50\%$  of the entire moisture transport through the cross-section. Yet, we also attribute the spread in relative  $TIVT$  errors to the large AR case-to-case variability.

350 In particular, the strong correlation of  $IVT_{\text{max}}$  to  $IVT$  variability (correlation coefficient  $r = 0.91$ ) may cause sonde errors in derived  $TIVT$ . Hence, we expect that the smallest sonde spacing is required for the strongest AR events. However, the distribution of the relative  $TIVT$  error behaves similarly, when we refer to the cross-sections with  $IVT_{\text{max}}$  larger than the 75th percentile from the bootstrapping sample, mainly from AR1 and AR3 (coloured box-whiskers in Fig. 7). The mean relative error increases more rapidly with larger spacing whereas the inter-case spread is slightly lower than in the entire sample. For

355 sonde spacing  $\geq 200$  km, the mean error becomes slightly lower than in the entirety but more robust.

We conclude that highest  $TIVT$  errors thus do not originate from the strong events when having very few sondes. Still, we emphasize that a minimum sounding spacing of 100-150 km has to be targeted for arctic ARs, which is less restrictive than for mid-latitude ARs in Ralph et al. (2017). In a larger set of arctic AR events than in this study, these recommendations for sonde spacing could be further specified in terms of arctic AR strength.

### 360 3.3 Variability of moisture and wind in arctic ARs

After investigating the overall moisture transport by its vertical integral  $IVT$ , we take a deeper look at moisture  $q$  and wind speed  $v$  (Eq. 1) individually in order to address Q2 (Sect. 1). For all arctic ARs, Figure 8 examines the cross-section variability of  $v$  and  $q$  over the vertical profile using the continuous AR representation (Sect. 2.3.1). Here, moisture transport in

**Figure 8.** Vertical statistics of wind speed (a), specific humidity (b) and moisture transport (c) from the inflow cross-sections of the nine ARs analysed. Shaded areas represent the overall mean values  $\pm$  the standard deviation. The error bars depict this distribution for the strongest AR (AR3). Vertical lines specify the cumulative contribution of moisture transport to  $IVT$  down to the given levels.

the lowest levels up to 850 hPa contains roughly 50 % of the  $IVT$  magnitude. Up to this height, both high moisture and wind  
 365 speeds are predominant, with a local maximum of wind speeds around 900 hPa. Further upwards, wind speed accelerates up to  
 20–30  $\text{m s}^{-1}$  while the atmosphere dries with height. The height decreasing moisture leads to a decline of moisture transport.  
 Through the entire troposphere,  $q$  overall remains below  $5 \text{ g kg}^{-1}$  in our arctic ARs.

The vertical moisture characteristics in Fig. 8b) resemble soundings of arctic early summer ARs at Ny-Alesund demonstrated  
 in Viceto et al. (2022) who showed  $q$  values up to  $5 \text{ g kg}^{-1}$ . However, the winds in our AR cross-sections (Fig. 8a) are roughly  
 370 twice as strong as given in the case study of Viceto et al. (2022). Note that the ground-based station from which Viceto et al.  
 (2022) depicted soundings were basically located at the outflow edge of the AR (with  $IVT \leq 250 \text{ kg m}^{-1} \text{ s}^{-1}$ ) on the Luv side.  
 Winds from the east were orographically slowed down by the massif of Svalbard. In this sense, the marine arctic ARs we  
 consider are undisturbed. This enables stronger winds whose magnitude is rather comparable to mid-latitude AR conditions.  
 Ralph et al. (2004) and Cobb et al. (2021b) report on mean low-level wind speeds from  $10\text{--}25 \text{ m s}^{-1}$  for a large set of ARs  
 375 over North-East Pacific. The slight local wind maximum at 900 hPa (Fig. 8a) arises from the presence of strong wind corridors  
 designated as LLJs that represent a common feature in mid-latitude ARs (Ralph et al., 2004; Demirdjian et al., 2020). Their  
 polar existence is verified in the case study of Terpstra et al. (2021). We find a very dominant LLJ inside our most intense  
 AR (AR3 in Fig. 8). Above the local wind maximum, the vertical profile of wind speed remains more homogeneous than in  
 sub-tropic/mid-latitude cases where Ralph et al. (2005) and Cobb et al. (2021a) registered a stronger intensification with height.  
 380 The cross-section variability of both moisture and winds strongly affects  $IVT$  variability. The shadings in Fig. 8 indicate that  
 the standard deviation of moisture transport resembles the standard deviation of the winds for the lower levels up to 850 hPa,  
 before moisture transport variability is apparently driven by the standard deviation of moisture in upper levels, although the  
 wind standard deviation becomes highest above 500 hPa. For the most intense AR (AR3), the LLJ exhibits high wind speeds

**Figure 9.** Vertical profile of relative standard deviation of wind ( $s_v$ ) and moisture ( $s_q$ ) for the AR cross-sections of each flight. The bold lines indicate the mean value over all ARs for both components. The sizes of the dots scale with the mean value at this height normed by the maximum mean value for the entire profile.

above  $30 \text{ m s}^{-1}$  that cause strong moisture transport whereas moisture is more or less average (Fig. 8a). While strong moisture  
 385 transport in AR3 originates from overall strong winds, moisture varies strongly and seemingly dominates the moisture transport  
 variability (Fig. 8b). Hence, we hypothesise that in strong arctic ARs with intense winds, moisture variability primarily steers  
*IVT* variability and leads to the bell-shaped *IVT* cross-section pattern depicted in Sect. 3.1.

The identification of the more variable quantity can improve measurement strategies. Specifically, moisture can be derived  
 from supplementary remote sensing devices on long-range research aircraft. For this reason, we quantify the relative standard  
 390 deviations of wind and moisture ( $s_q$  and  $s_v$ ), normalised by the horizontal mean. We investigate  $s_q$  and  $s_v$  as a function of  
 height (Fig. 9). Especially for the winds, the relative standard deviation in Fig. 9 remains rather consistent throughout the  
 troposphere and has a small magnitude (mean relative variability around 20 to 35 %). This is in accordance with the high but  
 rather homogeneous wind speeds in AR3 (Fig. 8). Besides a weak local maximum in the vicinity of the LLJ, the variability  
 increases near the upper-level polar jet, but with minor impact on the moisture transport (variability) due to dry air masses.

395 The variability of moisture behaves differently. In the boundary layer, moisture variability is negligible similar to wind  
 ( $s_q, s_v < 20\%$ ). Yet, the decline of mean moisture with height is opposed by an increase of its relative variability. Between 600  
 and 850 hPa, high moisture variability, increasing half as high as its mean, basically contributes to mean moisture transport  
 variability. Based on our AR cross-sections, we conclude that moisture represents the more variable quantity in arctic ARs.

