

1 **Short summary.** 250 m estimates of snow water equivalent in the Western US and Canada were improved by assimilating  
2 observations representative of a future snow-focused satellite mission with a land surface model. Here, by including a gap-  
3 filling strategy, snow estimates could be improved in forested regions where remote sensing is challenging. This approach  
4 improved estimates of winter maximum snow water volume to within 4%, on average, with persistent improvements to both  
5 spring snow and runoff throughout spring snowmelt in many regions.

## 6 **Extending the utility of space-borne snow water equivalent** 7 **observations over vegetated areas with data assimilation**

16 **Abstract.** Snow is a vital component of the Earth system. Yet, no snow-focused satellite remote sensing platform currently  
17 exists. In this study, we investigate how synthetic observations of snow water equivalent (SWE) representative of a synthetic  
18 aperture radar remote sensing platform could improve spatiotemporal estimates of snowpack. We use an Observational fraternal  
19 twin Observing System Simulation Experiment, specifically investigating how much snow simulated using popular/widely  
20 used models and forcing data could be improved by assimilating synthetic observations of SWE. We focus this study across a  
21 24°-by-37° domain in the Western United States (US) and Canada, simulating snow at 250 m resolution and hourly timesteps  
22 in water-year 2019. We perform two data assimilation experiments, including: 1) a simulation excluding synthetic observations  
23 in forests where canopies obstruct remote sensing retrievals, and 2) a simulation inferring snow distribution in forested grid  
24 cells using synthetic observations from nearby canopy-free grid cells. Results found that relative to a nature run, or assumed  
25 true simulation of snow evolution, assimilating synthetic SWE observations improved average SWE biases at peak maximum  
26 snowpack timing in shrub, grass, crop, bare-ground, and wetland land cover types from 14%, to within 1%. However, forested  
27 grid cells contained a disproportionate amount of SWE volume. In forests, SWE mean absolute errors at peak snowpack the  
28 time of maximum snow volume were 111 mm, and average SWE biases were on the order of 150%. Here, the data assimilation  
29 approach that estimated forest SWE using observations from the nearest canopy-free grid cells substantially improved these  
30 SWE biases (18%) and the SWE mean absolute error (27 mm). Simulations employing data assimilation also improved  
31 estimates of the temporal evolution of both SWE and runoff, even in spring snowmelt periods when melting snow and high  
32 snow liquid water content prevented synthetic SWE retrievals. In fact, in the Upper Colorado River basin region, melt-season

33 SWE biases were improved from 63% to within 1%, and the Nash Sutcliffe Efficiency of runoff improved from -2.59 to 0.22.  
34 These results demonstrate the value of data assimilation and a snow-focused globally relevant remote sensing platform for  
35 improving the characterization of SWE and associated water availability.

## 36 **1 Introduction**

37 Snow plays important roles in the Earth system, by regulating global temperatures and cooling the land surface because of  
38 its reflective properties (Barry, 2002). ~~The insulative properties of snow are also vital in ecological balance by protecting plants~~  
39 ~~and animals from extreme cold and providing moisture when it melts. Snow is~~(Barry, 2002). ~~Snow is also~~ a major source of  
40 water storage for many regions, especially in areas that rely on snowpack to sustain water resources during the dry season. ~~In~~  
41 ~~fact, it~~ has been estimated that more than 2 billion people around the world are reliant on seasonal snow melt for their water  
42 supply (Barnett et al., 2005). Snowpack is the natural 'integrator' of climatic conditions and offers more predictability of water  
43 availability than variables with shorter memory, such as precipitation and streamflow (Terzago et al., 2023). ~~As a result,~~  
44 ~~Accurate~~ wintertime estimates of snowpack are ~~therefore~~ critical for water management and agricultural planning (Koster et  
45 al., 2010). ~~Water managers can prepare mitigation strategies for extreme dry or wet possibilities based on the wintertime~~  
46 ~~snowpack.~~(Koster et al., 2010). For example, in the Western ~~U.S.,~~US, where a vast majority of streamflow originates from  
47 snow (Li et al., 2017), it is common practice to use the April 1 snowpack, the historic ~~peak for~~date of maximum snowpack in  
48 that region, for developing water supply estimates for later in the season. However, climate change impacts have led to  
49 increased variability in the snow seasonality (Livneh and Badger, 2020), with warmer temperatures reducing the amount of  
50 snow accumulation and seasonal snow storage, and advancing the timing of the spring melt. Therefore, accurate  
51 characterization of winter snowpack and its variability is critically important for making informed water supply quantifications.

52 In recognition of the critical need to have spatially distributed measurements of snow mass, there have been several efforts  
53 to measure ~~and estimate SWE~~snowpack and snow water equivalent from many different remote sensing platforms in the past  
54 several decades. Airborne lidar systems have been able to provide high resolution, accurate measurements of snow mass  
55 (Painter et al., 2016), but this approach has significant logistical barriers for global and frequent snow measurements, and the  
56 hydrological utility of a practical spaceborne lidar platform is limited (Kwon et al., 2021). In the past three decades, snow  
57 depth and SWE estimates have been derived from passive microwave remote sensing measurements, but ~~they tend to be of these~~  
58 ~~measurements are at~~ coarse spatial resolutions, and have limited accuracies over deep and wet snow, complex terrain, and  
59 dense vegetation (Derksen et al., 2014; Foster et al., 2005)(REF). Active microwave remote sensing instruments such as  
60 Synthetic Aperture Radars (SARs) can provide finer spatial resolution measurements ~~to help resolve some of these issues.,~~ For  
61 ~~example, C-band SAR observations from the Sentinel-1 constellation and~~ have shown promise in obtaining high quality,  
62 ~~moderate resolution (1km)~~ observations in deep snow environments (Lievens et al., 2019). ~~A volume scattering radar approach,~~  
63 ~~using X- and Ku-band SAR, has also been demonstrated in several airborne campaigns and proposed for multiple snow mission~~  
64 ~~concepts (Yueh et al 2009, Rott et al 2010) because of its potential to achieve high resolution and global coverage over a range~~

65 of snow depths. While these microwave instruments can observe in night-time and cloudy conditions, they are still limited  
66 over areas with dense vegetation (Tsang et al., 2022). Further, all spaceborne instruments have inherent coverage gaps due to  
67 their orbital and revisit configurations.

68 To overcome these limitations, modeling and data assimilation systems are needed that can extend the coverage and utility  
69 of available measurements to areas, times, and variables that are not directly observed. In this article, we present a novel  
70 approach through data assimilation, designed specifically to improve the usefulness of spaceborne SWE retrievals over forested  
71 areas. The approach is demonstrated using an observing system simulation experiment (OSSE; e.g., Cho et al., 20222023;  
72 Errico et al., 2007) which is an approach used to formally assess the impact of the data to be collected from an anticipated  
73 mission. Several prior studies have examined the use of OSSEs for snow mission studies (Garnaud et al., 2019; Kwon et al.,  
74 2021; Wrzesien et al., 2022).(Garnaud et al., 2019; Kwon et al., 2021; Wrzesien et al., 2022). Among them, SAR-focused  
75 OSSEs have been conducted by Garnaud et al. (2019) and Cho et al. (20222023) to assess the utility of hypothetical snow  
76 observations. Garnaud et al. (2019) focused on a Ku-band SAR to quantify trade-offs between sensor configurations (e.g.,  
77 various spatial resolutions and revisit frequencies) with retrieval algorithm accuracy and SWE performance in southern  
78 Quebec, Canada, where temperate forests are dominant with shallow and moderate snowpack conditions. Cho et al. (20222023)  
79 conducted a X-/Ku-band SAR OSSE with an achievable sensor configuration (1 km spatial resolution, 7-day revisit frequency,  
80 and orbital configurations ~~using the Trade space Analysis Tool for Constellations [TAT-C] simulator~~) focusing on  
81 mountainous environments in a western Colorado. ~~To comprise diverse snow environments, specifically for~~ and testing the  
82 degree to which various ~~forested landscapes in this study, we focus on~~ SAR retrieval capabilities in different forest densities  
83 and snow volumes could improve observationally-based SWE estimates. Here, we build on this prior research by developing  
84 an OSSE covering the entire western ~~United States domain along with the proposed, more realistic constellations using TAT-~~  
85 C-US and portions of Canada. We simulate finer-scale (250 m) synthetic SWE observations that could be provided from a  
86 future X-/Ku-band SAR mission, which are then incorporated within a land surface model through data assimilation to assess  
87 their capability to improve snow state estimates, and the integrated impact on hydrologic states in space and time. The  
88 assimilation experiments here are conducted with and without a novel strategy to extend SAR-based ~~observational coverage~~  
89 ~~of snow mass to various~~ SWE estimates from unforested regions into forested landscapes where SAR retrievals of the snowpack  
90 may be obscured by the forest canopy.

91 The primary contribution of this paper is the development of a viable strategy for extending ~~space borne remote~~  
92 ~~sensing~~ hypothetical remotely sensed SWE ~~measurements in preparation of~~ retrievals from a ~~future snow mission concept (a~~  
93 ~~volume-scattering X-/Ku-band SAR)-~~ satellite mission into difficult-to-observe forest landscapes. We specifically focus on  
94 addressing the following research questions: 1) what is the added utility of spaceborne active remote sensing SWE retrievals  
95 across the ~~western United States?~~ Western US and Canada? 2) how much can spatiotemporal representations of SWE be  
96 improved by focusing on developing observationally based snow estimates over areas with dense vegetation, where SAR

97 sensors may be limited? 3) How much added hydrological utility can be obtained through spaceborne active remote sensing  
98 measurements and data assimilation approaches, particularly when coverage over forested areas is improved?

