21

22 **Abstract**

23

24 Reliable reconstructions of paleoseismicity are useful for understanding, and mitigating,
25 seismic hazard risks. In this study, we apply cosmogenic ³⁶Cl exposure-age dating and
26 concentrations of rare-earth elements and yttrium (REY) to unravelling the paleoseismic
27 history of the Sparta fault, Greece, which is a range-bounding normal fault developed in
28 limestone. Modeling of ³⁶Cl concentrations along two vertical profiles on the Sparta Fault
29 indicates a clustering of four earthquakes within a 1.5 kyr period that culminated with the 464
30 B.C.E. event that devastated Spartan society. Cumulative uplift was as high as 2.8 mm yr⁻¹
31 during that period, compared with ~0.6–0.9 mm a⁻¹ over the preceding 2.7–4.4 kyr. Because
32 earthquake activity may shift between faults in extensional settings, a large magnitude
33 earthquake is not necessarily indicated as being overdue by the present ~2.5 kyr quiescent
34 period. More generally, accurate identification of individual earthquakes is presently
35 constrained by spatial variations in ³⁶Cl concentration profiles that reflect neither exposure
36 duration nor imprints of former soil profiles. In cases where this is attributable to

37 mineralogical variations, such as in the Sparta fault scarp, present chemical preparation
38 techniques for AMS measurement of ^{36}Cl may insufficiently account for those variations.

39

40 The Sparta fault scarp is composed of fault breccia, which contains quartz and clay-lined
41 pores, in addition to host rock-derived clasts of calcite and microcrystalline calcite cement.

42 The exchange of REY between the hanging wall colluvium and the fault scarp calcite, which
43 has been applied to the study of paleoseismicity on other limestone normal faults, is
44 overwhelmed on this fault scarp by REY attached to the breccia pore clays. Holocene
45 earthquakes and their magnitudes, inferred from fault slip lengths, therefore cannot be
46 inferred from REY data for impure limestone faults such as the Sparta fault but, rather, these
47 data may indicate processes of fault evolution in the Earth's near surface.

52

53 **1 Introduction**

54

55 Seismic hazard risks are significant in many parts of the world and studying the magnitude,
56 recurrence, mechanisms, and impacts of past earthquakes helps form a basis for mitigating
57 current and future risk. While historical earthquake records are a crucial archive (Gürpınar,
58 2005), their spatial distribution is patchy and the recurrence interval of large earthquakes on
59 many faults exceeds historical record lengths. Paleoseismic studies that use geologic evidence
60 to infer past earthquakes, and even potentially unravel key earthquake characteristics, such as
61 timing, recurrence intervals, and the magnitudes of slip and shaking intensity, are therefore an

62 essential component of seismic hazard risk mitigation (McCalpin, 2009, p. 24). Topographic
63 expressions of tectonic faults, the displacement of surficial sediments revealed in trenches,
64 and geochemical alterations on subaerially exposed fault surfaces, may each provide evidence
65 useful to the study of paleoseismicity (e.g., Benedetti et al., 2002; Dramis and Blumetti,
66 2005; Michetti et al., 2005; Carcaillet et al., 2008; Manighetti et al., 2010; Mouslopoulou et
67 al., 2011; Smith et al., 2014; Cowie et al., 2017; Mozafari et al., 2022). In this study we use
68 cosmogenic ^{36}Cl and concentrations of rare-earth elements and yttrium (REY) to study the
69 paleoseismic history of the Sparta fault at Anogia, Greece (Fig. 1a, b).

70

71 The Mediterranean is a densely populated seismically active region that was subjected to
72 7360 earthquakes of magnitude (M) > 4 during 1998–2010 (Godey et al., 2013). Within the
73 Aegean tectonic plate (Fig. 1a), and around its margins, there were >1450 such earthquakes
74 during this period, 77 of which were $M > 5$. In central Greece, earthquakes are associated
75 with normal faults, which occur because of extension of the Aegean plate (Jolivet et al.,
76 2013). In limestone, they may be identified by spectacular scarps, which form from the
77 accumulation of bedrock slip that occurs during successive earthquakes. Holocene fault
78 scarps can be well-preserved (Armijo et al., 1991), which makes them potentially suitable
79 targets for paleoseismic studies.

80

81 Earthquakes inferred from incremental slips of limestone normal faults have been dated with
82 concentrations of *in situ*-produced cosmogenic ^{36}Cl (Zreda and Noller, 1998; Mitchell et al.,
83 2001; Benedetti et al., 2002; Palumbo et al., 2004; Schlagenhauf et al., 2010; Tesson et al.,
84 2016; Cowie et al., 2017; Mozafari et al., 2022). This nuclide is produced from spallogenic
85 and muonic reactions that occur in ^{40}Ca when limestone is exposed to cosmogenic radiation.
86 Following an earthquake, the newly exposed scarp segment accumulates ^{36}Cl , the

87 concentration of which is dependent upon the duration of subaerial exposure, thereby
88 potentially allowing the **earthquake to be dated**. More recently, ^{36}Cl dating has been
89 complemented with measurements of REY because their distribution vertically along fault
90 scarps may indicate imprints of former hanging-wall soil REY that have been uplifted by
91 successive earthquakes (Carcaillet et al., 2008; Manighetti et al., 2010; Mouslopoulou et al.,
92 2011; Moraetis et al., 2015). Peaks in REY may represent former soil surfaces and their
93 spacing may permit paleoseismic inferences such as the number of slip events, vertical
94 displacement lengths, and earthquake magnitudes. These inferences **can be made**
95 independently of ^{36}Cl measurements, which can help to verify and strengthen **interpretations**
96 of past earthquakes using this nuclide.

97

98 A pioneering cosmogenic ^{36}Cl study of the Sparta fault by Benedetti et al. (2002) guided our
99 interest because they found evidence at Parori (Fig. 1b) for the historically recorded 464
100 B.C.E. earthquake that destroyed Sparta (Armijo et al., 1991), and inferred an additional five
101 older earthquakes. However, they were unable to date the historical slip at nearby Anogia.

102 Our study objectives were to: (i) **Re-date** the paleoseismicity of the Sparta fault at Anogia, to
103 test for the surprising absence of the 464 B.C.E. earthquake, by taking advantage of recent
104 advances in both the measurement of ^{36}Cl and earthquake modelling that accounts for all ^{36}Cl
105 production pathways and shielding effects (Schlagenhauf et al., 2010), and; (ii) Complement
106 the ^{36}Cl dating with measurement of REY to best constrain the paleoseismic history of this
107 fault.

108

109 **2 Geological Setting**

110

111 The Sparta fault is a 64 km long, NNW–SSE striking, range-bounding normal fault in
112 southern Peloponnese (Fig. 1a, b). It separates the eastern flank of the Taygetos Mountains
113 (maximum elevation of 2407 m a.s.l.) from the Sparta Basin (Fig. 1b). The Sparta fault is part
114 of a larger normal fault system, which exceeds 150 km in length, and is matched on the
115 western margin of the Taygetos Mountains by the antithetical Kalamata fault and other
116 similar faults located offshore of the Mani Peninsula (Fig. 1a; Armijo et al., 1991). The
117 subaerially exposed scarp of the Sparta fault is developed in late Senonian-Eocene limestones
118 of the Ionian unit (Institute for Geology and Subsurface Research, 1969; Armijo et al., 1991).
119 Folded and tilted Permian to early Triassic pelitic and psammitic sedimentary and
120 metasedimentary units outcrop in the Taygetos Mountains and are also offset by the Sparta
121 fault at depth (Institute for Geology and Subsurface Research, 1969; Armijo et al., 1991).
122 Geomorphic evidence for Quaternary uplift along the eastern flank of the Taygetos
123 Mountains includes steep triangular facets (20° – 40°) that are hundreds of meters high along
124 the central portion of the range and decrease in height towards the N and S, wineglass
125 canyons, perched valleys, and alluvial fans having up to 4 m of entrenchment near the Sparta
126 fault trace (Armijo et al., 1991; Benedetti et al., 2002; Pope and Wilkinson, 2005;
127 Papanikolaou et al., 2013). Collectively, the evidence indicates a tectonically active
128 environment.

129

130 The Sparta fault scarp is nearly continuous along strike and it reaches a maximum height of
131 10–12 m in its central portion but tapers towards both ends. Hanging wall erosion associated
132 with stream incision can locally form higher scarp segments. The scarp has a 65° – 68° dip
133 and, in all but a few locations, slickensides have been eroded away following exhumation.
134 The slope of the hanging wall ground surface matches that upslope of the footwall, which
135 indicates a contiguous hillslope prior to formation of the present scarp and that sediment

136 accumulation at the scarp base is generally minor. However, wedges of sediment are locally
137 present on the hanging wall and in some places are welded to the scarp face, in positions now
138 perched above the hanging wall (Fig. S1). These wedges may have been perched by
139 earthquake-induced displacement on the Sparta fault or are debris deposits from mass
140 movements that have partly eroded. It is possible that other sediment wedges were also
141 formerly attached to the scarp face but have since fallen off.

142

143 Our sampling site is located at Anogia, where the Sparta fault scarp is 6.8 m high (Fig. 1c),
144 sparsely fractured, and displays a smooth surface texture (Fig. 1d-e). Slickenside traces are
145 visible, and the surface displays a black coating, like those commonly occurring on limestone
146 and which contain higher concentrations of SiO_2 and Al_2O_3 than the underlying rock
147 (Carcaillet et al., 2008). The scarp surface at Anogia also displays a spatially variable
148 distribution of subaerial weathering features such as rills and dissolution pits, which we
149 avoided in our sampling. The lower-angle hillslopes on both the foot wall (above the fault
150 scarp) and hanging wall display a patchy distribution of frequent bedrock outcrops and an
151 indurated allochthonous regolith composed of limestone clasts, with a matrix of red aeolian
152 dust and calcite cement. An outcrop of limestone about 50 m upslope of the fault scarp
153 reveals folded and tilted bedding. The bedding nearest to the scarp has a dip of $45\text{--}60^\circ$ and a
154 strike of $268\text{--}279^\circ$, which corresponds with those for the fault scarp, indicating that faulting
155 appears to exploit these structural weaknesses in the bedrock.