### 3.4 Coherence of moisture and wind

400 For the moisture transport, it is not only important whether moisture and wind anomalies are high separately (Sect. 3.3), but also  
 how correlated they evolve along the AR cross-sections and whether connected patterns contribute significantly to AR-*IVT*  
 (Q2). If both patterns do, carefully collocated observations are essential to determine *TIVT*, otherwise independent estimates

of mean moisture and wind are sufficient. The overall moisture transport  $\overline{q \cdot v}$  is basically a combination of transport by the mean quantities  $\bar{q}$  and  $\bar{v}$  and their correlated cross-section variability, i.e spatial fluctuations  $q'$  and  $v'$ , according to:

$$405 \quad \overline{q \cdot v} = \overline{(\bar{q} + q')(\bar{v} + v')} = \bar{q} \cdot \bar{v} + \underbrace{\overline{q' \bar{v}}}_{=0} + \underbrace{\overline{\bar{q} v'}}_{=0} + \underbrace{\overline{q' \cdot v'}}_{\text{cov}(q,v)}. \quad (6)$$

While the second and third summand equal zero, the last term represents the covariance  $\text{cov}()$  between  $q$  and  $v$ . Using the relation between correlation coefficient  $r_{\text{corr}}$  and  $\text{cov}()$ , we obtain:

$$\text{cov}(q, v) = r_{\text{corr}}(q, v) \cdot \text{std}(q) \cdot \text{std}(v), \quad (7)$$

and expanding by  $\bar{q}$  and  $\bar{v}$ , we can reformulate Eq. 6 as:

$$410 \quad \overline{q \cdot v} = \bar{q} \cdot \bar{v} \cdot \underbrace{\left(1 + r_{\text{corr}}(q, v) \cdot \underbrace{\frac{\text{std}(q)}{\bar{q}}}_{s_q} \cdot \underbrace{\frac{\text{std}(v)}{\bar{v}}}_{s_v}\right)}_{\text{cov}_{\text{norm}}}. \quad (8)$$

The normalised covariance  $\text{cov}_{\text{norm}}$  (right summand in Eq. 8) weighs the coherent transport relative to the non-coherent  $\bar{q} \cdot \bar{v}$ .

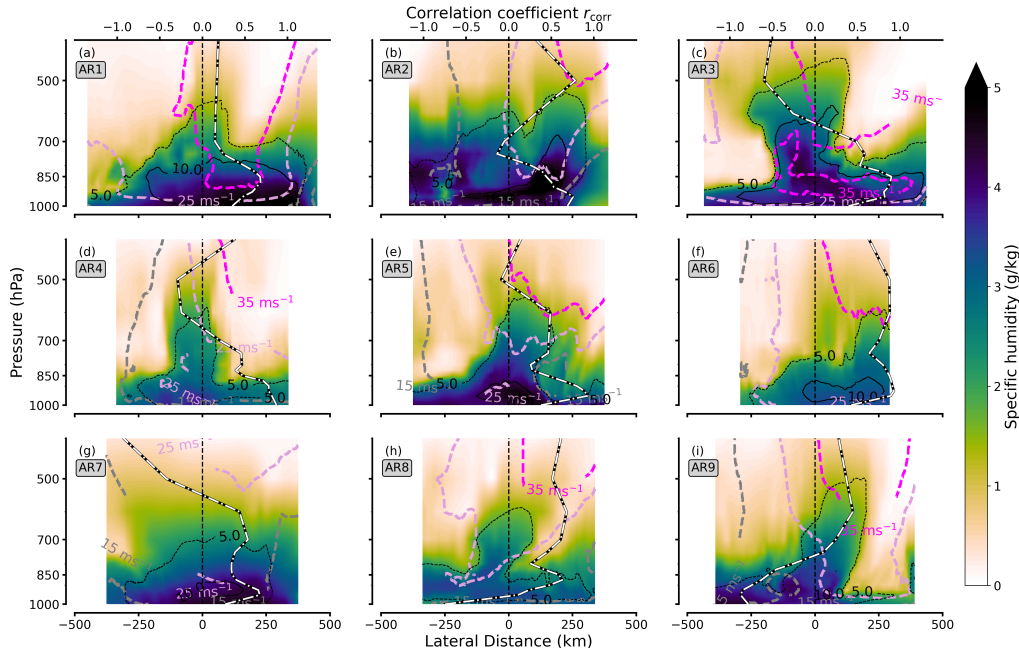

Using  $\text{cov}_{\text{norm}}$ , Figure 10 finds rather little coherence between moisture and wind in arctic AR cross-sections. The magnitude of the contribution of moisture transport variability to the overall moisture transport is below  $\pm 10\%$  for each height. Accordingly, the coherence is of minor influence for the entire  $IVT$  variability. Main reasons for the low contribution of coherent patterns  
 415 are the relatively low standard deviations compared to their mean (see  $s_q$  and especially  $s_v$ ). Even considerable correlation ( $r_{\text{corr}} \geq 0.5$ , Fig. 10) cannot generate relevant moisture transport contributions. Over the vertical extension,  $\text{cov}_{\text{norm}}$  mostly remains below 5%. Even in moisture transport dominated levels (below 700 hPa), the cross-sections reveal a contribution of moisture transport variability to Eq. 8 in the range of 5 to 10%. Only for some ARs, the strongest variability ( $> \pm 10\%$ ) primarily occurs in higher levels above 500 hPa, where, in turn, moisture transport is weak (Fig. 8 and Fig. 10). The correlation  
 420 between moisture and wind  $r_{\text{corr}}$  shows a large spread between the single ARs (grey lines in Fig. 10), so that we take a closer look into the spatial patterns of moisture and wind for our AR cross-sections in Figure 11.

Inspecting the vertical AR curtains in Fig. 11, we recognise several features that we know from mid-latitude ARs. For instance, Ralph et al. (2004) and Cordeira et al. (2013) found the vertical slanted structure of moisture transport in AR cross-sections from dropsondes and reanalyses, where Ralph et al. (2017) verified the vertical interaction between the upper-level jet and the  
 425 LLJ that dominates the AR moisture transport. In Fig. 11, their conceptual depictions reflect mostly for AR5 and AR6 where moisture and wind are most coherent. Here, moist air masses residing in the warm conveyor belt are lifted over the cold-frontal sector. The downward intrusion of the upper-level jet on the eastern flank causes the slanted structure in the moisture transport. For the windy arctic AR events, e.g. AR3 and AR5, we detect the presence of LLJs stronger than  $25 \text{ m s}^{-1}$ . The LLJ is situated at a height of around 900 hPa, slightly lower than Cobb et al. (2021a) summarised for mid-latitude ARs. In almost every cross-  
 430 section (Fig. 11), the specific humidity exceeds  $4 \text{ g kg}^{-1}$  indicating that our events are rather moist for arctic AR conditions (e.g. Viceto et al., 2022), but much drier than mid-latitude ARs where  $q$  easily exceeds  $8 \text{ g kg}^{-1}$  (Cobb et al., 2021a).