99 Section 2 describes the study domain and OSSE modeling setup. This is followed by the description of the results (Sect. 3),  
100 a discussion of the findings (Sect. 4), and the study's conclusions (Sect. 5).

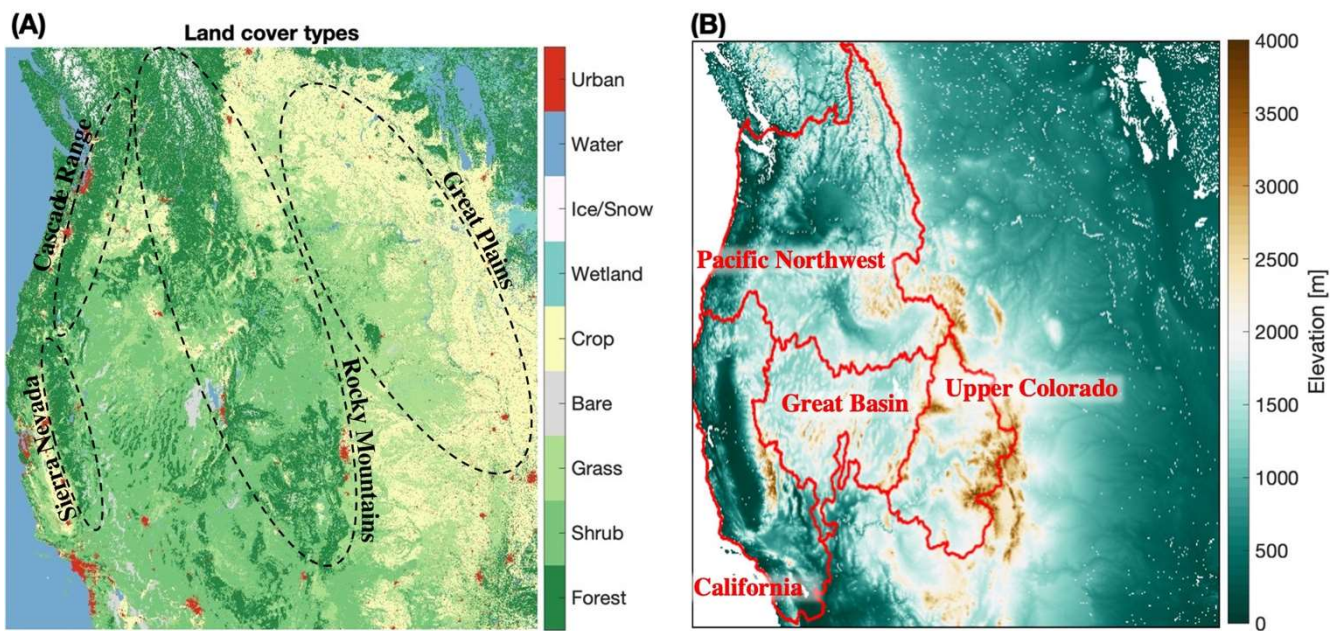

## 101 2.1 Study domain and OSSE setup

102 ~~As noted above, an~~ OSSE is ~~a typical approach~~ used to assess the value of the data to be collected from an anticipated  
103 mission, ~~and consists.~~ OSSEs ~~often consist~~ of the following steps: 1) ~~Development of an assumed “true state” of the relevant~~  
104 ~~system is produced by~~ Developing a “nature run” that ~~involves the use of~~ uses a state-of-the-art model employed with the best  
105 available boundary conditions (Sect. 2.1); 2) ~~simulation of synthetic observations from using~~ the nature run ~~to generate~~  
106 ~~simulated remote sensing observations~~, accounting for sources of sensing limitations, sensing uncertainties, and orbital  
107 configurations (Sect. 2.2); 3) ~~incorporation of~~ incorporating the simulated observations (often through data assimilation, Sect.  
108 2.3) in a ~~different, separate,~~ “open loop” model configuration with accuracies representative of common modeling biases and  
109 uncertainties, ~~often called the ‘open loop’~~; and 4) ~~evaluation of the impact that~~ ~~evaluating how much~~ the simulated ~~remote~~  
110 ~~sensing data have on improving~~ improve the ~~open loop model~~ performance relative to the nature run. ~~The details of the OSSE~~  
111 ~~setup used in this manuscript, are described below.~~ In addition to this OSSE approach, this study goes further by 1) ~~testing the~~  
112 ~~degree of improvement to both the remotely-sensed variable (i.e., SWE) and the resulting changes to land surface runoff in~~  
113 ~~snowy regions, and 2) developing two separate data assimilation experiments, one which masks simulated observations in~~  
114 ~~forested pixels where SAR retrievals may be most challenging, and the other~~ including a novel approach for inferring SWE in  
115 forested ~~landscapes~~ pixels using simulated observations from nearby, unforested ~~simulated observations~~ pixels (Sect. 2.4). ~~The~~  
116 ~~details of the OSSE setup used in this study are described in more depth throughout this section.~~

117 We employ the NASA Land Information System (LIS; Kumar et al., 2006), an infrastructure for high performance,  
118 ensemble-based land surface modelling and data assimilation to enable this OSSE. LIS encompasses several advanced land  
119 surface models that can simulate terrestrial water, energy, and carbon balances and related states such as soil moisture, land  
120 surface temperature, and SWE, among others. These include different versions of community models such as Noah (Ek et al.,  
121 2003), Variable Infiltration Capacity (VIC; Liang et al., 1994), Catchment (Koster et al., 2000), Joint UK Land Environment  
122 Simulator (JULES; Best et al., 2011), and Noah-MP (Niu et al., 2011). The LIS framework also includes support for specialized  
123 models that are designed to provide more detailed representations of certain land surface processes (e.g. snow), while enabling  
124 interaction with LSMs that solve for water, energy, and carbon balances at a macroscale. For example, the advanced snow  
125 physics model called SnowModel (Liston and Elder, 2006) has been incorporated within LIS in a manner that allows coupling  
126 to existing LSMs. This structure allows the use of the advanced snow physics from SnowModel while leveraging the existing

127 process schemes (e.g., sub-surface, groundwater, canopy) within the LSMs. Here we utilize these unique capabilities for  
128 enabling the OSSE integrations.

129 . The study is conducted over a large domain (Fig. 1), covering the Western U.S. and southern Canada from 31-55N and  
130 93-130W at a 250 m spatial resolution. As shown in Fig. 1, this modeling domain encompasses a broad range of vegetation  
131 types, topographical regimes and river-basins water resources regions of the Pacific Northwest, California, Great Basin, and  
132 Upper Colorado. 22% of the domain is covered by forests, with grasslands, croplands, and shrublands accounting for 20%,  
133 23%, and 26% of the domain, respectively. Forests dominate the coverage of areas with significant snowpack, occupying 58%  
134 of regions that are in the mid-elevation range of 2500-3500m, and 15% of the areas with elevations over 3500m. From a  
135 modelling perspective, the domain extent of Fig. 1 (~83 million land grid points) is computationally challenging. The  
136 scalable high performance computational and parallel inputting and outputting capabilities of NASA LIS were leveraged to  
137 enable these simulations. A multiprocessor configuration involving approximately 1000 processors was employed to facilitate  
138 large model simulations for the nature run, open loop simulation, and two simulations with data assimilation.

139 **Figure 1:** Maps of the land and vegetation classes (A; left panel) and elevation (in meters) (B; right panel) used in the  
140 simulations. Outlines and labels in the left panel indicate regions discussed in the Results (Sect. 4). Red contours in the right  
141 panel indicate basin hydrologic regions used in the analysis.  
142

143 ~~The “nature-run” Simulations in this study was performed using a model configuration that coupled a state-of-the-art and~~  
144 ~~physically based snow model (named SnowModel, discussed later in this section) with the Noah model with multi-~~  
145 ~~parameterization (Noah-MP) version 4.0.1. The simulations are conducted by forcing this coupled model setup LIS LSMs with~~

146 the surface meteorology from NASA's Modern Era Retrospective Reanalysis, version 2 (~~MERRA2~~MERRA-2; Gelaro et al.,  
147 2017) ~~product, with LIS-provided downscaling to 250 m resolution using lapse rates and topographical downscaling~~  
148 ~~approaches, like SW corrections based on topographical shading (Arsenault and ECMWF Reanalysis, version 5 (ERA5;~~  
149 ~~Hersbach et al., 2020) products.~~ The model integrations were conducted for the water year 2019 (September 2018 – September  
150 2019), which was a wetter than normal year based on the long-term average meteorological conditions over this domain. ~~The~~  
151 ~~open loop and data assimilation integrations performed in this study were conducted using Noah-MP alone.~~

152 The ~~open loop and data assimilation integrations performed in this study are conducted using the Noah land surface model~~  
153 ~~with multi-parameterization (Noah-MP model discussed above) version 4.0.1 (Niu et al., 2011) and forcing from ERA5.~~The  
154 ~~Noah-MP model~~ evolved from the Noah LSM, with multiple options for various land surface processes. It represents ~~processes~~  
155 ~~related to~~ energy, water, and carbon balances at the land surface by accounting for processes related to infiltration, evaporation,  
156 transpiration, runoff generation and groundwater recharge. A TOPMODEL-based runoff model (~~Beven et al., 2021~~) is used to  
157 calculate surface runoff and groundwater discharge. Options for prognostic vegetation dynamics models that represent the  
158 growth and senescence of vegetation are also available within Noah-MP. A two-stream radiative transfer approach is employed  
159 to calculate surface energy processes. ~~Finally, a~~ multilayer snowpack model (with up to three layers) ~~that can be used to~~  
160 account for snow melt metamorphisms, compaction by overlying snow, sublimation of canopy intercepted snow, and  
161 snowmelt-refreeze cycles ~~is available within Noah-MP (Niu and Yang, 2004).~~within Noah-MP (Niu and Yang, 2004).