156

157

158 **3 Methods**

159

160 To study the paleoseismicity of the Sparta fault, we combined Accelerated Mass
161 Spectrometry (AMS) measurements of cosmogenic ^{36}Cl concentrations from samples
162 collected from the Sparta fault scarp with field and laboratory analyses of scarp composition
163 and mineralogy, and with field measurements of hanging wall soil composition and pH. We
164 made these measurements by sampling a vertical ^{36}Cl profile at Anogia, upwards from the
165 ground surface and adjacent to the sampling transect of Benedetti et al. (2002) for direct
166 comparison with that pre-existing record (Fig. 1c). We also took samples for ^{36}Cl and
167 mineralogical analyses, including REY, from a second vertical profile located about 50 m to
168 the south (Fig. 1c). We chose this additional site for its smooth, non-fractured, fault scarp
169 surface, and sampling was completed from the top of the scarp to 80 cm below the present
170 ground surface, following hand excavation of a pit.

171

172 3.1 ^{36}Cl concentrations

173 We sampled the first profile, adjacent to the southern margin of the Benedetti et al. (2002)
174 profile, for ^{36}Cl by using an angle grinder to cut $10*20*2.5$ cm ($h*w*d$) slabs from the
175 ground surface to a height of 3.9 m (Fig. 1c, d). Because of a crack in the fault scarp at 1.1 m
176 above the ground, the transect was shifted sideways (towards the north) by 40 cm, thus
177 duplicating the measurement at 1.1 m. A total of 37 samples from this profile were measured
178 for ^{36}Cl concentration. We sampled the second profile, ~ 50 m further to the south, for ^{36}Cl
179 and mineralogical analyses initially by drilling 14 cores of 4 cm diameter to a depth of 3 cm
180 into the scarp surface (Fig. 1c, e). Four of these cores were spaced at 20 cm intervals below
181 the ground surface and eight were spaced at 80 cm intervals above the ground surface to a
182 height of 6.4 m, which is 0.4 m below the top of the scarp. These samples were augmented by
183 another two drill core samples at 1.2 m and at 6.0 m. Subsequently, we took 20 samples from
184 this profile using an angle grinder to cut $10*20*2.5$ cm ($h*w*d$) slabs from the ground

185 surface to a height of 2.0 m (Fig. 1c). A total of 71 samples from the three profiles were
186 subjected to preparation chemistry for ^{36}Cl targets and measured using AMS.
187
188 For ^{36}Cl measurements, limestone samples were crushed to approximately 0.5 mm diameter
189 and the whole sample was used without removing any size fraction through sieving. Prior to
190 partial dissolution approximately 120 g of crushed material was washed with deionized water
191 to remove fines. Following Stone et al. (1996), meteoric ^{36}Cl was removed using two cycles
192 of partial dissolution with nitric acid to dissolve 5% (by mass) of the carbonate each time. To
193 prepare the AMS target we used 30 g of dried sample, spiked with 1 mg of ^{35}Cl -enriched
194 sodium chloride carrier (Source: Icon Isotopes, ^{35}Cl 99.635 atom %, $^{35}\text{Cl}/^{37}\text{Cl} = 273$) to
195 measure native chloride by isotope dilution. A slurry of the sample and 120 g of deionized
196 water was slowly dissolved with 60 g of concentrated trace-metal grade nitric acid. Post-
197 dissolution, both liquid and undissolved solids were quantitatively transferred to a centrifuge
198 bottle where the solids were removed by centrifugation. The supernatant was decanted to
199 another centrifuge bottle and chloride was precipitated using one molar silver nitrate. After a
200 settling period, the bottle was centrifuged to isolate the silver chloride which was then
201 washed, dissolved with ammonium hydroxide, and treated with barium nitrate to remove
202 sulfate in preparation for further purification by chromatography. The solution was loaded
203 onto 5 ml of Bio-Rad AG 1-X8 strong anion-exchange resin and chloride was moved through
204 with 0.50 mmol, and then 0.150 mmol, nitric acid. After re-precipitation with silver nitrate
205 and a washing step the silver chloride was dried and packed into silver bromide-cored copper
206 holders. AMS measurements were performed at the Purdue Rare Isotope Measurement
207 Laboratory according to procedures in Muzikar et al. (2003); standards used for the
208 measurement are described in Sharma et al. (1990).
209

210 We applied a model developed by Schlagenhauf et al. (2010) for the interpretation of
211 earthquakes from cosmogenic ^{36}Cl concentrations to the Sparta fault scarp. This model
212 accounts for various parameters that control the ^{36}Cl concentration in a limestone normal
213 fault scarp, including geomagnetic field variations, host rock and hanging wall colluvium
214 chemical compositions and densities, scarp erosion rate, shielding of the scarp base by a
215 colluvial wedge, and the geometries of the fault scarp, the slope above the scarp, and the
216 hanging wall colluvial wedge. Their model uses three statistical parameters, the weighted root
217 mean square (RMSw), the reduced Chi-square (χ_{red}^2), and Akaike Information Criterion
218 (AIC) to assess the quality of fit between modelled and measured data to provide an objective
219 assessment of the number, and spatial and temporal spacing, of inferred earthquakes. For our
220 age calculations, we used the sea-level high-latitude (SLHL) ^{36}Cl production rate from
221 spallation in calcite of $59.4 \text{ atoms g}^{-1} \text{ yr}^{-1}$ and a temporally variable geomagnetic field to scale
222 the ^{36}Cl production rate from Lifton et al. (2005). A more recent ^{36}Cl production rate
223 calibration by Marrero et al. (2016) is not used here because it is scaled using Lifton et al.
224 (2014), which is not included in the model of Schlagenhauf et al. (2010). The Marrero et al.
225 (2016) production rate overlaps with the ^{36}Cl production rate from Lifton et al. (2005), within
226 uncertainty. We complemented the modelling of our new ^{36}Cl results with a re-modelling of
227 the Benedetti et al. (2002) data, using our own data for fault scarp and colluvium
228 composition. Our method of inferring earthquakes was based on fitting ^{36}Cl concentration
229 profiles derived from the Schlagenhauf et al. (2010) model to the actual ^{36}Cl concentration
230 profiles and inferring former soils surfaces from inflection points in the real ^{36}Cl
231 concentration profiles. This allows us to best constrain the paleoseismic history of the Sparta
232 fault over the late Holocene.

233

234 3.2 Sparta fault scarp composition

235 Fault scarp chemical composition and mineralogy were analyzed from the second sampling
236 profile, 50 m to the south of the first sampling profile, as follows. An initial elemental
237 analysis was done in the field on the Sparta fault scarp surface using an Olympus Innov-X
238 Delta (40 kV) handheld X-ray fluorescence (XRF) device. This instrument performs
239 elemental analyses with a circular sample spot of 8 mm diameter and can measure elements
240 heavier than Na. All elements lighter than Mg are reported as lighter elements (LE). Of the
241 elements that compose REY, it was only capable of measuring yttrium. Sampling was done at
242 an interval of 5 cm (or less) over a 7.7 m vertical profile, beginning ~90 cm below the
243 hanging wall soil surface. This profile corresponds with the location of the drill core and 2.0
244 m-long ³⁶Cl profiles but was measured before either drilling or slab sampling (Fig. 1c).

245

246 For more detailed analyses of elements, including REY, a total of 39 cores (22 mm and 35
247 mm diameters and to depths of ~4 cm) were collected every 20 cm from the fault scarp
248 vertical transect using a portable drill (Fig. 1d). The outermost 1 mm was removed from each
249 core prior to crushing to avoid contamination from the black surface coating. The next 15 mm
250 of each core were then rinsed with cold water, air dried, and crushed using a grinder with a
251 steel mortar to a grain size of <100 µm. This crushing technique might supply additional
252 REY to samples (Hickson and Juras, 1986) but if so, this likely occurs systematically across
253 samples and we are more interested in spatial trends, which we confirm independently using
254 the handheld XRF, than absolute abundances. The crushed samples were then analyzed for
255 major and trace elements using fusion inductively coupled plasma mass spectrometry (FUS-
256 ICP-MS) at Activation Laboratories (Ontario, Canada).

257

258 We complemented the FUS-ICP-MS analyses with spot elemental analysis of one rock core
259 from 1.1 m above the scarp base to make a high-resolution determination of any spatial

260 variations in the scarp composition. This was done with an energy-dispersive X-ray
261 spectroscope (EDS) attached to an environmental scanning electron microscope (ESEM). We
262 used a Quanta FEG 650 with Oxford-Inka EDS, and the analysis was made in a high-vacuum
263 environment at 20 kV. The technique is incapable of detecting REY because their
264 concentrations are too low. Photomicrographs and backscatter images of pore spaces were
265 also taken using the ESEM. These analyses were completed at the Department of Geological
266 Sciences, Stockholm University.