**Figure 10.** Vertical profile of AR moisture and wind normalised covariance ( $COV_{norm}$ ) and their correlation  $r_{corr}$  along the cross-sections. The bold lines indicate the mean value over all AR for each of the components. The sizes of the dots scales with the mean moisture transport value at this height normalized by the maximum mean value of the entire profile.

Still, we notice a large case-to-case variability in Fig. 11 and partially less compliance to the conceptualised AR schematics illustrated in Ralph et al. (2017). This shows for the vertical structure of moisture, the presence and intensity of the LLJ (strongly distinctive in AR1, AR3, AR5, AR7, but missing in the other ARs) and how patterns of moisture and wind are correlated. Apart from AR5, other ARs exhibit less coherent patterns where wind and moisture do not necessarily align with each other. Especially AR9 indicates a clear horizontal displacement, causing a negative correlation along the cross-section. Here, subsiding dry air masses in the cold sector counteract the westward increase of wind speeds. For all ARs except for AR1, AR8 and AR9, the correlation between moisture and wind peaks in the LLJ height ( $r_{corr} > 0.7$ , Fig. 11). AR1 and AR3 exhibit small horizontal variability in the wind field, as winds are almost constant along the entire cross-section ( $> 25 \text{ ms}^{-1}$ ). Here, it is the moisture variability steering the moisture transport variability. The ARs, being variable in moisture, consist of an elevated moist plume only residing in the AR core that is surrounded by dry air. The strength of dry air subsidence is primarily relevant for slanting the moisture transport along the cross-section. We find this most effective for ARs close to the dry air masses east of the Greenland coast (AR3) and when the backside of the embedded cyclone advects the dry Greenland air masses (AR9). The variety of moisture transport characteristics comes with the very different synoptic patterns (troughs, ridges, smaller cyclones embedded in a meridional, but rather weak flow) causing the arctic ARs. In addition, we consider different corridors of the respective ARs. While AR5 was mainly observed in the AR center, other ARs such as AR2-4 and AR7 are observed in the exit region of the AR (see Fig.1 and Fig. 2). Terpstra et al. (2021) detected that moisture and wind patterns and their coherence in polar ARs strongly change along the AR direction. In their case study, the pronounced AR pattern, as depicted in Ralph et al. (2017), vanishes out more towards the Poles and the AR exit region. Similarly, the most textbook AR among our cases, AR5, is also the southernmost AR (Fig. 1). Moreover, Terpstra et al. (2021) identified decreasing coincidence between moisture and wind in the polar AR exit region. In their case, the LLJ resides in rather dry regimes below the local moisture maximum. While

**Figure 11.** Cross-sections of AR inflow legs for moisture (color-coded contours), as well as wind contour lines for (pinkish) and moisture transport (both as contour lines). Shown moisture transport values have the unit  $\text{gkg}^{-1}\text{ms}^{-1}$ . The black-white dashed vertical line represents the cross-sectoral mean of the correlation coefficient  $r_{\text{corr}}$  between moisture and wind for each pressure level.

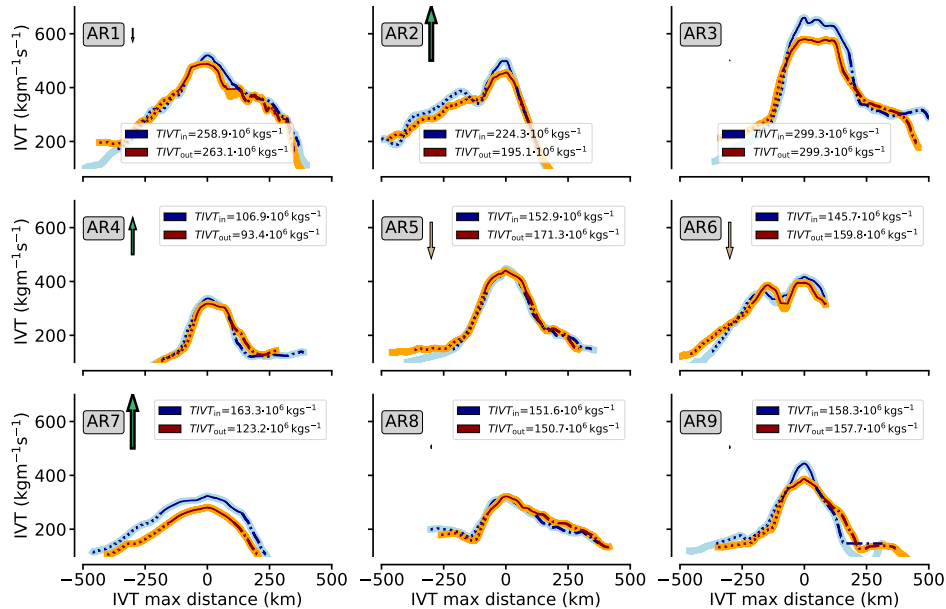

we detect this vertical separation of moisture and wind patterns mainly for AR4, but less uplifting of maximum moisture than in Terpstra et al. (2021), we emphasise the horizontal displacement of moisture and wind sectors in AR exit corridors (Fig. 11).

We conclude that mean moisture and wind account for 95 % of overall moisture transport in arctic ARs. Moisture and wind patterns exhibit little coherence especially in arctic AR exit corridors, but show high inter-case variability. Despite the variability, we postulate that strong ARs ( $IVT \geq 400 \text{ kg m}^{-1}\text{s}^{-1}$ ) tend to feature strong, but rather constant winds. Instead, narrow and high-reaching moisture plumes in the core control moisture transport variability. The effectiveness of dry subsidence backwards the AR modulates the AR moisture transport pattern. An improvement for observing the moisture transport variability should thus be built upon supplementary moisture measurements rather than those of the winds. Incoherent cross-section patterns motivate investigating separate sectors along the AR front as they exhibit different processes (Cobb et al., 2021a). When moisture and wind patterns do not coincide, we can expect cross-frontal differences in the divergence components (Eq. 5).