162 Snow states like snow depth and SWE were also modelled across the Western ~~United States~~ (domain highlighted in Fig.  
163 1) at 250 m resolution and hourly time steps using ~~the state-of-the-art and physically based single-layer snow~~  
164 ~~model implementation of SnowModel (named SnowModel; Liston and Elder, 2006), provided forcing from MERRA-2 with~~  
165 ~~LIS-provided lapse rates and topography-based meteorological downscaling approaches, like incoming shortwave corrections~~  
166 ~~based on topographical shading (Cosgrove et al., 2003; Kumar et al., 2013).~~ ~~SnowModel~~ This model has seen widespread use  
167 in the snow community, demonstrating the capability to resolve snow evolution in a variety of landscapes and complex snow  
168 processes like the redistribution of snow via wind, and the resulting impact on snow distribution, melt season snow duration,  
169 glacier mass balance, and snow habitat for species like polar bears and Dall sheep (Hiemstra et al., 2002; Liston et al., 2016;  
170 Mahoney et al., 2018; Mernild et al., 2017; Sturm and Wagner, 2010). ~~In addition to wind redistribution,~~ ~~S~~snow evolution  
171 ~~within SnowModel at each grid cell accounted accounts~~ for a wide set of snow processes, including snow sublimation, snow  
172 grain size evolution, solar topographical shading, canopy shading, ~~and~~ canopy snow interception, ~~and wind redistribution.~~  
173 Through the coupling ~~within LIS,~~ Noah-MP snow states and the resulting snow-driven runoff were updated using the  
174 SnowModel outputs at ~~hourly-daily~~ timesteps for each grid cell.

175 Preliminary research has shown that relative to Noah-MP, LIS simulations coupling Noah-MP with SnowModel have  
176 improved the volume and spatial distribution of simulated snow depth and SWE (~~Arsenault et al., 2021;~~ Wrzesien et al., 2022).

177 Therefore, the coupled SnowModel and Noah-MP model was a prime candidate for the “nature run” in this study, or the  
178 simulation most representative of the true underlying spatiotemporal snow states from which simulated observations were  
179 derived (Sect. 2.2), and the assimilated model was compared against. Here, the nature run and open loop simulations detailed  
180 above were compared to a widely-used Western US snow reanalysis product (Fang et al., 2022) to ensure that 1) the nature  
181 run exhibited reasonable model accuracy, and 2) the departure between the open loop simulation and nature run are  
182 representative of common regional, continental, and global modeling efforts (Figure S1 and S2). The OSSE developed for this  
183 study is a “fraternal twin” OSSE, wherein two different models are used to simulate snow in the open loop (Noah-MP) and  
184 nature run (SnowModel) simulations. This approach is selected since “identical twin” OSSEs, which use the same model, can  
185 result in less divergence in model states and information content, biasing the degree of model improvement that could come  
186 from assimilating an observation (e.g., Yu et al., 2019). More information on the difference between the open loop and nature  
187 run models can be found in Table S1.

## 188 2.2 Observation simulator

189 ~~— From the nature run integrations conducted with Noah-MP coupled to SnowModel in LIS, synthetic SWE retrievals at 250~~  
190 ~~m spatial resolution, expected from a hypothetical SAR mission, were simulated. First, the orbital swaths were simulated using~~  
191 ~~TAT-C (Le Moigne et al., 2017). TAT-C, a NASA software system designed for future Distribution Spacecraft Missions~~  
192 ~~(DSM),. Synthetic SWE retrievals at 250 m spatial resolution, representative of a hypothetical X- and Ku-band SAR mission,~~  
193 ~~are simulated from the nature run. To do this, the orbital swaths are simulated using TAT-C (Le Moigne et al., 2017). TAT-C~~  
194 ~~is a NASA software system designed for future Distribution Spacecraft Missions (DSM), which enables us to explore a range~~  
195 ~~of feasible design options (e.g., constellation vs. single, geostationary vs. polar-orbiting, low vs. high temporal frequencies) to~~  
196 ~~estimate optimal gains for the given mission configuration. Using an assumed 10–14 day revisit frequency, these~~  
197 ~~OSSEs have been conducted to test the impact from different snow mission configurations (e.g. Garnaud et al 2019). Here we~~  
198 ~~instead focus on demonstrating the value of a gap-filling approach (Sect. 2.4) for estimating snow in forested landscapes where~~  
199 ~~SAR retrievals may be most challenging. Therefore, we used TAT-C to design a conservative mission configuration consisting~~  
200 ~~of a small constellation of X- and Ku-band SAR satellites. Using a 10-14 day revisit frequency, depending on latitude, TAT-~~  
201 ~~C orbital swaths were applied to the nature run outputs to simulate the satellite viewing area. The ~~realistier~~remote sensing spatial~~  
202 ~~coverage is simulated by extending the ground track to a swath width (i.e., 50 km). The daily viewing extents are then simulated~~  
203 ~~as a daily binary map (so-called “cookie cutter”) masking the surface as viewed or not at a 250 m spatial resolution.~~

204 \_\_ Additionally, bBased on an error level of 20%, spatially and temporally uncorrelated random errors drawn from a Gaussian  
205 distribution ~~we~~are added to the synthetic SWE retrievals. ~~Note that here we use an optimistic~~This 20% error level is selected  
206 using a conservative estimate of SWE measurement uncertainty for a volume-scattering X-/Ku -band SAR mission based on  
207 developed mission design concepts and ground validation. For example, the ESA Cold Regions Hydrology High-Resolution  
208 Observatory (CoREH2O) mission expected to meet instrument and retrieval requirements of  $\pm 30$  mm accuracies for SWE of

209 300 mm, ±10% for SWE greater than 300 mm (Rott et al 2010, 2012). Similarly, the Canadian Terrestrial Snow Mass Mission  
 210 (TSMM) concept that is currently under development aims to achieve better than 20% measurement uncertainty for SWE  
 211 greater than 50 mm, though it is limited to SWE less than 200 mm due to the dual Ku-band system (Garnaud et al. 2019).  
 212 Airborne and tower-based field data have demonstrated that a combination X- and Ku-band system can provide SWE retrievals  
 213 over a range of snow conditions at accuracies better than 20% (Zhu et al. 2018, 2021, Tsang et al 2022, Durand et al. 2023,  
 214 Singh et al. 2023). However, we use an assumption of uniform error levels throughout the domain, whereas in reality, the  
 215 errors are likely to be dependent on other factors, including the terrain characteristics, ~~vegetation, and precipitation regime.~~  
 216 snow characteristics, and vegetation. This is discussed more in Section 4.

### 217 2.3 Data assimilation setup

218 A one-dimensional ensemble Kalman Filter (EnKF; Reichle et al., 2002) ~~was~~ used to assimilate the synthetic observations  
 219 within the open loop configuration of the model. EnKF is widely used for land data assimilation studies (Kumar et al., 2022),  
 220 as it provides a flexible approach for the treatment of model and observation errors and non-linear models. An ensemble of  
 221 model realizations is used by EnKF to assess and propagate model errors. In this instance, the ensemble requirement further  
 222 adds to the significant computational requirements of the large model domain (Fig. 1) and fine spatial resolution of the  
 223 simulations (250 m). Therefore, a 5-member ensemble with perturbations applied to the meteorological variables and model  
 224 prognostic fields are used for ~~simulating~~ uncertainty in the modeled estimates. Table 1 details the parameters for  
 225 meteorological and model state perturbations, which are based on recent snow data assimilation studies (Lahmers et al., 2022;  
 226 Kwon et al., 2021). ~~Though~~ a larger ensemble size is better for ensuring sufficient sampling density, our choice of five  
 227 ensembles is reasonable given that the model state vector used in the assimilation only consists of two variables; the total SWE  
 228 and snow depth. The assimilation setup employs a sequential update strategy, where at each time step an ensemble of model  
 229 forecasts is propagated forward in time, followed by an update based on observational inputs. The model states are updated  
 230 toward the observations based on the relative uncertainties in the model and observations using the following formulation, at  
 231 a certain time  $k$ .

$$232 \quad x_k^{i+} = x_k^{i-} + K_k [y_k^i - H_k x_k^{i-}] \quad \text{Eq. (1)}$$

233 Where  $x_k$  and  $y_k$  are the model and observation state vectors, respectively. The term  $H_k$  represents the observation operator  
 234 that maps the model states to the observed variables. The superscripts  $i -$  and  $i +$  represent the  $i$ th ensemble member before  
 235 and after the update, respectively.  $K_k$  is the “Kalman gain” term, that allows the weighting of the observations and model  
 236 forecasts is a function of the model and observation error covariances.