267

268 **3.3 Sparta fault scarp mineralogy**

269 A modal analysis of mineral fractions was completed on thin sections taken from the
270 remaining 38 core samples. This was done by counting 1000 points on each thin section
271 (Hutchison, 1974) using a Pelcon automatic point counter, attached to a Leica (DM LSP)
272 optical microscope. This point counter comprises a stepping frame attached to a control box
273 (power supply) and is also connected to a computer for statistical analyses using Pelcon
274 software version 2. The point counting and mineral identification was made using an
275 objective working distance of 1.52 mm. The line section pre-set step-length was 0.3 mm and
276 the line section distance was 1.5–2 mm. The point counting permitted a detailed quantitative
277 analysis of the mineralogy of the Sparta fault scarp surface. This detailed mineralogy was
278 then compared with the chemical composition data to determine whether phases other than
279 the host limestone are present.

280

281 **3.4 Hanging wall soil chemistry and pH**

282 Soil chemistry and pH were measured in samples taken at ~10 cm intervals to a depth of ~90
283 cm in the pit excavated at the base of the Sparta fault scarp (Fig. 1c). The elemental analysis
284 was again done with the handheld XRF device. Indicator strips were used to measure pH

285 from mixtures of 1:1 mass ratio of soil:distilled water, and soil:1 M KCl (Sikora and Moore,
286 2014). These analyses help determine the vertical distribution of REY in the soil (using
287 yttrium as a proxy) and indicate how they might correlate with pH and the vertical
288 distribution of REY in the fault scarp below the soil surface.

289

290 **4 Results**

291

292 **4.1 Sparta fault ^{36}Cl concentrations**

293 The cosmogenic nuclide ^{36}Cl concentrations from our three profiles (Table S1) and the
294 original Benedetti et al. (2002) ^{36}Cl concentrations are compared in Figure 2. The lowest ^{36}Cl
295 concentrations occur in **our drill-core samples**. Whereas age reversals are non-apparent in this
296 profile, comprised of widely dispersed sample points, there is a clear decrease in ^{36}Cl with
297 depth, including below the soil surface. Our 2.0 m- and 3.9 m-long profiles display
298 corresponding trends with increasing concentrations with increasing height on the fault scarp.
299 Only at 1.6 m do the trends strongly deviate from each other. The 2.0 m-long profile indicates
300 generally lower ^{36}Cl concentrations including six of 19 points that do not overlap within
301 uncertainty of data points at corresponding elevations on the 3.9 m-long profile. Four of those
302 points are located from 1.0 m to 1.3 m. In comparison with our 3.9 m-long profile, the
303 adjacent segment of the Benedetti et al. (2002) profile shows ^{36}Cl concentrations that are on
304 average 19% higher (0-4 m). Uncertainties (1σ) for data points comprising each profile are
305 almost identical, displaying a mean of 3.8% for the Benedetti et al. (2002) profile versus
306 3.9% for our 3.9 m-long and 2.0 m-long profiles. However, the Benedetti et al. (2002) profile
307 displays more variation between adjacent sample points than is evident in our profiles.

308 **Whereas concentrations differ between the three longest profiles**, they show a consistent

309 gradient up to ~4 m on the scarp face equivalent to an average uplift rate of 1.0–1.3 mm yr⁻¹.

310 Above 4 m on the scarp, both our drill-core profile and the Benedetti et al. (2002) profile
311 display matching lower gradients, which indicates a lower average uplift rate of 0.6–0.9 mm
312 yr⁻¹. If uplift rates are alternatively calculated as occurring prior to the subaerial exposure of
313 the lowermost samples by the most recent earthquake, cumulative uplift rates increase to 2.8
314 mm yr⁻¹ and 1.8 mm yr⁻¹ for the lower parts of the 3.9 m-long and Benedetti et al. (2002)
315 profiles, respectively. Both our 2.0 m-long and 3.9 m-long profiles indicate a local low in
316 ³⁶Cl concentration at ~0.5 m above the ground surface, which is opposite to the Benedetti et
317 al. (2002) profile, where concentrations reach a local high at ~0.5 m. Both of our profiles also
318 display an age reversal at 1.4–1.6 m, which is comparable to the age reversal at 1.2–1.5 m on
319 the Benedetti et al. (2002) profile. Our 3.9 m-long profile and the Benedetti et al. (2002)
320 profile each display additional age reversals at 2.6–2.7 m and 3.1–3.2 m on the scarp.
321 Another reversal is also apparent at 3.7–3.9 m in both profiles (including the drill-core
322 sample at 4 m). These reversals complement the gradients in being similarities shared by the
323 profiles that are key characteristics for a further analysis of its paleoseismicity using the
324 model of Schlagenhauf et al. (2010).

325

326 Using the Schlagenhauf et al. (2010) model, we analyze the number, ages, and magnitudes of
327 earthquakes inferred from a composite ³⁶Cl concentration profile; principally this record
328 contains the 3.9 m profile, but also includes the subsurface samples from our drill-core
329 profile, and the drill-core samples from 4.1 to 6.4 m (Fig. 3a). The total length of this record
330 then becomes 7.2 m. To match these two data sets, we increase the concentration of each drill
331 core sample by 5%. Integrating these two data sets is necessary to generating fits to the ³⁶Cl
332 data because subsurface data are required by the Schlagenhauf et al. (2010) model. The 5% is
333 chosen to match the ³⁶Cl concentrations in the four drill core samples between 0.8 m and 2.4
334 m with those in the corresponding segments of the 2.0 m and 3.9 m profiles, while

335 maintaining subsurface ^{36}Cl concentrations below those in the samples at 0.1 m on the 2.0 m
336 and 3.9 m profiles. Then, using the same parameters that generated the best model fit to the
337 3.9 m-long plus drill-core profile (Table 1), we apply the best model fit to our 2.0 m-long
338 profile (Fig. 3b) and the Benedetti et al. (2002) profile (Fig. 3c). In both cases, we use the
339 adjusted subsurface data from the drill-core profile. For our 2.0 m plus subsurface drill core
340 profile, we used the scarp mineralogy measured for each sample. For the 3.9 m-long plus drill
341 core profile and the Benedetti et al. (2002) plus subsurface drill core profile **we used a mean**
342 **composition from our measured scarp mineralogy** because we did not determine mineralogies
343 along these profiles. We further compare earthquakes modelled from age reversals in the ^{36}Cl
344 data with earthquakes modelled from potential soil profiles mirrored in scarp geochemistry
345 (REY, SiO_2 and Al_2O_3 ; Fig. 3d). We then use all data to infer the most likely earthquake
346 history for this segment of the Sparta fault.

347

348 From the combined 7.2 m-long profile, modelling indicates that five earthquakes at 1.4 m
349 (2.3 kyr B.P.), 2.6 m (2.8 kyr B.P.), 3.9 m (3.2 kyr B.P.), 5.1 m (3.8 kyr B.P.), and 6.5 m (5.9
350 kyr B.P.) provide the best statistical fit to our data (Fig. 3a; Table 1). Our best fit parameters,
351 taken either directly from field measurement or assumed (in the case of ϵ and pre-exposure),
352 are listed in Table 1. The two inferred earthquakes at 1.4 m (2.3 kyr B.P.) and 2.6 m (2.8 kyr
353 B.P.) also provide a good statistical fit to our 2.0 m-long profile (Fig. 3b). An inferred five
354 earthquakes on the Benedetti et al. (2002) profile (Fig. 3c) at the same elevations on the scarp
355 as our adjacent composite profile (Fig. 3a) display a statistically weaker fit than obtained for
356 our data (Table 1). Older ages and longer exposure prior to the oldest earthquake (pre-
357 exposure) are necessitated by the systematically higher ^{36}Cl concentrations. Earthquakes
358 inferred from the record of scarp geochemistry (Section 4.3) occur at 0.8 m (1.9 kyr B.P.), 2.6
359 m (2.8 kyr B.P.), 4.0 m (3.0 kyr B.P.), and at 6.4 m (5.9 kyr B.P.) on our 7.2 m-long profile

360 (Fig. 3d). Interestingly, this reconstruction has a statistically weaker fit than for earthquakes
361 inferred from reversals in ^{36}Cl concentrations (Fig. 3a; Table 1). We note that for the
362 applicable ^{36}Cl concentration profiles, model fits overestimate ^{36}Cl concentrations at 4 m on
363 the scarp surface (Figs. 3a, c, and d). In Figure 3a, c, and d, an (artificial) earthquake is added
364 to the top of the ^{36}Cl concentration profile to fit all data (Earthquake 1, shown in grey).
365 Because this oldest earthquake is tied to the highest sample on the scarp, without an
366 associated age reversal, and because ^{36}Cl measurements are sparsely spaced above 4 m, the
367 inferred locations on the fault scarp and timing of this earthquake are approximate. We
368 therefore focus our interpretations on the inferred earthquakes lower down on the fault scarp.
369

370 The model fit to our data is sensitive to input parameters, at least two of which are difficult to
371 accurately measure (Fig. 4). It is most sensitive to the scarp dip angle (e.g., a 5° decrease
372 causes the AICc to increase by 12%), followed by the density of colluvium mantling the
373 hanging wall and the rate of scarp surface erosion. It is least sensitive to variations in rock
374 density and hillslope gradient. The colluvium density depends on relative abundances of
375 limestone clasts, mineral soil, organic matter, and water, which vary spatially. Due to, for
376 example, wetting and drying, colluvium density is expected to also vary temporally. Scarp
377 erosion rates remain undetermined. The adopted values for colluvium density and scarp
378 erosion rate are, therefore, those which provide the best model fits to the data. In both cases,
379 those values are also realistic (Table 1). Rock density is prescribed from the literature and
380 colluvium dip, scarp dip, and hillslope gradient are based on measurements. Optimal
381 colluvium and scarp dips are adjusted slightly relative to measured values (i.e., $1\text{--}2^\circ$, which is
382 within measurement uncertainty).