#### 4 Moisture transport divergence from sondes

This section analyses how the divergence of moisture transport is characterised along cross-sections of arctic ARs (Q3). Resuming the decomposed terms (Eq. 5), we inspect whether high moisture advection occurs more frequently in strong moisture-dominated AR sectors and whether mass convergence dominates in windy AR sectors. We categorise our results based on

**Figure 12.** *IVT* along inflow (outflow) legs in blue (orange) for all nine ARs (Fig. 1). Changes in line styles denote the frontal sector classifications (Sect. 2.5): Dotted lines represent cross-section periods attributed to pre-frontal sectors, while dashed lines refer to post-frontal sectors. The legend depicts *TIVT* values for the in- and outflow cross-section parts within the AR. They include *IVT* purely internal of determined AR borders (Sect. 2.5). Arrows indicate the *TIVT* difference between in- and outflow leg scaled in length and width. The differences can be viewed as simple estimates of *IVT* divergence in between both legs, according to Sect. 2.4. Upward (downward) arrow scales represent estimated convergence (divergence) magnitudes. Note the x-axis orientation is from east (left) to west (right).

frontal sectors defined in Sect. 2.5. Synthetic sondes illuminate how discrete soundings reflect such characteristics against the continuous flight representation along the AR cross-sections (Sect. 2.3.1).

#### 4.1 In- and outflow *IVT*

Before coming to the moisture transport divergence at single levels, we compare the integrated quantities, namely cross-section *IVT* of the in- and outflow leg and their AR-*TIVT* for all nine arctic ARs (Fig. 12). The comparison of *TIVT* in both legs reveals first simplified estimates of the prevailing divergence. Idealising that no entrainment into the AR corridor (Sect. 3) takes place, Figure 12 contrasts *TIVT* of the in- and outflow cross-section to estimate whether convergence or divergence of moisture transport inside the AR corridor exists. Figure 12 indicates that maximum *IVT* values vary between 200–650 kg m<sup>-1</sup>s<sup>-1</sup>, with the outflow *IVT* generally having a similar intensity to the inflow leg. The strongest AR in terms of maximum *IVT* also has the highest total transport in both flight legs. Overall, *TIVT* overall ranges from 100–300 · 10<sup>6</sup> kg s<sup>-1</sup>. Recall that this is approximately one third to one half the *TIVT* magnitude found in mid-latitude ARs (Ralph et al., 2017). Figure 12 further separates the AR cross-sections in the three sectors (pre-frontal, core, post-frontal). Although the AR cores

are roughly 200–300 km narrow (slim lines in Fig. 12), they provide more than half of the entire AR-*TIVT*. This contribution of the AR core agrees with findings from Cobb et al. (2021a) in mid-latitude ARs. Except for AR2 and AR7, weaker slopes of *IVT* are generally in the cold sector as opposed to the warm sector. In turn, the steep post-frontal *IVT* decline in AR2 and AR7 results from calm air masses on the backside of the AR (see also Fig. 11).

Comparing both legs (Fig. 12), cross-section *TIVT* tends to decrease downstream in some arctic ARs. Here, higher *IVT* and *TIVT* in the inflow leg suggests potential convergence in the AR corridor. Yet, we likewise identify cases with weak streamward tendencies in total moisture transport or with slight increases. Moreover, the downstream difference of *TIVT* is unevenly distributed over the cross-section *IVT*. It is mainly within the AR core where *IVT* decreases towards the outflow leg (e.g. AR3, AR9), thus suggesting internal convergence. However, counteracting behavior in the frontal sectors partially compensates the core and stream-ward decrease of *IVT*. Like in AR6, the increase of warm sector *IVT* towards the outflow conveys a seeming divergence. This is in contrast to the findings in Guan et al. (2020), where the pre-frontal sector is denoted as a region of moisture transport convergence. Nonetheless, although the *IVT* patterns of AR5 and AR6 (Fig. 1) allow slight divergence in the pre-frontal sector, we emphasize that a *TIVT*-based interpretation of predominant moisture transport divergence underlies strong idealisation. It considers neither moisture flow being non-perpendicular to the flight, nor does it separate contributions of moisture advection and mass convergence. Therefore, we insist on the regression approach from Sect. 2.4 to diagnose moisture transport divergence in each frontal sector of the arctic ARs.

## 4.2 Sonde-based divergence and its representativeness

This section derives the *IVT* divergence ( $\nabla IVT$ ) in arctic ARs, Using the regression-based approach (Sect. 2.4). The moisture transport divergence is specified for the frontal sectors (Sect. 2.5) and for the decomposed terms, namely moisture advection *ADV* and mass convergence *CONV* (Eq. 5). Again, the results from the continuous cross-section flight legs (Sect. 2.3.1) represent our idealised reference. We compare them to the results referring to seven synthetic sondes per cross-section (as in Fig. 5). This comparison assesses uncertainties of sonde-based  $\nabla IVT$ , representative for arctic AR conditions. In doing so, we build on Norris et al. (2020) who pioneered the airborne derivation of all AR moisture budget components, including moisture transport divergence, by sampling a mid-latitude AR event.

In a first step, Figure 13 delineates the divergence components for the frontal sectors within the intense AR3. In the continuous AR representation, *ADV* and *CONV* exhibit different vertical profiles throughout the frontal cross-section (Fig. 13). Comparing moisture transport divergence in the sectors for the continuous representation, we see that values range from  $-3$  to  $+1 \cdot 10^{-4} \text{ g kg}^{-1} \text{ s}^{-1}$ . While moisture advection (*ADV*) does not rise above  $\pm 1 \cdot 10^{-4} \text{ g kg}^{-1} \text{ s}^{-1}$ , mass divergence (*CONV*) decreases below  $-2 \cdot 10^{-4} \text{ g kg}^{-1} \text{ s}^{-1}$ . For AR3, the post-frontal sector is most crucial for moisture transport divergence. In detail, the warm pre-frontal sector and the core exhibit weak advection (Fig. 13a), whereas substantial advection occurs in the post-frontal cold sector. Similarly, the strongest mass convergence is found for the post-frontal sector (Fig. 13). Not only *ADV* and *CONV* act differently between the frontal sectors, they also dominate in different vertical levels. The maxima of *ADV* and *CONV* locate at the heights where also moisture and wind dominate (Fig. 11). While advection is predominant at mid-levels above 800 hPa up to 500 hPa, the mass divergence primarily acts below this level (Fig. 13 a and b). In the vicinity of the

**Figure 13.** Vertical contributions from *ADV* (a) and *CONV* (b) to moisture transport divergence (c) for the frontal sectors in AR3. Bold lines represent the continuous AR representation while dashed lines depict the sonde-based representation with the deviations as shadings.