237 **Table 1.** Model forcing and state-variable perturbations used by the 5-member ensemble of LIS simulations

Variable	Perturbation Type	Cross Correlation across variables
	8	
	8	

Meteorological Forcing		Std. Dev.	SW corr	LW corr	PCP corr	T corr
Downward Shortwave (SW)	Multiplicative	0.2	1	-0.3	-0.5	0.3

Precipitation (PCP)	Multiplicative	0.5	-0.5	0.5	1	-0.1
Near surface Air Temperature (T)	Additive	0.5	0.3	0.6	-0.1	1
Noah-MP LSM snow states			SWE	Snow depth		
SWE	Multiplicative	0.01	1	0.9		
Snow depth	Multiplicative	0.01	0.9	1		

238

239 The data assimilation procedure detailed here assimilated the synthetic SWE retrievals (Sect. 2.2) with the open loop  
240 simulation. The degree to which the simulation with data assimilation approached SWE simulated by the nature run is intended  
241 to represent the extent to which a SAR remote sensing platform with the SWE retrieval characteristics from Sect. 2.2 could be  
242 combined with a land surface model to provide near real-time estimates of SWE at 250 m resolution. However, the SAR  
243 observations synthesized in this study have known issues with observing snow with high liquid water contents and dense forest  
244 cover. Therefore, synthetic observations at each timestep were masked at grid cells with where the most-dominant landcover  
245 type from the North American Land Change Monitoring System (NALCMS; Latifovic et al., 2017) was forested, including  
246 deciduous, evergreen, and mixed forest cover (Fig. 1), and 1). Synthetic observations were also masked at grid cells where and  
247 when snow was experiencing melt-, identified by the presence of liquid water in the snowpack from the nature run. Although  
248 limited in area, grid cells with “ice” landcover (Fig. 1) were also excluded. In this study, this simulation which used assimilation  
249 only in unforested, non-melting, and ice-free grid cells is termed “Data Assimilation, without the forest strategy” (DA). In  
250 Sect. 2.4 below, we present a novel approach used to infer SWE in grid cells with forests using the nearest canopy-free synthetic  
251 observations.

## 252 2.4 Extending observations over forests

253 The 1-d EnKF approach employed here updated each model grid SWE from the open loop simulation based on the  
254 observations available at that grid point. Though studies have employed 3-d EnKF approaches to spatially propagate

255 observational information to neighbouring grid cells (De Lannoy et al., 2012)-, here we relied on 1-d updates due to several  
256 factors. First, a 2-d update requires the knowledge of spatial error correlations and their variability, which is challenging to  
257 specify (Ying, 2020). Most prior studies using such schemes employ uniform specifications and are limited to small domains.  
258 Second, a 2-d update increases the size of the state vector and consequently requires the use of a larger ensemble. This,  
259 combined with the added computational expense of a 2-d analysis significantly increases the computational cost. Therefore,  
260 we employed an alternate approach that is computationally more efficient while allowing the extension of observations to  
261 nearby areas.

262 Assuming that the SWE retrievals from the hypothetical SAR instrument are limited over ~~forested areas, here~~areas where  
263 the dominant vegetation type are forests (Fig. 1a), we employ a novel approach to extend the observations obtained in non-  
264 forested areas (Fig 2). For every forested location, valid retrievals over nearby non-forested locations within a radius of  
265 influence of 750 m are identified. An observation at the forested pixel is then estimated by scaling the model SWE by the ratio  
266 of the average observed SWE to modeled SWE over the ‘clearing’ areas (Fig. 2). This scaled observation is then used for  
267 assimilation over the forested pixel. Here we implicitly use the spatial correlations inherent in the model between forested and  
268 clearing areas to extend observational coverage over the clearing to forested locations. This simulation is termed “Data  
269 Assimilation, with the forest strategy” (symbolized by DA+F in Section 3). To evaluate the accuracy and added value of this  
270 scaling approach, we compare SWE and runoff from the nature run simulation, versus simulations with data assimilation both  
271 1) employing the forest scaling strategy discussed here, and 2) masking synthetic observations in forested grid cells (Sect. 2.3).

$$SWE_{obs,f} = SWE_{model,f} \times \frac{\overline{SWE_{obs,c}}}{\overline{SWE_{model,c}}}$$

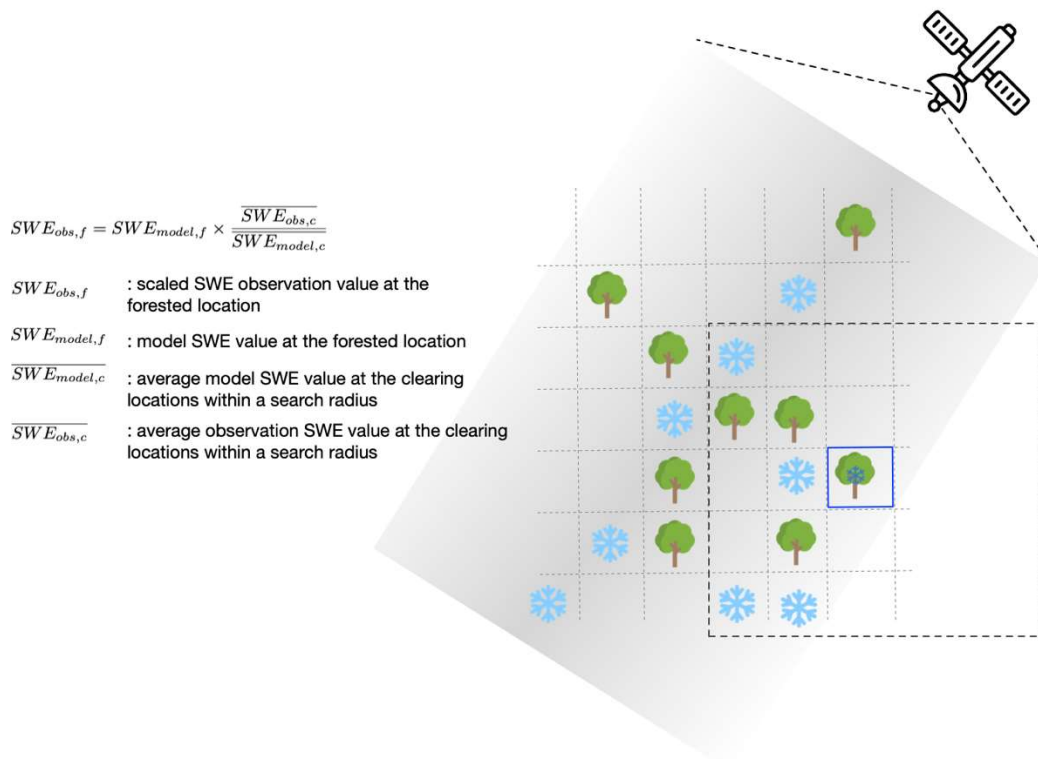

$SWE_{obs,f}$  : scaled SWE observation value at the forested location

$SWE_{model,f}$  : model SWE value at the forested location

$\overline{SWE_{model,c}}$  : average model SWE value at the clearing locations within a search radius

$\overline{SWE_{obs,c}}$  : average observation SWE value at the clearing locations within a search radius

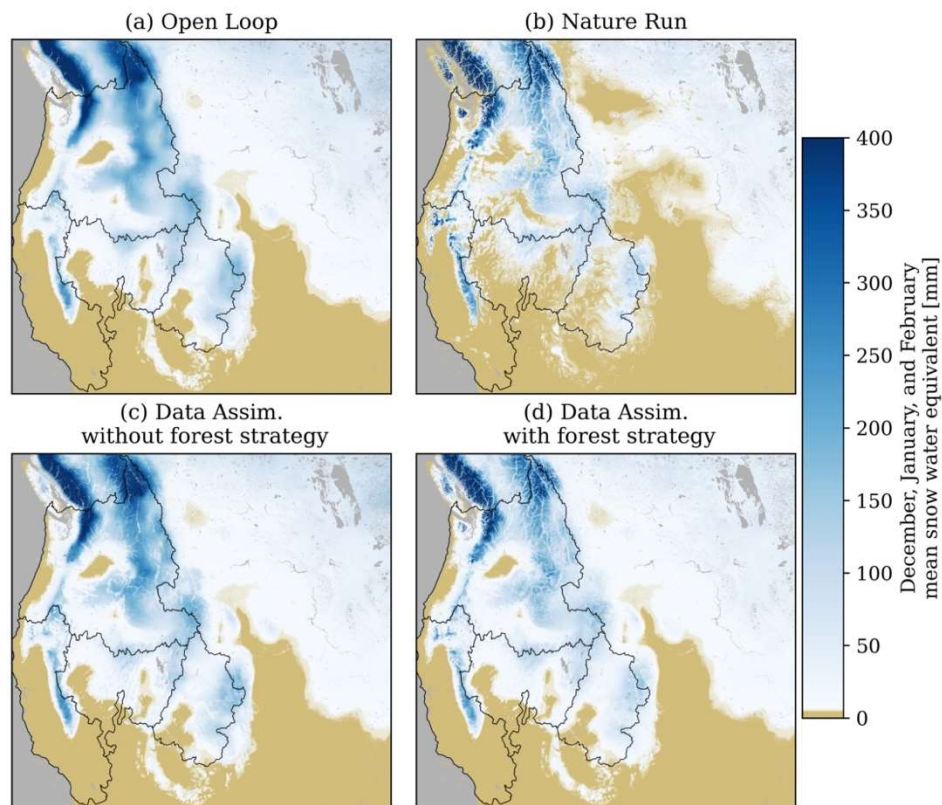

273

274 **Figure 2.** Conceptual depiction and equations demonstrating the forest strategy used here, which estimates a SWE observation  
 275 at a given grid cell (outlined box in blue color) based on the modeled SWE ( $SWE_{model,f}$ ) and the ratio between the average  
 276 synthetic SWE observations ( $\overline{SWE_{obs,c}}$ ) and average modeled SWE ( $\overline{SWE_{model,c}}$ ) from grid cells within a 750 m radius  
 277 (dashed box in red). The light gray shading represents the satellite swath, the tree icons indicate forested locations, and the  
 278 snowflake icons represent grid cells with valid SWE retrievals/measurements at non-forested locations. The grid cell from this  
 279 example is near the satellite swath edge, so observations are unavailable in the nearby regions South and East of this pixel.