383

384 **4.2 Granulometry of the Sparta fault scarp surface**

385 A first look at the Sparta fault scarp surface yields a misleading impression of homogeneous
386 limestone (Figs. 1, 5a), whereas close inspection of the core samples instead reveals a typical
387 fault breccia (Figs. 5b-d). This breccia consists of angular-to-rounded limestone clasts with
388 axes of 1–7 mm (in the two-dimensional view provided by thin sections) surrounded by
389 matrix/cement in which clasts are <0.1 mm in length. The fault breccia is defined as a
390 protocataclasite, according to the classification of Woodcock and Mort (2008). The
391 composition of the protocataclasite displays large spatial variations, with some portions
392 containing abundant clasts (Fig. 5c), whereas others are dominated by fine matrix (Fig. 5d).
393 The proportion of clasts >2 mm ranges from 5% to 20% vertically along the fault scarp and
394 the proportion of matrix ranges from 5% to 60%. We did not measure the thickness of the
395 protocataclasite but it everywhere exceeds the 4 cm depth of our drill cores.

396

397 **4.3 Sparta fault scarp composition and mineralogy**

398 In addition to a spatially variable granulometry, the fault scarp shows a spatially variable
399 distribution of major and trace elements. The major component is, as expected for limestone,
400 CaO (mean 52.22%) but its concentration varies between 43.83% and 56.64% (Table S2),
401 which exceeds spatial variations in CaO seen elsewhere in limestone normal fault scarps
402 (Carcaillet et al., 2008; Tesson et al., 2016). Quartz (SiO₂) also occurs, and it too displays
403 spatial variations (0.10%–20.82%), with broad peaks occurring at -0.5– -0.4 m, 0.9–1.2 m,
404 4.6–4.8 m, and 6.0–6.2 m along the vertical fault scarp profile (Fig. 6; Table S2). An
405 additional peak in SiO₂, but which is not seen in point counting of quartz, occurs at 6.2 m
406 (Fig. 6; Tables S2 and S3). Mean concentrations of other major elements are low in bulk
407 samples, including Al₂O₃ (0.21%), MgO (0.16%), Fe₂O₃ (0.09%), P₂O₅ (0.07%), and K₂O
408 (0.05%; Table S2). However, EDS measurements, such as shown in Figure 7a, reveal that the
409 concentrations of some elements are frequently much higher in intergranular pores (Fig. 7c)

410 than elsewhere in the fault scarp, including $\text{Si} \leq 38.3\%$, $\text{Al} \leq 11.7\%$, $\text{Fe} \leq 48.4\%$, and $\text{K} \leq$
411 7.1% (Table S4). Furthermore, intergranular pores and quartz frequently occur together (Fig.
412 7b) and the concentration of Al_2O_3 covaries with the much more abundant quartz (SiO_2) (Fig.
413 6).

414

415 Quartz is revealed by microscopy to be present as randomly oriented rounded-to-angular
416 grains that are $<50 \mu\text{m}$ in diameter (Figs. 5d, 7b). Quartz is a constituent of the
417 protocataclastic fine matrix that is mostly comprised of microcrystalline calcite precipitates
418 and which cements larger host rock-derived CaCO_3 clasts (Figs. 5b-d, 7b, 8a). Point counting
419 further reveals quartz modes ranging from 0.1% to 15.4% of thin section area (Table S3),
420 with higher abundances correlating to higher abundances of fine matrix. The spatial
421 correlations between SiO_2 , quartz abundances on point counting, and fine matrix are further
422 indicated by the EDS spot elemental analysis (Fig. 8). Here, the two selected spots in the fine
423 matrix display Si abundances of 29.7% and 28.9%, which contrasts with 1.7% and 0.9% for
424 the two spots located on clasts. CaO abundances display an inverse relationship with SiO_2
425 (33.7% and 31.2% for the clasts versus 4.8% and 5.1% for the fine matrix). SiO_2 is present
426 largely as quartz, as evidenced by the strong spatial correlation between quartz and SiO_2
427 along the vertical profile (Fig. 6). Quartz can therefore be used as a proxy for fine matrix
428 abundances in the Sparta fault scarp.

429

430 In addition to the spatial relationship between quartz and fine matrix, we observed in
431 backscatter SEM images that pore spaces, which frequently harbor higher concentrations of
432 Si, Al, K and/or Fe than host rock-derived clasts, are also more abundant in the fine matrix
433 (Fig. 7c). These observations provide evidence that clay particles ($< \mu\text{m}$ -scale) frequently

434 coat pore spaces. The abundance of quartz therefore also provides a proxy for the abundance
435 of clay-coated pore spaces.

436

437 Concentrations of yttrium are generally low (1.2–11.1 ppm; Table S5) but vary in a wave-like
438 pattern along the vertical profile, with maxima occurring at -0.4 m, 0.8 m, 2.6 m, 4.0 m, and
439 6.4 m (Fig. 9). These maxima do not systematically decrease with vertical distance above the
440 hanging wall and are not highest in the soil-mantled portion of the scarp. Yttrium (mean 6.3
441 ppm), La (mean 5.04 ppm), Nd (mean 3.54 ppm), and Ce (mean 2.31 ppm) have the highest
442 concentrations, whereas all other REY are <1 ppm (Table S5). The concentrations of REY
443 elements co-vary vertically along the scarp surface ($R^2 = 0.95$; Fig. 9), the proportion of
444 light-REY (LREY) to heavy-REY (HREY) remains constant (ratio ~7:1; Fig. 10; Table S5),
445 and concentration maxima occur at locations that correspond closely with the Al_2O_3 maxima
446 (Fig. 9; Table S5). Accordingly, there is a strong correlation between REY and Al_2O_3 ($R^2 =$
447 0.92 ; Fig. S2a). Spatial correlations between REY and SiO_2 and K_2O are also observed ($R^2 =$
448 0.56 and 0.87 , respectively; Fig. S2c, e). In contrast, the locations of REY maxima correlate
449 neither with the location of the present ground surface (-0.4 m) nor former ground surfaces at
450 1.4 m and 5.1 m inferred from ^{36}Cl data. There are, however, correlations between REY
451 maxima and former ground surfaces at 2.6 m, 3.9–4.0 m, and at 6.4–6.5 m modelled from the
452 ^{36}Cl data. No systematic relationship is therefore apparent between REY maxima and either
453 the present soil surface or former soil surfaces inferred from inflection points in ^{36}Cl
454 concentrations.

455

456 **4.4 Hanging wall soil chemistry and pH**

457 The terra rosa soil mantling the hanging wall primarily comprises aeolian dust (Muhs et al.,
458 2010) and carbonate clasts. At our sample site, the soil thickness at the base of the Sparta

459 fault scarp is 0.8 m and this appears to be stable, at least over the timescale of scarp surface
460 dissolution, as evidenced by a much smoother scarp surface texture below the soil surface
461 compared with the subaerially exposed scarp. Below the organic horizon (~0.1 m thick) the
462 soil is welded, probably by calcite precipitates, and horizons are absent. Soil pH is, in
463 general, slightly acidic along the excavated vertical profile, remaining within a 6.2 to 7.0
464 range (Fig. 11a; Table S6). An outlier occurs at -0.30 m, where the pH is 5.6 ± 0.2 . Soil
465 composition varies with depth (Fig. 11b; Table S7). Concentrations of Si, Al, and K are lower
466 in the organic horizon (11%, 0–5%, and 0.4%, respectively) compared with the remainder of
467 the profile (18%–30%, 5–10%, and 0.5–0.9%, respectively), whereas the concentrations of
468 LE, which includes C, are, as expected, higher in the organic horizon (75%–80%) than in the
469 lower profile segment (51%–64%). The concentration of yttrium ranges from a maximum of
470 36–39 ppm at -0.5– -0.6 m depth to a minimum of 11 ppm at -0.1 m depth and its vertical
471 distribution correlates positively with Si ($R^2 = 0.71$), Al ($R^2 = 0.45$), and K ($R^2 = 0.54$), but
472 negatively with pH ($R^2 = -0.52$; Figs. 11c, S1b,d,f; Table S7).

473

474 **5 Discussion**

475

476 **5.1. Modelling of earthquakes from ^{36}Cl concentration profiles**

477 Our modelling using Schlagenhauf et al. (2010) indicates that five earthquakes provide a best
478 fit to the Sparta fault ^{36}Cl data. The youngest inferred earthquake (2.3 kyr B.P.) corresponds
479 both with the historical 464 B.C.E. event and inflections in the ^{36}Cl data of the 2.0 m-long
480 and 3.9 m-long profiles. The penultimate inferred earthquake at 2.8 kyr B.P. correlates to an
481 inflection in ^{36}Cl concentration at 2.6 m in our 3.9 m-long profile. Because data density
482 decreases above 4.0 m, there are no clear inflections in ^{36}Cl concentrations to base the
483 occurrence of earthquakes on for this segment of the scarp. However, fitting the

484 Schlagenhauf et al. (2010) model to the measured gradient in ^{36}Cl concentrations yields an
485 additional record of three older earthquakes at 3.2 kyr B.P., 3.8 kyr B.P., and 5.9 kyr B.P. to
486 explain the exhumation of the exposed scarp surface. The four most recent earthquakes are
487 clustered within a 1.5 kyr period, whereas nearly 2.5 kyr have elapsed since the last
488 earthquake on the Sparta fault. A lower gradient in ^{36}Cl concentration on the fault scarp
489 above the location of the inferred 3.2 kyr B.P. earthquake also indicates a lower rate of scarp
490 exhumation prior to the 1.5 kyr period of apparently higher earthquake activity. The long
491 recent quiescent interval therefore does not necessarily provide evidence that another (large
492 magnitude) earthquake may be imminent. As a comparison, extensional faults in the central
493 Italian Apennines accumulate meters of displacement over several thousands of years, but
494 also display similar length periods where cumulative slip magnitudes are much lower,
495 because earthquake activity shifts between faults across-strike (Cowie et al., 2017). The same
496 may also apply to the Sparta fault and related extensional faults in the region.