LLJ in the AR core at around 850 hPa, predominant mass convergence (negative values) prevails, although the vertical column is slightly divergent in total. The advection of moisture in the prefrontal sector and core is too weak (Fig. 13a) to compensate the more prominent mass divergence (Fig. 13b). Overall, the moisture transport convergence (divergence) dominates in the  
 515 cold post-frontal (warm pre-frontal) sector of AR3 (Fig. 13). We attribute the drying in mid-levels of the cold sector in AR3 to the dry cold air masses overrunning the AR behind the cold front (as also visible in Fig. 11c). The change in *IVT* direction behind the cold front (see Fig. 5) accounts for the low-level mass convergence in the post-frontal sector.

The fact that the moisture transport divergence components differ across the frontal axis is in line with mid-latitude AR based statistics of Guan et al. (2020). In detail, the characteristics in AR3 described above differ quietly to the AR case observed by  
 520 Norris et al. (2020). In their airborne study of a mid-latitude AR, they found moisture transport convergence to be strongest close the AR core and rather opposite signs for the pre- and post-frontal regions than us. Especially the lack of pre-frontal moisture advection in AR3, which Guan et al. (2020) actually robustly found in mid-latitude AR statistics, is worth-mentioning. In contrast to both Norris et al. (2020) and Guan et al. (2020), we do not identify a dominance of dynamical convergence over advection. The magnitudes of moisture transport divergence in AR3 are also much lower. Nonetheless, we remind that Norris  
 525 et al. (2020) and Guan et al. (2020) consider even more intense mid-latitude AR near its centre. While AR3 is exceptionally strong for arctic conditions (Fig. 2), it is rather moderate for mid-latitude scales (Ralph et al., 2019).

Three synthetic sondes in each frontal sector leg (located as in Fig. 5) generally reproduce the divergence characteristics of the continuous reference within each frontal sector (Fig. 13). The highest deviations occur for the cold sector arising from mid-level moisture advection and low-level mass convergence overestimation. We note that slight cross-sectoral displacements  
 530 of the sonde positions deviate the divergence characteristics, but they all maintain the principle vertical characteristics for each component and sector (Fig. 13). When we contextualise our sonde results with the airborne study by Norris et al. (2020) using

real dropsondes, we recognize the strength of real sondes with a high vertical resolution. They provide much greater vertical variability. Thus, it is likely that the quite low divergence displayed in Fig. 13 does not only result from less divergence that prevails in arctic ARs compared to mid-latitude ARs, but may also be a consequence of the coarser vertical resolution averaging out larger values. Nevertheless, given the before mentioned contrasts of AR3 to mid-latitude AR moisture transport divergence, we should involve our other AR events in order to pinpoint robust commonalities and differences to mid-latitude ARs, and to what extent the airborne sondes can reproduce them (Q3-Q4).

To compare moisture transport divergence for all our arctic cases with statistics of mid-latitude ARs, we derive the vertical integral  $\nabla IVT$  (Eq. 5). This quantifies the contribution of moisture transport divergence to the moisture budget (Eq. 2). For our ARs, we summarise the daily contribution of  $\nabla IVT$  in  $\text{mm d}^{-1}$  (Fig. 14). Accordingly, the warm pre-frontal sector overall supplies moisture via advection that overcompensates weak mass divergence. In contrast, the core and post-frontal cold sector advection have a inter-case variability in the advection of either dry or moist airmasses. An overall large mass convergence in the post-frontal sector balances or even superimposes the advection. The post-frontal sector marks the highest inter-event variability. Surprisingly, the mass divergence in the core shows a robust negative contribution for the moisture budget (Fig. 14). For the arctic AR frontal sectors, the range of budget contributions from  $-3 \text{ mm d}^{-1}$  to  $+3 \text{ mm d}^{-1}$  in Fig. 14 is quite small compared to mid-latitude AR magnitudes. For statistics of mid-latitude ARs, Guan et al. (2020) summarises budget contributions in the range  $-10 \text{ mm d}^{-1}$  to  $+15 \text{ mm d}^{-1}$ . The frontal characteristics of *CONV* in arctic ARs contradict the understanding from Guan et al. (2020) who emphasized dominating mass convergence in and ahead of the AR front for mid-latitude AR. Unlike the mid-latitudes, the core of arctic ARs is characterised by the divergence of mass. This is surprising as our arctic ARs, like mid-latitude AR, contain LLJs, see again Fig. 11, which are associated with high mass convergence. This mass convergence is also found in many of our AR cases, but often superimposed by mid-level mass divergence above the LLJ. For the pre-frontal sector, moistening due to moisture advection is similarly identified for arctic (Fig. 14) and mid-latitude ARs (Guan et al., 2020). In the post-frontal sector, both types of advection coexist, whereby the effectiveness of subsidence of dry air overrunning the AR in the mid-levels becomes crucial (see also Fig. 11). High values in post-frontal mass convergence mainly arise from two AR cases (AR3, AR7), where low-level changes in wind direction induce the convergence of air masses (see also Fig. 1).

We emphasize that we cannot naively compare our frontal sector values with those of Guan et al. (2020). First, our arctic corridors along the sea ice edge are primarily attributed to the AR exit region as the centre is located more southwards (see Fig. 2). For this exit region, we expect stronger divergence than convergence when the outflows of the ARs spread out. Guan et al. (2020) refer to the conditions across the AR centers. Second, our frontal sectors are larger than those classified by single reanalysis pixel-based values used in Guan et al. (2020). Our sectors are, however, more comparable among the AR events as they are AR relative and restrict to our defined AR edges. Note that the post-frontal sector in Guan et al. (2020) is also more distant and exclusive from the actual AR, where we would already consider dissimilar flow patterns, such as southerly flow backside of the cyclone in AR7. In their airborne case study, Norris et al. (2020) highlight that much higher values of moisture transport divergence occur at smaller scales than the reanalysis resolution used in Guan et al. (2020). Hence, we postulate that the sector-based values of moisture transport divergence in Fig. 14 will also increase for smaller AR domains.

Applying three soundings per cross-section sector, the sondes replicate the cross-frontal divergence (grey box-whiskers in Fig.

**Figure 14.** Box plot of moisture transport divergence contributions to daily moisture budget for all nine ARs. Values specify both components (*ADV*, *CONV*) for all frontal AR sectors (colour-coded). They compare the continuous AR representation (coloured box-whiskers) with the sonde-based values (grey). The boxes refer to the quartiles and horizontal lines inside specify the respective mean.