280 **3 Results**

281 In this section, we compute the difference between the open loop simulation, nature run, and the two open loop simulations  
 282 with data assimilation, one masking synthetic observations over regions with forests, and time periods with melting snow, and  
 283 ice, and the other applying the same data assimilation but extending snow estimates in forested regions using the strategy from  
 284 Sect. 2.4 and Fig. 2. The differences between these simulations are detailed in Section 2 and Table S1. We focus on the  
 285 differences between these four simulations using: 1) average SWE from the winter snow accumulation season (December,  
 286 January, and February; DJF), when snowmelt is minimized and synthetic observations are masked by grid cells with liquid  
 287 water content to the smallest degree, 2) spatially distributed SWE on 13 March, the date corresponding to the timing of  
 288 maximum SWE volume in water-year 2019, and 3) daily average SWE and total runoff for each day in water-year 2019 over  
 289 a number of selected river-basin hydrologic regions including the Pacific Northwest, California, Great Basin, and Upper  
 290 Colorado (Fig. 1b).

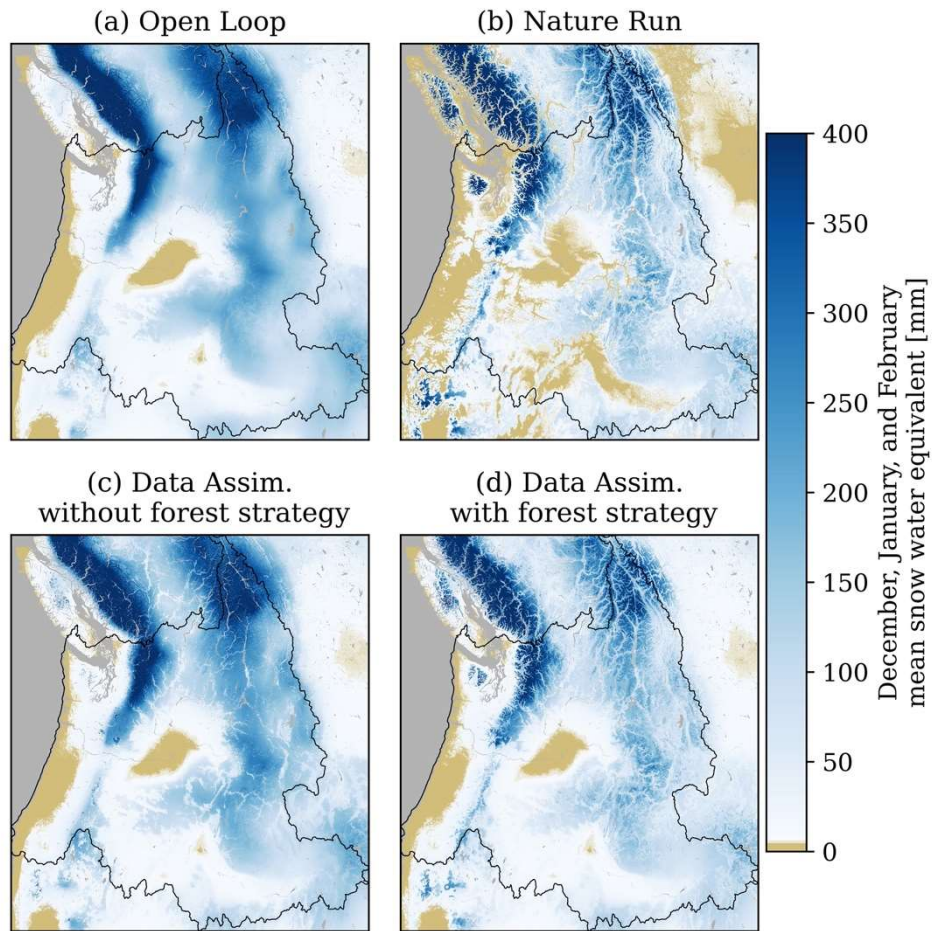

291 The open loop and nature run simulations exhibited differences in both the volume and spatial distribution of average winter  
 292 (December, January, and February; DJF) SWE (Fig. 3a and 3b). Relative to the nature run, the open loop simulation tended to  
 293 simulate lower elevation winter SWE that was both larger in magnitude and persisted for longer before melting. In the Pacific  
 294 Northwest domain (Fig. 4), DJF average snow cover (defined as grid cells with mean DJF SWE exceeding 5 mm), was  
 295 approximately 12% larger for the open loop simulation than the nature run (Table 2). These snow extent biases were also  
 296 apparent in the other [basinshydrologic regions](#) (Figs. S1—S3 – S5), where open loop snow extents exceeded snow extents  
 297 from the nature run by 26% in the Upper Colorado, 45% in the Great Basin, and 6% in California. Visually, the nature run had  
 298 significant increases in the spatial variability of winter SWE, better representing the differences in SWE between mountain  
 299 peaks and valleys, and the patchiness of snow cover in regions with winter snowmelt and ephemeral snow cover (e.g., Fig. 4,  
 300 [Fig. S1](#)). Relative to the nature run, DJF SWE from the open loop simulation was biased high across the full modeling region  
 301 (Fig. 3) by approximately 26%, on average, with a mean absolute error of 41 mm and spatial coefficient of correlation of  
 302 approximately 0.74. Across [snowy](#) the Pacific Northwest [basin](#) (Fig. 4), DJF mean SWE biases were approximately 37%, with  
 303 a mean absolute error of 55 mm. Open loop model performance for the other [basinshydrologic regions](#) can be found in Table  
 304 2.

305

306 **Figure 3.** Winter (December, January, and February) mean SWE simulated at 250 m resolution from the open loop (a), nature  
307 run (b), and data assimilation simulations, both with (d) and without (c) the forest strategy presented in Sect. 2.4.

308 **Figure 4.** Winter (December, January, and February) mean SWE in the Pacific Northwest region simulated at 250 m  
309 resolution from the open loop (a), nature run (b), and data assimilation simulations, both with (d) and without (c) the forest  
310 strategy.  
311

312 **Table 2.** Simulation performance, relative to the nature run simulation, for the open loop simulation (OL) and the  
 313 simulations with data assimilation, both with (DA+F) and without (DA) the forest strategy. Statistics are presented for the  
 314 full domain, the four hydrologic basins/regions, and all forested and unforested grid cells.

		DJF* snow- extent biases	13 March 2019 SWE			Seasonal SWE and runoff

\* DJF = December, January, and February; MAM = March, April, and May (averages)  
<sup>^</sup> OL = open loop simulation; DA = simulation with data assimilation without the forest strategy; DA+F = simulation with data assimilation and with the forest strategy

315 As expected, the simulations assimilating the synthetic SWE observations agreed with the nature run better than the open  
 316 loop simulation. However, on 13 March 2019 (the date of maximum domain SWE volume), the simulation with data  
 317 assimilation without the forest strategy had high-biased SWE across large portions of the Rocky Mountains and the Cascade  
 318 Mountain range (Fig. 1, Fig. 5b and Fig. 5e). Low biased SWE was more common in Northernmost Canadian portions of the  
 319 Rocky Mountains and Cascade Range, the Western montane regions in Washington State, the Northern portions of the Great  
 320 Basin, and the lower-lying elevations of the California Sierra Nevada. Additionally, despite the assimilation, snow extents  
 321 were still biased high relative to the nature run (Fig. 3) at magnitudes similar to the open loop simulation (Table 2). This was  
 322 driven by the expansive snow extents of the open loop simulation, which were decreased by data assimilation, but still resulted  
 323 in widespread early-season SWE increases for short periods of time between synthetic observations (at 10 – 14 day

324 frequencies), increasing to the number of grid cells with DJF SWE exceeding 5 mm (threshold used to define average winter  
325 snow extents in Fig. 3).

326 Assimilating the synthetic SAR observations without the forest strategy best improved SWE in shrub, grass, crop, bare, and  
327 wetland landcover types (Fig. 6b and 6c). For example, relative to the open loop simulation (Fig. 5a and 5d), data assimilation  
328 without the forest strategy (Fig. 5b and 5e) corrected the high SWE biases in the Great Plains (Fig. 1). While 13 March SWE  
329 in shrub, grass, crop, bare-ground, and wetland regions was typically small in magnitude, these landcover types accounted for  
330 77% of the modeling domain area, and 61% of the domain total SWE volume on 13 March (Fig. 6a). In these regions, SWE  
331 from the open loop simulation had a mean absolute error of 22 mm, and a mean bias of approximately 14%, relative to the  
332 nature run (Table 2). Data assimilation significantly improved the SWE bias in these land cover types to within 1%, on average  
333 (Fig. 6b), with a mean absolute error of 14 mm, relative to the nature run.