497

498 The precision at which we can interpret paleoseismicity is constrained by three factors. These
499 include (i) sparse ^{36}Cl data above 4.0 m on the Sparta fault scarp, (ii) uncertainties in scarp
500 erosion rate, pre-exposure length, and hanging wall surface dip angle and colluvium density
501 (Fig. 4), and (iii) fault scarp impurities that produce noise in the ^{36}Cl data and distortion of
502 potential REY indicators of former soil surfaces. Below, we will explore methodological and
503 geological sources of uncertainty in the ^{36}Cl data, reasons for mineralogical impurities in the
504 Sparta fault scarp, and how the observed REY distribution can be interpreted. This will be
505 achieved by comparing the 2.0 m-long profile with the equivalent segment of the 3.9 m-long
506 profile because both profiles have been sampled, processed, and analyzed in the same manner
507 and at the same time, and therefore provide a measure of repeatability.

508

509 **5.2 Methodological and geological sources of uncertainty in the ^{36}Cl data**

510 A peculiar feature of the ^{36}Cl data is that the profile comprised of small drill-core samples
511 generally yields younger exposure ages for the Sparta fault scarp than the 2.0 m- and 3.9 m-
512 long profiles, which, in turn, are systematically younger than the Benedetti et al. (2002)
513 profile (Fig. 2). The Benedetti et al. (2002) profile displays variations between adjacent
514 sample points that exceed those observed in our profiles and rival variations in ^{36}Cl
515 concentrations that may be attributable to earthquakes. We interpret the systematic
516 differences in ^{36}Cl concentration between the drill-core profile, the 2.0 m and 3.9 m profiles,
517 and the Benedetti et al. (2002) profile as reflecting methodological differences related to
518 advances in sample preparation chemistry at PRIME-Lab, Purdue University. Similarly, the
519 reason why we can directly infer the 464 B.C.E earthquake at Anogia, in contrast to Benedetti
520 et al. (2002), is attributable to advances in age calculations from ^{36}Cl concentrations.

521

522 Whereas our 2.0 m- and 3.9 m-long profiles display corresponding trends with increasing
523 elevation on the fault scarp, the 2.0 m profile has generally lower ^{36}Cl concentrations (Fig. 2).
524 Indeed, six of its 19 ^{36}Cl concentrations do not overlap within uncertainty with concentrations
525 of corresponding samples on the 3.9 m profile, including four points located between 1.0 m
526 and 1.3 m. We interpret these differences as indicating that the fault scarp of the 2.0 m profile
527 has been either partly shielded from cosmogenic radiation, has eroded more than the surface
528 of the 3.9 m profile, or contains a higher concentration of impurities. Of potential additional
529 relevance is that the texture of the scarp surface at the location of the 2.0 m profile is
530 smoother than at the location of the 3.9 m profile. Because a similarly smooth texture also
531 characterizes the scarp surface presently buried by colluvium mantling the hanging wall, the
532 smooth texture at the location of the 2.0 m profile may indicate either recent burial of the
533 scarp surface by colluvium and/or CaCO_3 dissolution occurring at a higher rate than at

534 locations where the exposed scarp surface texture is rougher. If a smooth texture reflects
535 erosion through CaCO_3 dissolution, there might be preferential flow, or seepage, of water
536 from the hillslope above the scarp at the location of the 2.0 m profile. Observed lumps of
537 colluvium cemented to the Sparta fault scarp, at locations perched above the present hanging
538 wall surface (Fig. S1) partially shield the underlying scarp surface. However, had this
539 previously occurred at the location of our 2.0 m profile, an eroded colluvial lump would be
540 evidenced in the hanging wall sediments. On the contrary, there is no colluvial lump, but
541 rather a sub-horizontal surface is present with an expression that differs little from the surface
542 below the 3.9 m profile. The inter-profile differences in ^{36}Cl concentrations illustrate the
543 value in taking samples for ^{36}Cl measurements from more than one vertical profile, because
544 evidence of past shielding by sediments or bedrock can otherwise be difficult, at best, to
545 detect. Partial shielding may impact the interpretation of the number of paleoearthquakes and
546 result in lower age estimates of earthquakes, with a corresponding decrease in recurrence
547 intervals.

548

549 **5.3. The effects of mineralogical impurities on ^{36}Cl concentration profiles**

550 Mineralogical impurities embedded in the fault breccia that comprises the scarp surface
551 appear to be a key geological reason for spatial variations in the concentration of ^{36}Cl . This
552 effect is best evidenced when comparing modelled ^{36}Cl concentrations for the 2.0 m-long
553 profile (Fig. 3b), including measured mineralogy for each sample location, with modelled
554 ^{36}Cl concentrations for the 3.9 m-long and Benedetti et al. (2002) profiles, including mean
555 values of the scarp composition derived from our measured data (Fig. 3a, c, d). Whereas the
556 latter modelled profiles appear smooth, the modelled 2.0 m profile contains inter-sample
557 noise, which reflects variations in calcite abundance, attributable to the additional, and
558 variable, presence of quartz and other minerals, including trace amounts of clay lining pores

559 (Figs. 5–9). Because ^{36}Cl is also produced by spallation on K (162 ± 24 atoms $\text{g}^{-1} \text{yr}^{-1}$ at
560 SLHL; Evans et al., 1997), Fe (1.9 ± 0.2 atoms $\text{g}^{-1} \text{yr}^{-1}$ at SLHL; Stone, 2005), and Ti (13 ± 3
561 atoms $\text{g}^{-1} \text{yr}^{-1}$ at SLHL; Fink et al., 2000), noise in the ^{36}Cl data might also partly reflect the
562 relative abundances of these elements. However, for the case of the Sparta fault, this appears
563 to be insignificant given that measured concentrations of these elements are extremely low
564 (concentrations of K_2O , Fe_2O_3 , and TiO_2 are 0–0.12%, 0.03–0.24%, and 0–0.02%,
565 respectively; Fig. S3, Table S2).

566

567 Mineralogical impurities may also explain two other enigmatic features in the ^{36}Cl data.

568 Firstly, an apparent age reversal occurs at 3.1 m in the 3.9 m-long profile (Fig. 3a). Although
569 this could indicate the location of a former soil horizon and thus inferred displacement by an
570 earthquake, a better model fit is gained by locating an earthquake higher up the scarp at 3.9
571 m. Secondly, ^{36}Cl concentrations at ~4 m in the 3.9 m profile and the Benedetti et al. (2002)
572 data (3.8–4.1 m, Fig. 3a; 3.7–4.3 m, Fig. 3c) are too low to overlap within uncertainty with
573 concentrations modeled using Schlagenhauf et al. (2010). A possible explanation for both
574 enigmatic features is an inability to fully capture the effects of mineralogical impurities on
575 ^{36}Cl production rates. This is largely because, in the absence of mineralogical data for these
576 profiles, we have calculated a mean composition based on the mineralogical data for the 2.0
577 m profile to model ^{36}Cl concentrations. However, even with the mineralogical data, current
578 laboratory techniques for preparing samples for ^{36}Cl measurement may not record
579 mineralogical variations at sufficient precision. In addition to highlighting the importance of
580 mineralogical analyses, we also highlight the value of using a model to identify the likely
581 displacements by paleoearthquakes through fitting model ^{36}Cl concentration profiles to real
582 ones, rather than overtly relying on apparent age reversals. It remains possible that two

583 earthquakes occurred in close succession, but with this data and methodology, we cannot

584 confidently infer both of those.

585

586 **5.4. Estimated magnitude of the 464 B.C.E. earthquake**

587 The 464 B.C.E. earthquake that destroyed Sparta had an estimated moment (M_o) of $1 - 4$ (x

588 10^{19}) N m. This is derived from multiplying the vertical displacement of 1.4 m (Fig. 3a-c)

589 with fault dimensions of 20×14 km – 64×14 km, and with a shear modulus of 3.23×10^{10} N

590 m^{-2} (Armijo et al., 1991). The values of 20 km, 14 km, and the shear modulus are from

591 Armijo et al. (1991) and 64 km is the mapped length of the Sparta fault in Figure 1. This

592 estimated range of M_o values straddles a previous “most probable” estimate of moment by

593 Armijo et al. (1991) of 3×10^{19} N m even though they lacked field constraints on fault slip

594 distance during the Sparta Earthquake. Hence, we conclude from this congruence of the

595 probable value with values based on the vertical displacement modelled from the ^{36}Cl data

596 (Fig. 3), that they are reliable. From the empirically derived equations of Pavlides and Caputo

597 (2004) and a vertical displacement of 1.4 m of the Sparta fault, we calculate a magnitude (M_s)

598 of 6.8-7.2 for the 464 B.C.E. earthquake. Given the severe destruction inflicted upon the

599 Spartan society (REF?), we consider that the upper estimate is most likely. A magnitude 7.2

600 earthquake is also in agreement with the estimate by Armijo et al. (1991), although they

601 based this on ~10 m of vertical displacement. We are less certain of the magnitudes and

602 timing of older earthquakes. However, it appears that the Sparta fault was exhumed by a

603 series of similarly large earthquakes over a period of about 3.5 kyr.