14), i.e. the weak mass convergence being omnipresent for our arctic ARs. The sonde configurations derive similar median values as the continuous AR representation and give evidence of the principle observability of moisture transport divergence by discrete dropsondes. Six sondes per sector are basically capable to reproduce the general frontal structure of moisture transport divergence and its vertically integrated contribution to the moisture budget. However, the percentiles between sondes and the continuous representation deviate. For individual events, sondes can misinterpret the magnitude of sector-specific divergence components considerably. Since this deviation is unbiased though, the sonde mean errors remain below  $0.5 \text{ mm d}^{-1}$  (Fig. 14). Another aspect not touched on in our discussion so far is that we mimic all observations of moisture transport divergence in terms of flight duration. This is a major difference from Guan et al. (2020), who derived divergence components for individual reanalysis time steps. The airborne continuous realisation (Sect. 2.3.1) is non-instantaneous. This realisation can cause considerable deterioration in our understanding of the AR corridors due to the temporal AR evolution meanwhile. This issue is also addressed in the airborne study of Norris et al. (2020), where they correct for the AR displacement over the flight duration by a time-to-space adjustment. However, they were not able to account for local temporal changes. Since our flight pattern cover larger AR corridors than in Norris et al. (2020), it is worth-investigating to what extent the temporal AR evolution during flight may distort the airborne moisture transport divergence results.

## 5 Deterioration by non-instantaneous soundings

This section examines the extent to which the temporal AR evolution during flight affects the sonde-based representation of *IVT* divergence. Up to 3 hours are needed to fly over AR corridors and consecutively observe the in- and outflow (Sect. 2.3.1). Meanwhile, temporal AR evolution can distort the airborne (non-instantaneous) representation of *IVT* divergence in the AR. Therefore, we establish an instantaneous reference consisting of the spatially collocated AR representation at the flight-centered

**Figure 15.** Comparison of divergence component contributions to daily moisture budget from spatially continuous AR representation referring to either evolving flight values (non-instantaneous) or to the values for the centered hour (instantaneous). Values are given for each frontal sector. Black error bars are identical to the coloured boxes in Fig. 14. Grey values represent centered hour-based values.

hour and quantify the error in observed moisture transport that evolves over the flight duration. For the spatially continuous AR representation, we contrast the cross-frontal  $\nabla IVT$  in both temporal perspectives (non-instantaneous and instantaneous). Summarising all ARs of Sect. 2.2, Figure 15 demonstrates that the frontal characteristics of  $\nabla IVT$  are more or less reasonably reproduced by the non-instantaneous representation. However, we note that the mean non-instantaneous error in divergence caused by the flight duration (red dots in Fig. 15) is much greater than the error by discrete sondes (compare to Fig. 14). In detail, the evolution of the ARs deviates the airborne estimates of moisture transport divergence by up to 25 % and even stronger on the backside of the AR. In the post-frontal sector, the mean error exceeds  $1.5 \text{ mm d}^{-1}$ , whereas sonde undersampling (Fig. 14) only induces mean errors  $\leq 0.5 \text{ mm d}^{-1}$ . The temporal evolution of the AR throughout the flight can thus strongly deteriorate the divergence estimates for individual sectors. It is *ADV* in the post-frontal sector where we find the highest deviations compared to the instantaneous snapshot (Fig. 15). The deviations show up in the mean, median and standard deviation. Not only does the instantaneous representation show more robust post-frontal dry advection than the airborne perspective, but there is also much greater case-to-case variability in its magnitude ( $-0.5$  to  $-4 \text{ mm d}^{-1}$ ) than seen from the aircraft. When we consider airborne (non-instantaneous) deviations for individual ARs, we find cases with errors in *ADV* that exceed more than  $8 \text{ mm d}^{-1}$  (not shown). In the prefrontal sector and core, the median of *CONV* is barely affected. Although *CONV* has higher mean errors in relative terms, these have less influence on the absolute deviation of moisture transport divergence.

Referring to the ideal representation of  $\nabla IVT$  in arctic AR cross-sections that is instantaneous and spatially continuous, the divergence characteristics in the frontal sectors agree more with the mid-latitude statistics in Guan et al. (2020). In particular, we also identify a frontal gradient in the divergence components with overall moistening in the pre-frontal sector and drying in the post-frontal sector. In the arctic ARs, this is mainly driven by advection. Mass convergence being predominant in mid-latitude ARs is however missing or is at least superimposed by mid-level mass divergence.

Having just confined ourselves to the spatially continuous representations of moisture transport divergence, we now contrast

**Figure 16.** Total sonde error (orange) and individual errors by only discrete sondes (green) and by non-instantaneous sampling (grey) for daily *IVT* divergence in each frontal sector and divergence component (Eq. 5). For all AR cross-sections, positive bars indicate the root-mean-square error (RMSE) while error markers and lines depict mean errors in combination with their standard deviations for the ARs.

these with the sonde-based divergence resulting from the combination of non-instantaneous and discrete spatial sampling (Sect. 4). Using the root-mean-square error (RMSE), Figure 16 compares the different spatial samplings (continuous and discrete) in both time perspectives with our reference, the instantaneous representation. Accordingly, the subsampling errors are minor compared to the errors induced by temporal evolution and cannot compensate the latter although they occasionally act in the opposite directions. The RMSEs for non-instantaneous sampling are much higher than the ones only induced by discrete sampling. Figure 16 underlines that the largest errors occur in the cold post-frontal sector. While the RMSE for the combination of non-instantaneous and discrete subsampling in the warm pre-frontal sector and core is around or slightly below  $1 \text{ mm d}^{-1}$ , the RMSE reaches up to  $3 \text{ mm d}^{-1}$  in the post-frontal sector. Non-instantaneous discrete sampling by sondes misrepresents the divergence components by more than 50 % of the actual values (compare with Fig. 15). In turn, the RMSE resulting from the discrete subsampling alone (green bars in Fig. 16) remains below  $1 \text{ mm d}^{-1}$  throughout all frontal sectors.

The values of moisture advection are more sensitive to airborne sampling than mass divergence values. In contrast to discrete sampling, errors induced by instationarity in *ADV* act in a more consistent direction (error bars in Fig. 16). In the cold sector, AR instationarity mainly leads to an underestimation of dry advection. These tendencies result from the oblique movement of the ARs which are not necessarily aligned with the moisture transport direction. In fact, our ARs move more or less to the northeast, while our flight pattern aims for cross-sections being orthogonal to the transport and are more zonally orientated. For the flight-centered hour (instantaneous reference), drier air masses are already more embedded in the post-frontal sector of the inflow cross-section leg, but less in the outflow leg. This changes the moisture gradient between both flight legs, increasing the overall dry advection. The winds exhibit less horizontal variability (Sect. 3.4). Temporal displacement thus varies *CONV* less than *ADV*, so that *CONV* remain less sensitive to non-instantaneous sampling.