334 **Figure 5.** 13 March 2019 SWE difference (top row) and percent-difference (bottom row), relative to the nature run, for the  
335 open loop simulation (a and d), and simulations with data assimilation, both with (c and f) and without (b and e) the forest  
336 strategy. SWE percent-difference maps (bottom row) only compare grid cells where SWE from the nature run was greater  
337 than 5 mm.  
338  
339

340 The data assimilation results discussed above did not use the synthetic observations over forested grid cells, where  
341 retrievals from SAR instruments may be either partially or fully occluded by the canopy overstory (Tsang et al., 2022; Ruiz  
342 et al., 2022; Huang et al., 2019). However, a significant portion of the snow volume in mid-latitude domains overlaps with  
343 forests. For example, although forests only covered approximately 22% of the study region investigated here (Fig. 1a),  
344 forested grid cells contained just over 34% of the total 13 March SWE volume, a volume about 10% higher than the snow  
345 volume contained in the next-largest landcover type (Fig. 6a). In forested grid cells, SWE simulated by the open loop  
346 simulation were biased high by approximately 87 mm (+150%) on average (Fig. 6), with a mean absolute error of 111 mm  
347 (Table 2). These errors were propagated into the simulation with data assimilation without the forest strategy. Fortunately,  
348 the ratio between modeled SWE and synthetic SWE observations in forested grid cells and the nearest canopy-free grid cells  
349 had high levels of similarity. Therefore, estimating snow in forest regions using the nearest canopy-free pixels (Fig. 2)  
350 improved snow simulations significantly (Fig. 3d, Fig. 4d, and Fig. 5c and 5f). In fact, snow simulated in forest landscapes  
351 using data assimilation with the forest strategy agreed well with the nature run, exhibiting a 13 March SWE average bias in  
352 forested grid cells of only 14 mm (+8%) (Fig. 6), and a mean absolute error of 27 mm. This forest strategy resulted in large-  
353 scale improvements to total domain SWE (Fig. 5), reducing the 13 March full-domain SWE volume bias by 28%, and  
354 improving the spatial coefficient of correlation by 0.12, relative to the data assimilation simulation without the forest  
355 strategy.

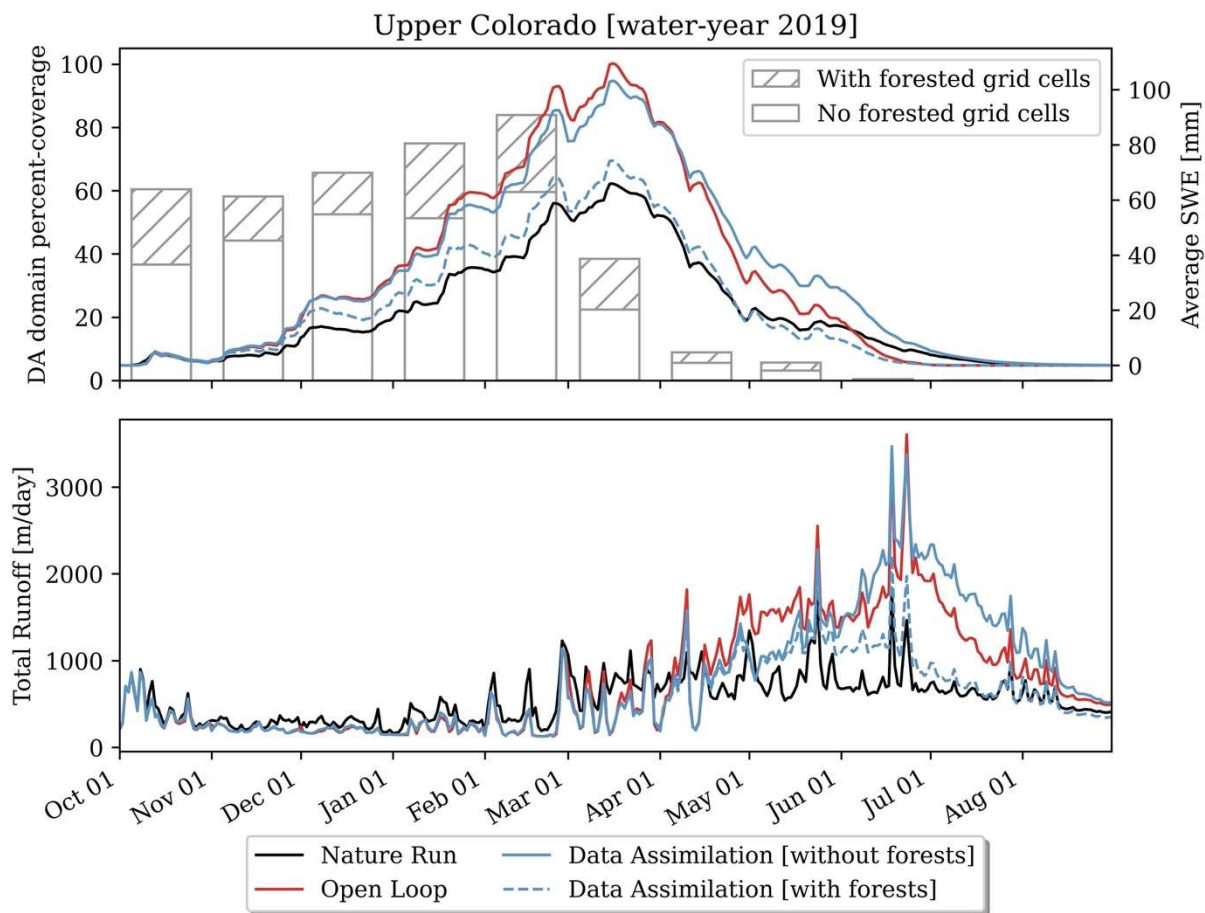

356

357 **Figure 6.** SWE volume on 13 March 2019 broken down by landcover type in subplot a. For each landcover type, the  
 358 interquartile range and median of SWE differences (b) and SWE percent-differences (c) are calculated for the open loop  
 359 simulation (black) and each simulation with data assimilation (blue bars). SWE differences (b) and (c) are calculated relative  
 360 to the nature run.

361 The comparisons above focused on mean DJF SWE and SWE from the date nearest peakmaximum snow volume (13  
 362 March, 2019). However, assimilating the synthetic SWE data also improved estimates of snow water resources throughout  
 363 the duration of the water year, even in periods when most snow-covered regions were experiencing snowmelt and synthetic  
 364 observations were masked. For example, in the Upper Colorado-basin, approximately 75% of the basinregion had DJF snow  
 365 cover with little or no winter snowmelt (Fig. 7). The simulation with data assimilation and the forest strategy substantially  
 366 improved basin-mean SWE evolution in the snow accumulation season in this basinhydrologic region (Fig. 7, October -  
 367 March). However, snowmelt onset in the March, April, and May (MAM) months increased the number of grid cells  
 368 experiencing snowmelt from the open loop model outputs, reducing the number of grid cells across the full Upper Colorado  
 369 Region that could be observed by the synthetic SAR observations to approximately 5%, on average, over this period of time.  
 370 Despite this, since the simulation with data assimilation improved the volume, timing, and spatial distribution of  
 371 peakmaximum SWE, mean SWE evolution tracked the nature run simulation significantly better than the open loop  
 372 simulation in the spring snowmelt period. In fact, relative to the nature run, MAM SWE from the open loop simulations was

373 biased high by approximately 63%, on average, in the Upper Colorado (Table 2). The simulation with data assimilation  
 374 using the forest strategy improved this bias to less than 1%, on average, over the same period. In this study, simulations  
 375 using Noah-MP (open loop and data assimilation simulations) melted snow more rapidly in the later-half of the spring  
 376 snowmelt season than the nature run simulation which evolved SWE using SnowModel (Section 2.1). Therefore, although  
 377 peakmaximum SWE volume, peakmaximum SWE timing, and MAM SWE were improved by data assimilation, the timing  
 378 of snow disappearance for the simulation with data assimilation using the forest strategy was approximately 18 days earlier  
 379 than the nature run in the Upper Colorado.

380  
 381 **Figure 7.** Time series comparison of basin-mean SWE (top) and total runoff (bottom) between the open loop, nature run, and  
 382 simulations assimilating the synthetic observations, both with and without the forest strategy in the Upper Colorado-basin.  
 383 Dashed bars in the top plot represent the monthly percentage of the Upper Colorado grid cells with no snowmelt. Solid bars  
 384 also exclude grid cells with forest coverage.

385 Much like the Upper Colorado-Basin, SWE simulated by the open loop simulation in the Pacific Northwest (Fig. [S5S7](#))  
 386 was biased high for the entirety of the snow season. Both domains also had greater than 80% synthetic snow observation

387 coverage in March (including grid cells that filled snow estimates using the forest strategy), and as a result, the simulation  
388 with data assimilation using the forest strategy closely matched SWE from the nature run. However, both of these domains  
389 had a significant portion of the seasonal snowpack in forested landcover (Fig. 7 and Fig. [S5S7](#), difference between the  
390 hatched and solid bars). These grid cells had winter SWE estimates from the open loop simulation that were predominately  
391 high-biased (Fig. 3 and Fig. 5). Therefore, although data assimilation improved winter SWE in non-forested landcover types  
392 (Fig. 6), the simulation without the forest strategy caused little-to-no improvement in the simulated domain mean  
393 [peakmaximum](#) SWE (Table 2). This highlights the value of the forest strategy used here (Fig. 2), which drew information  
394 from synthetic observations in relatively few nearby pixels to infer the mean snow volume in forested grid cells. Given the  
395 four [basinhydrologic regions](#) investigated in this study, a far smaller volume of snow existed in forested landcover for the  
396 California (Fig. [S6S8](#)) and Great [BasinsBasin regions](#) (Fig. [S4S6](#)), resulting in DJF domain-mean SWE evolution that was  
397 more similar between the simulations with and without the forest strategy. We expect results in these domains to be more  
398 indicative of the value of winter SAR observations in less-vegetated snowy landscapes, such as Tundra and Prairie snow  
399 regimes (Sturm and Liston, 2021).