604

605 **5.4. Interpretation of REY distributions**

606 REY cannot be used to infer imprints of former soil profiles on the Sparta fault at Anogia.

607 Petrographic analyses indicate that the Sparta fault scarp is composed of a protocataclasite

608 consisting of calcite clasts derived from the host limestone, microcrystalline calcite cement,
609 and quartz (Figs. 5, 6). Furthermore, EDS analysis indicates that trace amounts of clay, such
610 as illite, are lining pores where microcrystalline calcite cement and quartz are located (Fig. 7;
611 Carcaillet et al., 2008). Given the correlations between REY and each of Al, K, and Si ($R^2 =$
612 0.92, 0.87, and 0.56, respectively; Fig. S2a-c), we infer that the clays embedded in the fault
613 scarp are hosting REY. This is a likely explanation for why REY peaks 0.4 m below the
614 current soil surface (Fig. 9), rather than at the soil surface as has been observed on the
615 Magnola fault in Italy (Manighetti et al., 2010).

616

617 The formation of protocataclasite occurs beneath the Earth's surface at depths that may range
618 from meters to up to thousands of meters. A model for this involves fluids moving along the
619 Sparta fault, primarily associated with seismic events. These fluids dissolve CaCO_3 from the
620 host-limestones and potentially also silicate minerals from psammitic and pelitic
621 (meta)sediments, where they are dissected by the fault. In association with variations in
622 temperature and pressure along the fault, chemical saturation of these fluids results in
623 precipitation of clay, quartz, and microcrystalline calcite, which cements clasts of host-rock
624 derived limestone into the fault breccia. Subsequent faulting re-fractures the breccia and
625 particle comminution over time produces quartz grains that are rounded-to-angular in shape,
626 randomly oriented, and $<50 \mu\text{m}$ (Figs. 5, 7). The fault breccia may also have undergone
627 multiple generations of microcrystalline calcite re-cementing from re-circulating fluids. As an
628 alternative to a dissolution-precipitation model, clay and quartz emplacement may involve
629 fluid entrainment of particles and grains from clay- and quartz-bearing sedimentary units
630 during faulting, as has been observed elsewhere (e.g., Darwin, 1840; Roy, 1946; Brandon,
631 1972; Röshoff and Cosgrove, 2002). This process may also be accompanied by comminution
632 of fault-zone quartz grains derived from psammitic rocks. We tentatively exclude a

633 contemporary aeolian source for the clay and quartz because there is no documented
634 mechanism to transport clay particles and quartz grains from the soil to centimeters into a
635 fault scarp. We cannot distinguish soil to scarp clay and quartz migrations on the Sparta fault
636 which has been observed, for example, at the micrometer scale in surface coatings on the
637 Magnola fault, because that scarp is comprised of pure carbonate (Carcaillet et al., 2008). It is
638 likely that limestone fault scarps are generally composed of fault breccias (Agosta and Aydin,
639 2006; Carcaillet et al., 2008; Nuriel et al., 2012) and that where a fault intersects varying
640 lithologies, chemical and mineralogical heterogeneities may occur in the fault breccia, as
641 observed on the Sparta fault. Where they occur, these heterogeneities may control the spatial
642 distribution of REY, independent of any spatial reorganization of REY attributable to
643 subaerial weathering.

644

645 REY correlates with inferred clay abundances on the Sparta fault scarp (Fig. 9), rather than
646 systematically with former soil profiles inferred from ^{36}Cl concentrations. A correlation of
647 REY with Si and Al is indeed observed in the soils mantling the Sparta ($R^2 = 0.71$ and 0.45 ,
648 respectively; Figs. 11c and S2b,c), Kaparelli ($R^2 = 0.95$ for Si; Figs. 1a and S4a), and
649 Magnola fault hanging walls ($R^2 = 0.98$ for both Si and Al; Fig. S4b,c and electronic
650 appendix to Manighetti et al., 2010). These correlations generally contrast with a weaker
651 negative correlation between Y and pH ($R^2 = 0.52$) for the hanging wall soil on the Sparta
652 Fault (Fig. 11c). We propose a causative relationship between the vertical distributions of
653 REY and clay on the Sparta fault scarp. The presence of clay likely relates to fault breccia
654 formation at considerable depths beneath the Earth's surface, rather than subaerial weathering
655 processes. This reasoning is supported by the following observations:

- 656 (i) The Sparta fault scarp REY concentrations are equivalent to (Nuriel et al., 2012;
657 Goodfellow et al., 2017) or higher than those measured elsewhere in platformal

658 limestone (Carcaillet et al., 2008; Mouslopoulou et al., 2011), but yttrium
659 concentrations are lower than in the adjacent hanging wall soil (rare-earth elements
660 were not measured; Tables S5, S7).

661 (ii) If REY exchange between the soil and fault scarp occurs according to the Carcaillet
662 et al. (2008) model, fractionation of LREY and HREY elements is expected. For
663 example, LREY might be preferentially mobilized (Takahashi et al., 2005;
664 Carcaillet et al., 2008), leading to an enrichment of LREY relative to HREY in the
665 fault scarp, where there are peaks in total REY. Conversely, LREY may be depleted
666 relative to HREY where there are troughs in total REY. However, the proportion of
667 LREY to HREY remains constant vertically along the Sparta fault scarp (Fig. 10).

668 (iii) There is no systematic decrease in total REY along the vertical scarp profile (Fig.
669 9), in contrast to declining concentrations with distance above the hanging wall on
670 the Magnola fault (Carcaillet et al., 2008).

671 Whereas these observations discount subaerial weathering as the dominant mechanism for
672 REY enrichment and depletion on the Sparta fault, there may be some weathering-induced
673 exchange. This is evidenced by the peak in REY on the buried Sparta fault scarp correlating
674 with the peak in soil acidity (Figs. 9, 11a, b), but which notably occurs in the subsurface,
675 rather than at the soil surface. If, as we infer, the spatial patterning of REY, quartz, and clay
676 (as indicated by Al) is inherited from depth, the observed wave-like signal (Figs. 6, 9) may
677 reflect sorting and cementing of breccia around surface asperities on the fault plane. The
678 resulting infilling of depressions with fault gouge may create a successively more polished
679 and localized fault plane along which friction is lowered, thereby permitting larger slip (i.e.,
680 larger earthquakes) along the fault (Sagy and Brodsky, 2009). Whereas REY concentrations
681 do not appear to be a reliable indicator of Holocene paleoseismicity along the Sparta fault,
682 they may instead reveal processes that localize slip to a discrete fault plane.

683

684 **6 Conclusion**

685

686 In applying cosmogenic ^{36}Cl exposure-age dating and rare-earth elements and yttrium (REY)
687 measurements to unravelling the paleoseismic history of the Sparta fault, Greece, we
688 conclude the following: Modeling of ^{36}Cl concentrations along two vertical profiles on the
689 Sparta Fault, closely adjacent to a ^{36}Cl concentration profile previously measured and
690 interpreted by Benedetti et al. (2002), indicates that the scarp was likely exhumed over 5
691 earthquakes, including one at $\sim 2.3 \pm 0.2$ kyr B.P., which correlates with the 464 B.C.E. event.
692 Four earthquakes were clustered within a 1.5 kyr period that culminated with the 464 B.C.E.
693 event. Cumulative uplift was as high as 2.8 mm yr^{-1} during that period, compared with ~ 0.6 –
694 0.9 mm a^{-1} over the preceding 2.7–4.4 kyr. Because earthquake activity may shift between
695 faults in extensional settings, a large magnitude earthquake is not necessarily indicated as
696 being overdue by the ~ 2.5 kyr that have elapsed since the 464 B.C.E. event. More generally,
697 accurate identification of individual earthquakes is presently constrained by spatial variations
698 in ^{36}Cl concentration profiles that reflect neither exposure duration nor imprints of former soil
699 profiles. In cases where this is attributable to mineralogical variations, such as in the Sparta
700 fault scarp, present chemical preparation techniques for AMS measurement of ^{36}Cl may
701 insufficiently account for those variations.

702

703 The Sparta fault scarp is impure; it is composed of fault breccia, which contains quartz and
704 clay-lined pores in addition to calcite. The vertical distribution of REY is highly correlated
705 with the pore-clay and may indicate processes of fault evolution deep below the ground
706 surface. The potential exchange of REY between the hanging wall colluvium and the adjacent
707 footwall scarp is overwhelmed at this site by REY attached to the pore clays inherited from

708 depth. Because of this, Holocene earthquakes and their slip distances and magnitudes cannot
709 be inferred for the Sparta fault from REY concentrations. This is probably true also for
710 similar impure limestone fault scarps elsewhere.

711 **Author contribution**

712 AS conceived the study and AS, APS, MWC, RF, and BWG participated in fieldwork. RF
713 conducted the analysis of scarp composition, made initial interpretations, and compiled an
714 initial manuscript as a part of research studies at Stockholm University. BWG made
715 additional analyses, including earthquake modelling, and led writing of this manuscript. GC
716 led the laboratory preparation of samples for ^{36}Cl measurement, in which BWG also
717 participated. GC calculated ^{36}Cl concentrations from the AMS data. All authors contributed
718 to data interpretation and manuscript editing.

719

879 **Table 1:** Parameters used to give best fits of modelled profiles to measured ³⁶Cl
 880 concentration profiles, following Schlagenhauf et al. (2010).