We deduce that our flight pattern is subject to the strongest sonde-based misrepresentation in  $\nabla IVT$  from advection in the cold post-frontal sector. Flight planning should involve weather forecasts to adapt the flight legs for AR evolution. Forecasts can estimate the mean propagation speed and direction of the AR corridor center so that in- and outflow legs can be shifted adequately. Similar to the error magnitudes, the inter-case variability in the divergence misrepresentation is much higher for advection (Fig. 16). The large inter-AR variability in the results highlights that more ARs should be considered in order to generalise the errors for arctic ARs. This includes differentiating errors not only by the AR strength, but by their AR corridor type (entry, centre, exit). If flights are located in intense AR centres, we expect mass convergence to contribute more and errors due to sounding spacing to increase. The mass convergence may be more similar to the mid-latitude values in Guan et al. (2020). However, AR centers are rarely encountered near the sea ice in spring (Fig. 2). The occurrence of AR exit corridors over arctic sea ice is significantly higher. This underpins the usefulness of our error estimates for research flights in arctic ARs.

## 6 Conclusions and perspectives

This assessment study investigated the characteristics of the moisture transport divergence in arctic Atmospheric Rivers (ARs). We analysed the ARs from an airborne perspective to assess the dropsonde-based observability of moisture transport divergence of arctic AR. We characterised airborne uncertainties in sonde-based representation of the AR moisture transport divergence inside arctic ARs, focusing on two sonde-based limitations: subsampling by too large sounding spacing and the instationarity of the AR over the flight duration. For this, we followed a synthetic approach using reanalysis data as virtual truth. CARRA reanalysis data were interpolated on synthetic flight patterns that consist of two cross-sections covering frontal sectors over the entire AR transect. Single vertical profiles emulate dropsondes.

We considered nine arctic AR events over the Atlantic pathway to the Arctic ocean in the vicinity of the sea-ice edge from last decade. The values of Integrated Water Vapour Transport ( $IVT$ ) in the AR cores range from 300–600 kg m<sup>-1</sup> s<sup>-1</sup>, although the ARs are primarily examined north of their center. We thus classify these ARs as overall strong for arctic conditions. Still, the bell shape of  $IVT$  across the AR varies strongly in between the AR cases. The considered cases cover a large variability and consist of various synoptic patterns (extended troughs, blocking situations, single cyclones) in which the AR are embedded. This study delivers benchmarks of uncertainties in the airborne representation of sonde-based AR moisture transport divergence. We conclude the four pursued questions (Q1-Q4) as:

### **What is the maximum distance between sondes to determine the total moisture transport through AR corridors? (Q1)**

– For the sonde-based determination of Total Integrated Water Vapour Transport ( $TIVT$ ) in arctic AR cross-sections, sonde spacing below 100 km robustly keeps  $TIVT$  errors below 10 % (Fig. 7). In strong ARs with  $IVT$  exceeding 500 kg m<sup>-1</sup> s<sup>-1</sup>, too coarse  $IVT$  representation at the AR core leads to  $TIVT$  underestimation. Gaussian fits help to reproduce the cross-section  $IVT$  shape but are sensitive to how sondes estimate maximum  $IVT$  and its location. Thus, precedent flight planning should aim for a sonde release at the forecasted  $IVT$  maximum and place additional sondes symmetrically around. For arctic AR widths of 400–800 km, we suggest a minimum of seven soundings per cross-section (roughly 60 to 120 km spacing) to derive  $TIVT$  in both cross-section legs. The maximum  $IVT$  is more correlated to

660 *IVT* variability than the AR width is. The planning of sonde releases should thus rely on the steepness of *IVT* along the cross-section. We highlight that the differences of *TIVT* between the in- and outflow cross-sections are in a range of 2–15 % (Fig. 12). If we want to reliably estimate moisture transport divergence based on *TIVT* from both cross-sections, the sonde-based uncertainty of *TIVT* for a single flight leg must be considerably lower.

#### **How correlated are moisture and winds in arctic ARs and do coherent patterns contribute significantly to *IVT*? (Q2)**

665 – Moisture and wind in arctic ARs along the flight transects are only moderately correlated with mean correlation coefficient of 0.5 at about 850 hPa height and less below and above. At the same time, the standard deviation of both quantities is smaller than its mean respectively. Moderate correlation and limited variability result in a small contribution of coherent patterns to *IVT*, which is smaller than 10 % of the moisture transport by the mean quantities. We draw the conclusion that collocated sampling of wind and moisture to assess the coherent transport is not of first priority. It is worth noting that the moisture variability dominates the wind variability over most of the profile between 850 and 500 hPa. Only close to the surface, the wind variability peaks at about 850 hPa and plays an essential role. Thus, we prioritise supplementary airborne measurements of moisture to better represent arctic AR-*IVT* variability.

#### **How can the divergence of moisture transport be characterised along cross-sections of arctic ARs? (Q3)**

675 – By contrasting the in- and outflow *TIVT* through both cross-sections of all ARs, we expect an overall divergence in moisture transport. Yet, the ARs show frontal specific characteristics in *IVT* divergence, which have to be separated into moisture advection (*ADV*) and mass convergence (*CONV*), see Sect. 4. The pre-frontal AR sectors contribute to the moisture budget via moisture advection, while the post-frontal sectors generally show dry advection, but also occasional mass convergence. However, in contrast to mid-latitude ARs, mass convergence is much less dominant in the Arctic ARs. Although the mass convergence is generally dominant, especially below 850 hPa, it is often superimposed by upper-level divergence. In turn, moisture advection is much more relevant and dominates at levels higher than 850 hPa. Across the front, the total contribution of *IVT* divergence to the moisture budget is up to +3 (pre-frontal moisture advection) to -5 mm d<sup>-1</sup> (post-frontal dry advection). This is less than half the magnitude compared to the mid-latitudes.