400 Finally, the improvements to the spatial and temporal estimates of SWE discussed above had trickle-down improvements  
401 on simulated runoff. For example, in the Upper Colorado (Fig. 7), total annual runoff from the open loop simulation was  
402 biased high by approximately 35%, relative to the nature run. This error was driven most by high-biased winter snow  
403 accumulation, which nearly doubled the melt season (March – July) runoff estimated by the nature run simulation. Here, by  
404 assimilating the synthetic SWE observations, and estimating forest snowpack from the relationship between modeled and  
405 observed SWE from the nearest canopy-free pixels, total annual streamflow in this domain was improved to within 1%. Not  
406 only was domain total runoff improved, but the seasonal evolution of high and low-flows vital for water management and  
407 planning was also improved. This improved the Nash-Sutcliffe Efficiency (NSE) from  $-2.59$  to  $0.22$  between the open loop  
408 simulation and simulation with data assimilation employing the forest strategy (Table 2). These results were similar for the  
409 Pacific Northwest, which had an NSE that improved from  $-0.17$  to  $0.39$ . [HereHowever](#), due to the smaller changes to SWE  
410 and more-rapid snowmelt simulated by Noah-MP, changes to runoff from data assimilation in California and the Great Basin  
411 were small (Table 2-), [with improvements that were largely outweighed by the difference in snowmelt timing and rates](#)  
412 [between Noah-MP and SnowModel](#).

#### 413 **4. Discussion**

414 The differences between the open loop simulation and nature run in this study were representative of [typical](#) snow modeling  
415 errors [reported in the literaturecommon for continental and global-scale models used for seasonal to long-term future snow](#)  
416 [predictions](#) (e.g., Franz et al., 2010; Garousi-Nejad and Tarboton, 2022; Kim et al, 2021; [Liu et al, 2022](#)). The greatest source  
417 of these snow modeling errors is commonly errors in meteorological forcing data, and in particular, biases in precipitation

418 (Garousi-Nejad and Tarboton, 2022; Henn et al., 2018; Pflug et al., 2021; Raleigh and Lundquist, 2012; Wayand et al., 2013).  
419 These biases are especially prevalent in the portions of the earth’s surface with the greatest volumes of snow, such as the tundra  
420 and montane regions (Kim et al., 2021), where ground observations and observation station maintenance are hindered by harsh  
421 winter conditions and inaccessibility. This suggests that the greatest need for improving global estimates of snow is improved  
422 estimates of snow accumulation in remote, under sampled landscapes. Here, we expect that the SAR observations evaluated  
423 in this study could address these needs, thus providing a path forward for pairing common snow models with observations as  
424 a basis for determining global snow mass. For example, assimilating SAR observations at 10 – 14 day intervals with the  
425 observational error characteristics reported in Sect. 2.2, improved midlatitude winter SWE volume by approximately 22%, on  
426 average (Table 2). In unforested landscapes, which account for a majority of the Earth’s snow water storage (Kim et al., 2021),  
427 assimilation improved the mean SWE bias at peak-maximum SWE timing to within 1%, on average, and reduced the standard  
428 deviation of errors by approximately 45 mm (~85%) (Fig. 6).

429 Despite the benefits discussed above, SAR observations have known limitations in forested landscapes where the canopy  
430 overstory obstructs retrievals from the underlying snowpack (Huang et al., 2019; Ruiz et al., 2022; Tsang et al., 2022).  
431 Therefore, this study was designed to investigate a forest strategy that uses the relationship between modeled SWE estimates  
432 and synthetic SWE observations from neighboring grid cells as the basis for inferring snow distribution in regions with forested  
433 landcover (Fig. 2). To focus on the benefits of this approach, we chose a domain (Fig. 1) that included both significant forest  
434 spatial coverage (22%) with disproportionate amounts of winter snow (34%) within the forested pixels (Fig. 6). Relative to the  
435 open loop simulation, the simulation with data assimilation and the forest strategy dramatically improved the spatial  
436 distribution of SWE (e.g., Fig. 3 and Fig. 4) and the resulting SWE biases at peak-domain maximum snowpack timing (Fig.  
437 5). In fact, in forested grid cells, SWE on 13 March was only biased by 14 mm (mean absolute error of 27 mm), on average,  
438 for the simulation with data assimilation and the forest strategy, relative to the nature run. This was opposed to the open loop  
439 simulation, which was biased by 87 mm (mean absolute error of 111 mm) over the same regions and date. Despite the fact that  
440 the two simulations with data assimilation agreed in all grid cells except forested grid cells, the simulation employing the forest  
441 strategy had a mean absolute error (17 mm) across the full modeling region that was approximately 51% smaller than the  
442 simulation without the forest strategy. Here, we recognize that this study used a single date (13 March) to represent snow water  
443 resources at maximum SWE timing. However, the date of maximum SWE volume from the nature run varied by less than a  
444 week across the four hydrologic regions (11 - 16 March; Fig. 7, Fig. S6 - S8). Therefore, this was a relevant date for model  
445 comparisons, especially given that water resource and allocation decisions in the Western US are often based on the volume  
446 of snow at maximum snow timing.

447 This research shows how a modeling framework and relatively few observations can be used to gap-fill estimates of snow  
448 in regions where remote sensing observations from a future platform may be most challenged. Despite the fact that snowpack  
449 with properties able to be retrieved by SAR instrumentation (i.e., canopy-free landcover and no snowmelt) sometimes only

450 accounted for only small portions of a modeling domain (e.g., Fig. 7),- SWE from the model and SAR observations in nearby  
451 canopy-free grid cells were predictive of the snow in forested grid cells. We hypothesize that this could have partly been driven  
452 by the 250 m resolution of synthetic observations and simulations. At this length scale, snow distribution is typically driven  
453 by processes like [synoptiemesoscale](#) weather patterns and their interaction (e.g., orographic lapse rates, wind  
454 loading/sheltering, terrain-shading, etc.) with static topographical features like elevation, slope, and aspect (e.g., Clark et al.,  
455 2011; Lehning et al., 2011; McGrath et al., 2018; Minder et al., 2008; Trujillo et al., 2007). However, we acknowledge that  
456 snow in forested and open grid cells is subject to different snow processes. In fact, the nature run simulation used here attempts  
457 to simulate snow-canopy interactions, such as snow interception and solar shading from the canopy overstory (Liston and  
458 Elder, 2006). Here, since we focus predominantly on model improvements from data assimilation in the SWE accumulation  
459 season, we hypothesize that the primary difference between SWE accumulation in forested pixels, and the nearest canopy-free  
460 grid cells could be driven by canopy interception, or the lack thereof. In other words, inferring forested snowpack using the  
461 nearest canopy-free grid cells could bias snow in forested regions where snow processes differ slightly. While the forest  
462 strategy improved SWE simulated in forested grid cells at the date of [peak-maximum](#) SWE volume, SWE was still biased high  
463 relative to the nature run (Fig. 6). We hypothesize that a correction factor, based on variables like forest canopy type, vegetation  
464 density, [wind speed](#), and temperature during snowfall, all of which influence snow interception, ([Lundquist et al., 2021](#)), could  
465 be used to facilitate the difference in snow accumulation expected between a forest pixel and SWE observations from nearby  
466 canopy-free grid cells. This approach will be a topic of future research. However, since errors with precipitation are often the  
467 overwhelming source of model errors, we hypothesize that the forest strategy (Fig. 2), which corrected modeled SWE in  
468 forested areas using the ratio between modeled and observed SWE in nearby open areas, was well-suited to correct precipitation  
469 biases.