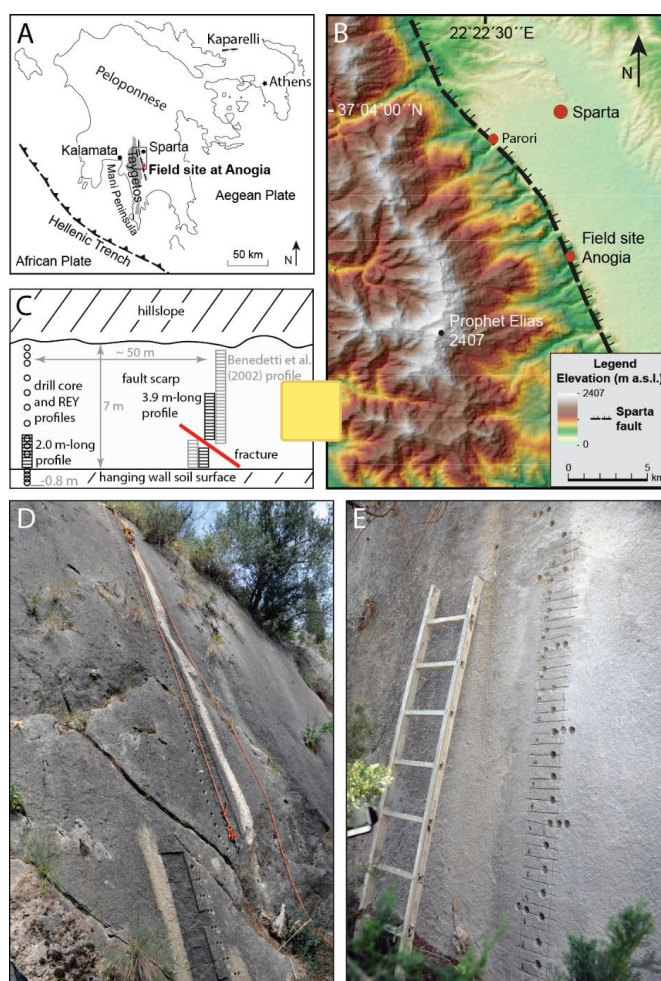

Profile	α (°)	β (°)	γ (°)	Scarp (cm)	ρ_{rock} (g cm ⁻³)	$\rho_{colluvium}$ (g cm ⁻³)	³⁶ Cl P ₀ (at. g ⁻¹ yr ⁻¹)	ϵ (mm yr ⁻¹)	Pre (yr)	Age (kyr B.P.)	Slip (cm)	RMSw	AICc	χ^2_{red}
Fig. 3a	42	61	20	730	2.65	1.95	59.4	0.02	10 300	5.98 ± 0.4, 3.8 ± 0.3, 3.2 ± 0.3, 2.8 ± 0.2, 2.3 ± 0.2	140, 120, 130, 120, 140	10	859	3
Fig. 3b	49	61	20	730	2.65	2.01	59.4	0.02	3 900	2.5 ± 0.2, 2.3 ± 0.2	60, 140	5	406	2
Fig. 3c	42	61	20	742	2.65	1.95	59.4	0.02	12 000	8.6 ± 0.6, 5.8 ± 0.4, 3.8 ± 0.3, 3.2 ± 0.3, 2.5 ± 0.3	140, 120, 130, 120, 140	19	1338	7
Fig. 3d	42	61	20	730	2.65	1.95	59.4	0.02	10 300	5.9 ± 0.4, 3.0 ± 0.3, 2.8 ± 0.2, 1.9 ± 0.2	240, 140, 180, 80	12	875	5

881 α is hanging wall colluvial surface dip angle; β is scarp dip angle; γ is the dip angle of the hillslope above the fault scarp; ϵ is
 882 scarp erosion rate; Pre is pre-exposure; Age is inferred earthquake age(s) with 0 inserted to model scarp samples from below
 883 the surface of the hanging wall colluvium; Slip is the inferred displacement for each earthquake. On each profile, the oldest age
 884 and associated displacement, shown in grey, are fitted to the top of the vertical sample transect rather than fitted to a step in
 885 ³⁶Cl concentration; RMSw is weighted root mean square; AICc is Akaike Information Criterion; χ^2_{red} is reduced Chi-square.
 886 Model best fits for each data set are shown in black. The ³⁶Cl production rate of 59.4 ± 4.3 at g⁻¹ yr⁻¹ is taken from Lifton et al.
 887 (2005).

 892 are shown. Box indicates location of panel B. B. The location of the Sparta fault, separating
 893 the Taygetos Mountains from the Sparta basin. The location of the Anogia field site used both
 894 in this study and in Benedetti et al. (2002) is shown. Benedetti et al. (2002) located a second
 895 sampling transect at Parori (also shown). The digital elevation model has a 24 m resolution
 896 and is derived from ASTER GDEM (GDEM2), which is a product of NASA and METI
 897 (Japan). C. Schematic diagram of the Sparta fault scarp at Anogia, showing the locations of
 898 our vertical ^{36}Cl and REY sampling transects, and the ^{36}Cl sampling transect of Benedetti et
 899 al. (2002). D. Photograph showing the location of our 3.9 m-long profile, prior to sampling.
 900 The existing sample scar is from Benedetti et al. (2002). E. Photograph showing the location
 901 of our REY and drill core profiles, after sampling, and our 2.0 m long profile, before
 902 sampling.

903

904

905 **Fig. 2:** Sparta fault ^{36}Cl concentration profiles. Error bars indicate 1σ measurement

906 uncertainties. Time-averaged uplift rates inferred from profile gradients are shown in grey.

907 For the lower, more recently exposed, parts of the scarp surface, uplift rates are calculated for

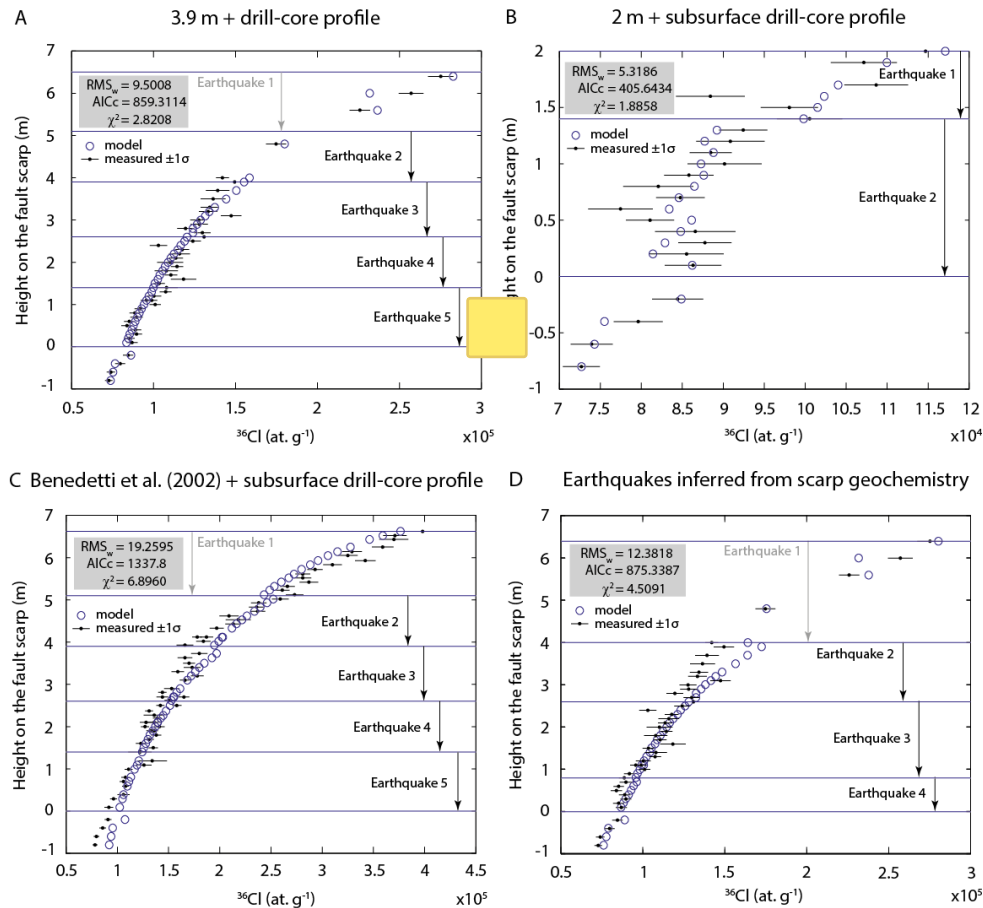

908 time starting from the present day. If uplift rates are alternatively calculated as occurring

909 prior to the subaerial exposure of the lowermost samples by the most recent earthquake,

910 cumulative uplift rates increase to 2.8 mm yr^{-1} and 1.8 mm yr^{-1} for the lower parts of the 3.9