#### **To what extent can non-instantaneous sondes reproduce *IVT* divergence in the light of AR evolution during flight? (Q4)**

685 – Three sondes per frontal sector leg are capable to reproduce the frontal characteristics of moisture transport divergence components with similar magnitudes. The mean absolute error to the continuous AR representation along the flight extends to around 0.5 mm d<sup>-1</sup> (Fig. 14). Sonde-based estimates are most sensitive in the post-frontal sector, where we also detect steeper gradients in moisture and winds than in the pre-frontal sectors. There is, in turn, high inter-case spread with positive and negative deviations. Noteworthy is that the error for moisture transport divergence by undersampling becomes minor compared to the error induced by the flight duration. For the post-frontal cold sector, the temporal AR evolution during the flight is responsible for more than twice the deviations in *ADV* and *CONV*. The divergence errors can exceed 50 % of the actual values. Unlike the undersampling errors, non-instantaneous sampling induces errors in a more consistent direction. Especially in the post-frontal sector, the divergence is stronger for both, *ADV* and

690

695 *CONV* than assumed by the sondes. Here the intensity and pace of dry intrusions on the backside of the AR front plays a fundamental rule in the distortion of airborne sonde-based moisture transport divergence estimates. We conclude that moisture advection on the arctic AR edges is most contributing to the moisture transport divergence and in the post-frontal most sensitive to the airborne strategy as the ARs do not necessarily displace along the moisture transport direction. Although mass convergence is much less predominant than in mid-latitude ARs, directional convergence becomes relevant in the post-frontal sector, but is overestimated by sondes during flight.

We confirm the observability of moisture transport divergence in arctic AR corridors by releasing sondes in such dedicated flight patterns. A maximum sonde spacing of 100 km within the AR cross-section can in principle characterise the divergence between  
700 both cross-sections with the given uncertainties of  $\leq 10\%$ . For the flight duration, we obtain the moisture transport divergence specified for frontal sectors with an uncertainty in the range of 25–50%. We deduce that sonde undersampling matters and recommend a sequence of at least seven sondes per section given the widths of arctic ARs. However, notwithstanding that we could release a higher number of sondes, it is the temporal evolution of the AR over the flight duration that leads to higher deviations in the divergence components rather than sonde undersampling. The dedicated planning of such sonde-based  
705 purposes should not only include the positioning of the sondes, but also the minimisation of the flight duration. The placement of cross-section legs and their spacing should carefully consider the AR displacement during flight. Shorter distances between the cross-sections not only reduce the flight duration, but also the area enclosed by sondes. Given the frontal-sector widths of the arctic ARs, both cross-sections should be no more than 200 km apart. For several of our cases, the meridional separation is higher and we have to expect considerable subgrid scale variability. Collocated flights by two aircraft, with both cross-sections  
710 being not far apart and sampled simultaneously, is the optimal and still feasible strategy. When faced with a limited number of dropsondes, supplementary measurements of moisture should be prioritised, as moisture is the more variable quantity and moisture advection mostly dominates the moisture transport divergence in the arctic AR corridors.

Additional limitations of our study need to be discussed. As our results are mainly based on corridors in the AR exit region, we strongly recommend extending our uncertainty assessment to other AR regions and expect the role of winds and mass  
715 convergence to increase in strong AR centers. This becomes an even more important issue with respect to the tendency of arctic ARs to shift more northward and intensify under climate change (O'Brien et al., 2022). Furthermore, as we include a large variability of synoptic AR patterns but a small sample, we propose statistics with a larger number of AR events. The statistics can improve our understanding of the moisture transport divergence pattern in arctic ARs and attribute it to the dynamic and thermodynamic atmospheric conditions. Here, CARRA represents a very suitable reanalysis framework for this  
720 purpose in follow-up studies. Again, we encourage the use of the higher vertical resolution of the model levels rather than our chosen pressure levels, although sufficient for initial estimates. For real sondes, we emphasise the added value of their high vertical resolution. Sondes provide more accurate information on the vertical composition of *ADV* and *CONV*. The sonde-based approach is limited to regression-based divergence where we consider only rather large areas and open meridional boundaries. Even with continuous lateral sampling, the meridional gradients are only coarsely sampled.

725 Therefore, a follow-up study should investigate how the arctic AR moisture transport divergence acts inside the flight corridor at grid-cell scales. This will allow two additional research topics to be addressed: First, the internal variability between both

cross-sections can be derived more precisely to improve the flight patterns, second the actual scales at which the moisture transport divergence varies significantly can be evaluated. This may also increase the divergence magnitudes, similarly to Norris et al. (2020) who found larger values of the divergence components. They considered smaller airborne AR corridors than the ERA-Interim pixels referred to in Guan et al. (2020).

Despite the aforementioned limitations, the orders of magnitudes for *IVT* variability and divergence that we provide are representative for arctic ARs and quantify benchmarks in the sonde-based derivation. Consistently mimicking the soundings is a fundamental step towards the understanding of the uncertainties when such airborne tactics are actually carried out. The benchmarks are not only useful for improving flight strategies, but also indicate deviations in corresponding model-observation comparisons. Only by illuminating the constraints on the AR representation from both models and observations, we establish a framework from which airborne observations can support modellers in terms of the resolution and complexity required for parameterisation of moisture transformation processes caused by *IVT* divergence in arctic ARs.

*Code and data availability.* The code created by HD analysing the downloaded reanalyses and creates the figures can be accessed via github and is made available under: [https://github.com/hdorff94/Synthetic\\_Airborne\\_Arctic\\_ARs](https://github.com/hdorff94/Synthetic_Airborne_Arctic_ARs). The reanalysis data from CARRA (Schyberg et al., 2021) and ERA5 (Hersbach et al., 2018) were accessed from the Copernicus Climate Change Service (C3S) Climate Data Store (CDS). The AR catalogue (Guan, 2022) used to pre-identify AR events of interest is provided by Bin Guan via <https://ucla.box.com/ARcatalog>. Its pendant in ERA5 is provided by M. Lauer and accessible under <https://doi.pangaea.de/10.1594/PANGAEA.957161>

*Author contributions.* HD, FA and HK were main initiators for the work in the scope of this manuscript. FA, HK and VS helped to conceptualise the manuscript. HD conducted the analysis presented and drafted the manuscript under scientific supervision of FA, HK and VS. All authors contributed to revising the manuscript.

*Competing interests.* The authors declare that they have no conflict of interest.

We thank the two anonymous reviewers, for providing us with helpful comments that improved the quality of the paper, and the associate editor Geraint Vaughan. We explicitly acknowledge the Copernicus Climate Change Service (C3S) Climate Data Store (CDS) for providing access to CARRA and ERA5 data. We thank Bin Guan for making the AR catalogue publically available via <https://ucla.box.com/ARcatalog>. Furthermore, we want to thank Melanie Lauer and Geet George for various helpful discussions. Henning Dorff is thankful to Jochem Marotzke and Dallas Murphy for providing fruitful comments on the writing style and structure of the manuscript. Thanks also go towards Norbert Noreiks for delivering sketches of the research aircraft.