470 The results presented here are subject to a number of assumptions. These assumptions were intended to apply regionally-  
471 consistent and conservative rules about how 1) synthetic SAR observations were generated, and 2) the grid cells and time  
472 periods that SAR observations occurred in. For example, we used a 20% and zero-mean random distribution of errors to  
473 generate observations from the nature run. We expect the error from a future satellite mission to be less than 20% over the  
474 majority of snow covered regions (Sect. 2.2). However, observational biases may be more common in certain locations and  
475 periods based on snow depth, particularly in very shallow or very deep snowpacks, terrain characteristics and vegetation  
476 characteristics. Additionally, the landcover classification used in this study (Fig. 1) was based on the dominant landcover type  
477 within each model grid cell, as defined from the North American Land Change Monitoring System (Latifovic et al., 2017). For  
478 forested grid cells, this included needleleaf, broadleaf, and mixed forest types. To be conservative, this study completely  
479 masked synthetic observations in 250 m grid cells classified as forest, thereby assuming 1) no observation capabilities in  
480 predominantly forested areas, and 2) full observation capabilities in grid cells where forests were not the dominant landcover  
481 type. In reality, SAR may be able to achieve accurate snow retrievals in some forested-dominated regions based on the forest  
482 type, forest distribution, and canopy density (Tsang et al., 2022). Conversely, some regions with sparser or no forest cover

483 may still have observation limitations based on the domain and snow characteristics mentioned above. The large domain used  
484 in this study also made tests over multiple years computationally challenging. Here, the intent of this study was to investigate  
485 a strategy for deriving SWE corrections in difficult to observe forest landscapes, and we hypothesize that precipitation biases  
486 and the resulting modeled SWE accumulation could be improved to a similar degree in years with both larger and smaller  
487 snow volumes. Finally, while strategies for identifying and correcting systematic SAR observation errors are a topic of  
488 continued research (e.g., Durand et al., 2023; Singh et al., 2023), OSSEs are an inherently flexible framework for evaluating  
489 sensor utility, so future research could use the simulations performed here to test a wider array of sensor configurations and  
490 non-normal retrieval errors. Future work could build upon these results to investigate multiple years, perhaps considering  
491 warmer and/or drier snow years, when the role of snowpack for water supply and midwinter snowmelt and rain-on-snow  
492 frequency may be more likely to increase snowpack liquid water content, or years with late-season spring snow accumulation.  
493 Future research should also investigate other gap-filling approaches, like methods to infer SWE in grid cells where snowmelt  
494 is occurring and liquid water may prevent SAR retrievals, and gap-filling approaches using different window sizes and/or  
495 searching windows that more heavily weight unforested grid cells with similar characteristics (elevation, aspect, etc.).

496 This study tested a simple model setup using a popular land surface model (Noah-MP) and Kalman-based data assimilation  
497 procedure. This data assimilation procedure updated modeled snow states, like snow depth and SWE, based only on synthetic  
498 SWE observations at 10 – 14 day temporal frequencies where/when snowmelt was not occurring. ~~We~~Despite the limitations  
499 and assumptions discussed above, we expect that the results presented here could represent the lower-bound of performance  
500 that could be achieved from a real-time modeling framework that could accompany a space-borne SAR remote sensing  
501 platform. For example, many studies have demonstrated repeatable patterns of snow accumulation in years with similar winter  
502 meteorological characteristics (e.g., Deems et al., 2008; Pflug et al, 2022; Schirmer et al., 2011; Sturm and Wagner, 2010;  
503 Woodruff and Qualls, 2019). This suggests that retrospective information about snow distribution patterns in previous years,  
504 could be used as the basis for extrapolating and updating snow model states in grid cells not covered by SAR observations on  
505 a given date. From the modeling perspective, only 5 ensemble members were used in the Ensemble-Kalman data assimilation  
506 (Sec 2.3), when a larger ensemble of simulations may have improved uncertainty characterization of simulated snow and  
507 hydrological states even more. This study also assumed that synthetic SAR observations were unable to observe snow in all  
508 forested landscapes, when retrievals of snow in forested stands could be achievable for some forested regions with smaller tree  
509 cover fractions and biomass (Montomoli et al., 2015; Tsang et al., 2022). Finally, the SAR configuration tested here had 10 –  
510 14 day repeat times, but future satellite configurations with more-frequent observational repeats ~~could be possible.~~are possible  
511 and have been recommended by the 2018 Decadal Survey (NASEM 2018). Despite all of these conservative assumptions, the  
512 difference between the open loop simulation (representative of current modeling accuracies), and the simulation with synthetic  
513 observation data assimilation using the forest strategy, demonstrated large-magnitude and widespread improvements to real-  
514 time estimates of winter SWE and the associated improvement to spring SWE and runoff. Therefore, we expect the findings

515 of this study, particularly the strategy to extend the observational utility to forested areas, to significantly aid in the full  
516 exploitation of the information from a future SAR-based snow satellite mission.

## 517 5. Conclusion

518 Global estimates of snow volume and distribution have uncertainties stemming from limited snow observations and  
519 biases in meteorological forcing data. These uncertainties stress the need for a global snow-focused satellite remote  
520 sensing platform. Here, we investigate the degree to which synthetic observations of ~~snow-water equivalent~~ (SWE  
521 representative of a Synthetic Aperture Radar (SAR) remote sensing platform, could correct common snow modeling  
522 errors and provide spatiotemporally continuous SWE estimates. We investigate this using an ~~Observation~~Observing  
523 System Simulation Experiment, specifically investigating how much snow simulated using a ~~popular~~widely used land  
524 surface model and meteorological forcing dataset, could be improved by assimilating synthetic SAR observations of  
525 SWE.

526 The difference between the open loop simulation and the nature run ~~were~~was representative of common modeling  
527 errors. Snow simulated by the open loop simulation had larger winter snow extents, and total snow volume that was  
528 biased high by approximately 35%. The open loop simulation also simulated snow that was more spatially homogeneous,  
529 underestimating the variability across variations in topography and underestimating lower-elevation snowmelt from the  
530 nature run. Assimilating the synthetic SWE observations improved SWE simulated in the shrub, grass, crop, bare-ground,  
531 and wetland land cover types. In fact, SWE biases on the date of domain ~~peak~~maximum SWE volume (13 March 2019)  
532 in these landcover types improved from 14% for the open loop simulation to within 1% after data assimilation. However,  
533 despite only covering 22% of the study area, forested grid cells contained just over 34% of the domain SWE on 13  
534 March. The open loop simulation and the simulation with data assimilation without the forest strategy had SWE that was  
535 high biased by 150% (87 mm), on average, in these forested grid cells. The relationship between modeled SWE and  
536 synthetic SWE observations in forested grid cells exhibited similarities with the nearest canopy-free grid cells. Therefore,  
537 SWE in forested regions was able to be inferred using the simple modeling framework and synthetic SAR observations  
538 from nearby canopy-free grid cells. In fact, the simulation with data assimilation using this forest gap-filling strategy  
539 substantially improved SWE biases to 4% (~22% improvement) at ~~peak~~maximum SWE timing, with a SWE mean  
540 absolute error of 17 mm (24 mm improvement) and spatial correlation of 0.91 (0.17 improvement) across the Western  
541 US

542 Improvements in winter SWE accumulation also improved estimates of melt-season SWE evolution and total runoff  
543 in four major Western ~~United States hydrological basins~~US hydrologic regions, even in periods when winter snowmelt

544 greatly reduced the number of grid cells that could be observed by the synthetic SWE observations. In fact, in the Upper  
545 Colorado River ~~basin~~, melt season SWE biases improved from 63% to less than 1% after assimilation, and the runoff  
546 Nash Sutcliffe Efficiency improved from -2.59 to 0.22. These results demonstrate the value of SAR observations and  
547 simple spatial-filling strategies in grid cells where SAR retrievals could be obstructed by the canopy. Here, we expect  
548 our results to represent a lower-boundary of model performance which could be improved further by more robust  
549 assimilation approaches, more-frequent SAR observations, [further developments to SAR retrieval algorithms in forested](#)  
550 [landscapes](#), and adaptations to the forest gap-filling strategy developed here. However, our results also show that  
551 widespread improvements to global SWE could be available in near real-time provided data assimilation approaches and  
552 a SAR remote sensing platform.

553 *Code availability:* The Land Information System (LIS; [lis.gsfc.nasa.gov](http://lis.gsfc.nasa.gov)) framework used to perform the nature run, open  
554 loop, and data assimilation simulations from this study can be accessed from a GitHub public repository  
555 (<https://github.com/NASA-LIS/LISF>). Model documentation and LIS tutorials can also be accessed from this repository. Users  
556 are encouraged to reference Kumar et al. (2006) for more information on LIS. The Trade-space Analysis Tool for designing  
557 Constellations (TAT-C) tool is currently available on-request for federal employees and contractors  
558 (<https://software.nasa.gov/software/GSC-18399-1>).

559 *Data availability:* The model outputs and data necessary to reproduce the figures and statistics reported in this study can  
560 be found at <https://www.hydroshare.org/resource/e0ad80f818bf4062a335e9e0d7362834/>. This repository includes  
561 domain static variables, such as land cover, elevation, and spatial coordinates, in addition to model outputs of winter-average  
562 SWE, SWE at the date of [peak-maximum](#) SWE volume (13 March 2019), and ~~basin-aggregated~~ SWE and runoff [aggregated](#)  
563 [across each region](#). MERRA-2 forcing data can be accessed from the Goddard Earth Sciences Data and Information Services  
564 Center (GES DISC, <https://disc.gsfc.nasa.gov/>), and ERA5 data can be accessed from the [European Centre for Medium-Range](#)  
565 [Weather Forecasts climate data store \(https://www.ecmwf.int/en/forecasts/dataset/ecmwf-reanalysis-v5\)](#).

566 *Author contributions:* CV and SK coordinated the manuscript question and research methodology. SK adapted LIS model  
567 source code to implement the forest gap-filling strategy in Sect. 2.4. MW set up the model domains and model configurations,  
568 and performed the open loop simulation. EC assisted with generating the synthetic SWE observations. With assistance from  
569 KA, JP performed code developments for the simulations using both the Noah-MP and coupled SnowModel models. KA  
570 implemented the SnowModel code and parameters into LIS and LDT. JP also performed the nature run and both data  
571 assimilation simulations. The manuscript was written provided text, figures, and feedback from all coauthors.

572 *Competing interests:* The authors declare that they have no conflict of interest.

573 *Acknowledgements:* This work was supported by the funding from the NASA Terrestrial Hydrology program. Computing was  
574 supported by the NASA Center for Climate Simulation (NCCS).