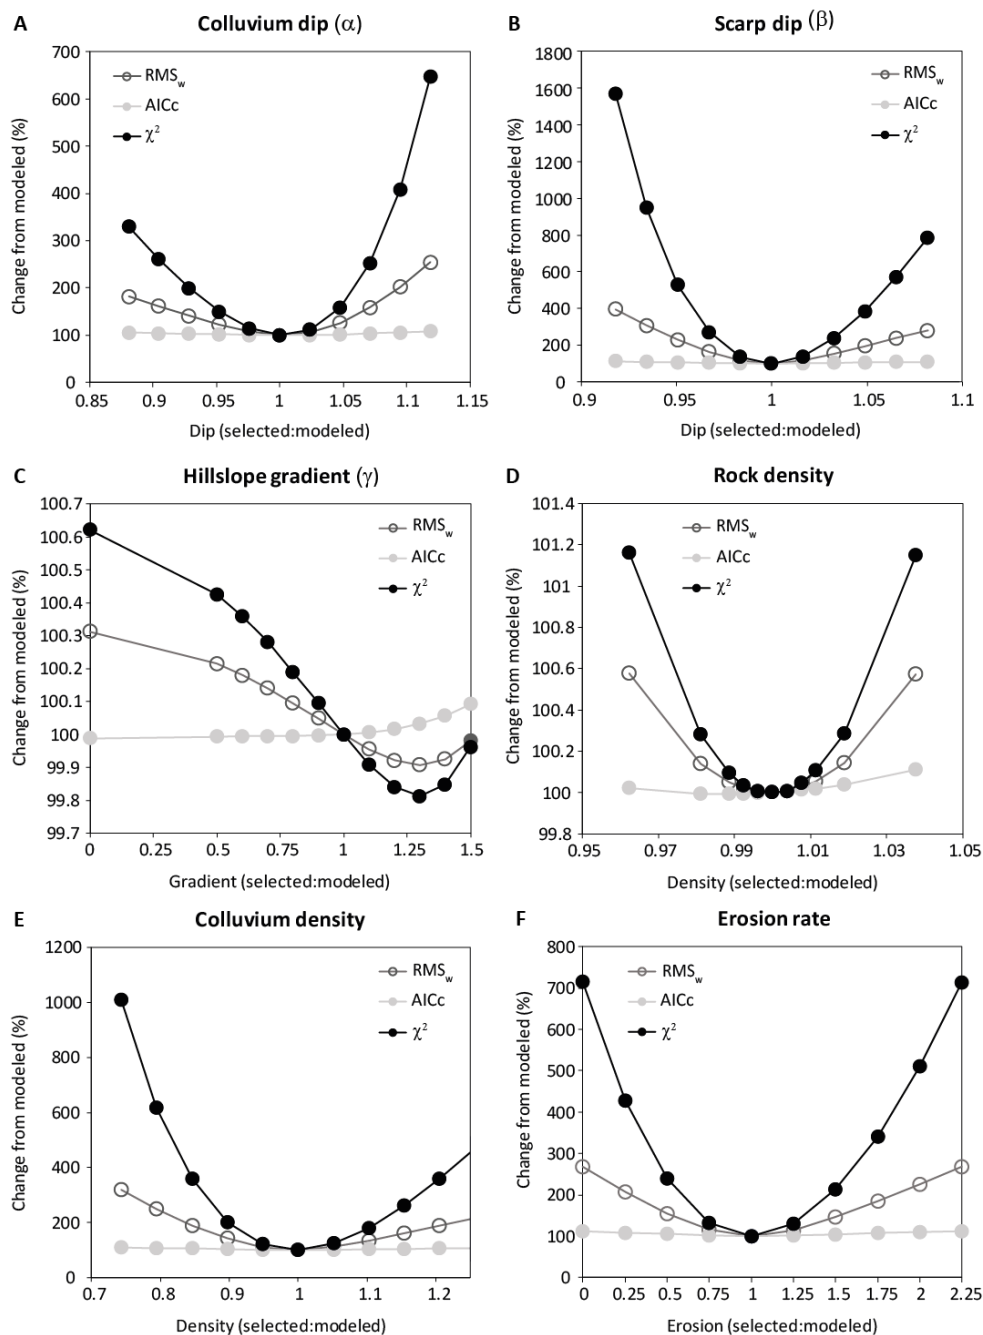

911 m-long and Benedetti et al. (2002) profiles, respectively.

912

913
914

915 **Fig. 3:** Best fits of profiles modelled according to Schlagenhaut et al. (2010) to measured
 916 Sparta fault ^{36}Cl concentration profiles. Down-arrows indicate the section of scarp exhumed
 917 during each earthquake. Best fits of modelled profiles to measured data are indicated by
 918 lowest attainable values for each of RMS_w , χ^2_{red} , and AICc . A. Anogia 3.9 m profile plus drill
 919 core profile data above 3.9 m and below the present hanging wall colluvium surface. B.
 920 Anogia 2.0 m profile plus drill core profile data from below the present hanging wall
 921 colluvium surface. C. Benedetti et al. (2002) data, remodeled using the same parameters as
 922 for panel A . The modelled profile is smooth because scarp composition is based on a mean
 923 value taken from our data. Our drill core subsurface samples were also used to help remodel
 924 the Benedetti et al. (2002) data, which required adding 13% on to their measured
 925 concentrations. D. Same profile as in A but with earthquakes inferred from the fault scarp
 926 geochemistry.

Fig. 4: Sensitivity of fits of profiles modelled according to Schlagenhauf et al. (2010) to measured Sparta fault ^{36}Cl concentration profiles, according to input parameters. A. Colluvial wedge dip B. Scarp dip C. Slope angle above the scarp. D. Scarp rock density E. Colluvium density F. Scarp erosion rate.

933
934 **Fig. 5:** The heterogeneous fault breccia that comprises the Sparta fault scarp surface. A. The
935 Sparta fault scarp surface appears smooth and homogenous, as illustrated by this photograph
936 of the scarp base at Anogia (upper half of the dug trench in the foreground). B. Fault breccia
937 is revealed in a cut drill core, where clasts of host limestone are cemented in a fine matrix. C.
938 A photomicrograph shows limestone clasts (dotted outlines) comprising about 60% of the
939 thin section area. D. A photomicrograph shows fine matrix comprising about 60% of the thin
940 section area. Arrows indicate quartz.
941

942

944 a vertical profile, Sparta fault scarp, Anogia. The concentration of each element (C_i) is

945 normalized to its mean concentration through the profile (C_i/\bar{C}). The locations of former soil

946 surface horizons inferred from ^{36}Cl concentrations and from the scarp geochemistry are

947 shown for reference.

948

949 **Fig. 7:** Energy-dispersive X-ray spectroscopy (EDS) elemental abundances, and
950 environmental scanning electron microscope (ESEM) and backscatter SEM imagery of a thin
951 section of fault breccia comprising the Sparta fault scarp surface at 1.1 m above the hanging
952 wall. (A). Element abundances in a pore, the location of which is shown in panels B and C.
953 Si, Al, and K are abundant relative to Ca, which indicates that clay, e.g., illite, is lining the
954 pore. (B) Quartz is an abundant constituent of the thin section matrix. (C) Porosity, shown in
955 black; note its spatial association with quartz. The location of the sample used in panel A is in
956 a small pore, shown in the inset.

957

958

959

Fig. 8: Concentrations of Si in the Sparta fault breccia, 1.1 m above the scarp base at Anogia.

960

A. A cut drill core from the Sparta fault scarp at Anogia showing limestone clasts cemented

961

in fine matrix. The circled fine matrix is examined under high resolution in panels B to D. B.

962

An ESEM image showing the sample location for spot elemental analysis (rectangle). C.

963

Sample points for elemental analysis using EDS, with values shown in the table. D. The

964

abundance of Si in the fine matrix illustrated in magenta for the circled part of the thin

965

section shown in panel A.

966

967

968

Fig. 9: Concentrations of rare-earth elements and yttrium (REY) along a vertical profile on

969

the Sparta fault at Anogia. Mean values for all REY elements at each sample point are shown

970

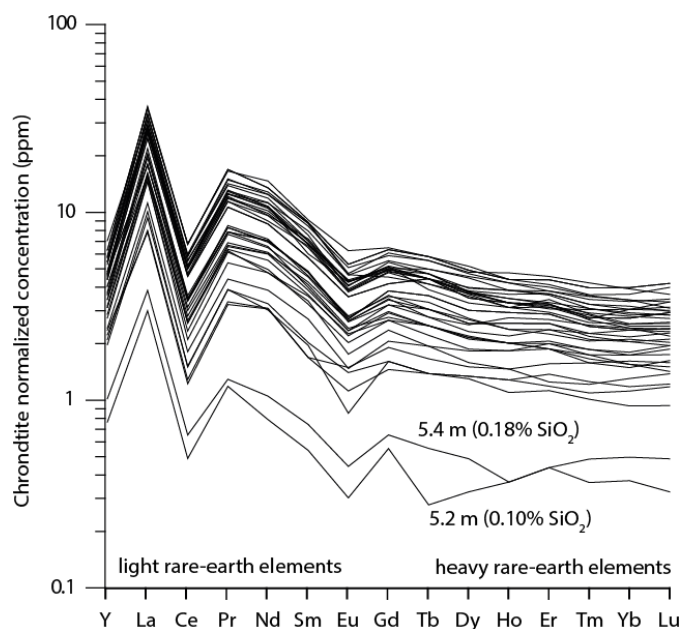

in red dots, whereas individual REY elements are shown in blue dots. The concentration of

971

each element (C_i) is normalized to its mean concentration through the profile (C_i/\bar{C}).

972 Concentrations of Al_2O_3 and former soil surface horizons inferred from ^{36}Cl concentrations
973 profiles and geochemical data, are shown for reference.
974

975
976 **Fig. 10:** Concentrations of rare-earth elements and yttrium (REY) normalized to chondrite
977 composition (McDonough and Sun, 1995) for the Sparta Fault scarp at Anogia. Each line
978 shows a measured location on the scarp surface. The two low REY outliers at 5.2 m and 5.4
979 m also have exceptionally low SiO_2 .
980

981

982 **Fig. 11:** Hanging wall soil chemistry, adjacent to the Sparta fault scarp at Anogia. A. Soil pH

983 uncertainty ranges show the ≤ 0.5 resolution of the indicator strips. B. Concentrations of Si,

984 Y, and elements too light to be measured using handheld XRF (LE, including C) along the

985 vertical soil profile. Each element has been normalized through division by its mean

986 concentration through the soil. C. Y concentrations plotted against pH (measured from 1:1

987 KCl) and Si concentration at each measured depth interval beneath the soil surface.

988
