**Abstract.** Explosive eruption events have been clustered by machine learning techniques applied on strain signal recorded by high-precision borehole strainmeters. We focus on the extraordinary intense and frequent eruptive activity at Etna in the period December 2020 – February 2022 when more than 60 lava fountains occurred. We apply the k-means algorithm on the associated strain variations which are representative of the eruptive dynamics. A novel procedure was developed to ensure a high-quality clustering process and obtain robust results. The analysis identified four distinct groups of strain variations which characterize the events in terms of amplitude, and duration and time derivative of the signal. The temporal distribution of the clusters provides useful insights into the evolution of the volcano activity and reveals transitions in the eruptive style.

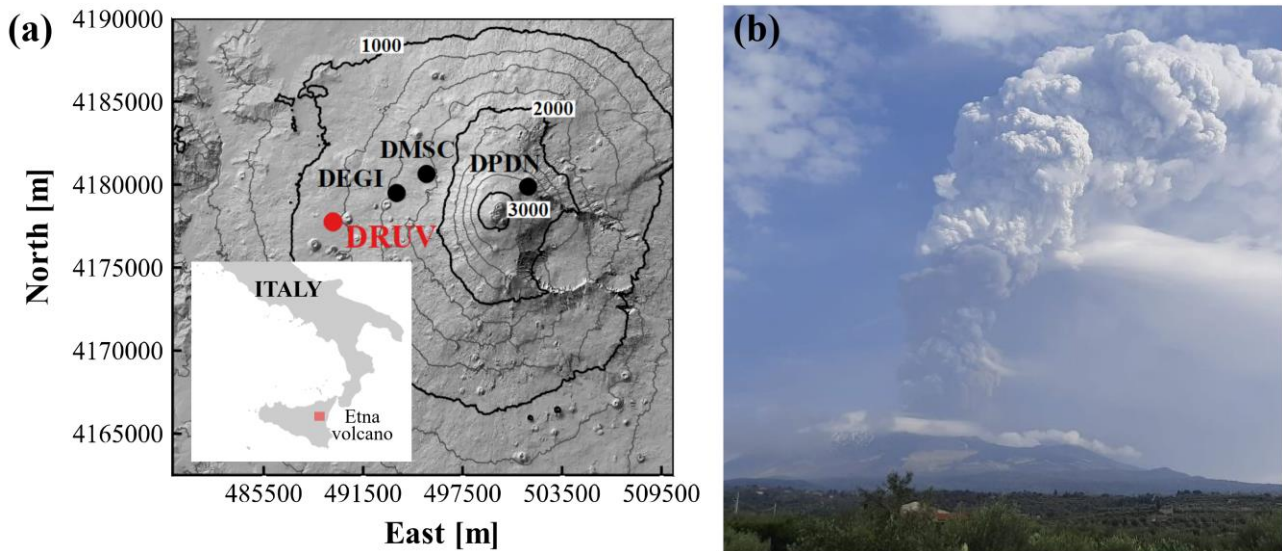

## 1 Introduction

In the last decade, lava fountains represented a typical eruptive style at the Etna volcano (i.e., Calvari et al., 2018; Andronico et al., 2021). These eruptive events are powerful jets that can expel hot mixtures of solid particles and volcanic gases to heights ranging from tens to several hundred meters. The ash dispersal and fall-out deposits of the solid particles, known as tephra, cause critical hazards to civil infrastructures and to aviation, frequently provoking the temporary closure of southern Italy airports. The characterization of such eruptive events is thus fundamental for both monitoring the volcano activity and evaluating the associated hazards.

At Etna, lava fountain events produce short-term and small deformations of the ground (Bonaccorso and Calvari, 2017; Bonaccorso et al., 2013b; Bonaccorso et al., 2016; Bonaccorso et al., 2021) that are well-captured by the Sacks-Evertson dilatometer (Sacks et al., 1971), a widely employed geophysical instrument to study ground deformation processes associated with volcano unrest (i.e. Amoroso et al., 2015; Bonaccorso et al., 2012; Bonaccorso et al., 2020; Linde and Sacks, 1995; Linde et al., 2016; Linde et al., 1993; Voight et al., 2006). This dilatometer is particularly appropriate to monitor lava fountains since it measures the volumetric strain with a very wide frequency range ( $10^{-7}$  to  $>20$  Hz) and with the highest resolution ( $10^{-10}$  to  $10^{-11}$ ) achievable among geophysical instruments (i.e. NASEM, 2017; Roeloffs and Linde, 2007). Other geodetic techniques such as GPS and InSAR are unable to detect the deformations associated with lava fountains because of their lower accuracy (GPS  $> 0.5$  cm) or lower frequency sampling (InSAR periodic passages). These technical characteristics

make the strain measurements fundamental for monitoring lava fountains, especially when images from surveillance cameras  
 30 do not allow the event detection because of poor visibility (Carleo et al. 2022b; Calvari and Nunnari, 2022).  
 From December 2020 to February 2022, Etna underwent an intense eruptive activity with more than 60 lava fountain events  
 from the South East Crater (Calvari and Nunnari, 2022). A variability in terms of duration, degree of explosiveness and  
 portion of effusive flows, has been observed (Calvari and Nunnari, 2022; Calvari et al., 2022), implying a different degree of  
 the hazard associated with these eruptive events. Indeed, the onset and the dynamic of the lava fountain is usually a gradual  
 35 growing process, starting from weak Strombolian activity, continuing with transitional explosive activity, and eventually  
 leading to sustained eruptive columns. The intensity and the duration of these three main phases are not always the same and  
 characterize the temporal evolution of the episodes. A preliminary inspection on the strain signal recorded during the lava  
 fountains reveals a similar pattern for all the events and a strict relationship with their temporal evolution (Bonaccorso et al.,  
 2021; Calvari et al., 2021) allowing tracing the waxing and waning of each episode and marking the onset and the end of the  
 40 eruptions. On average, but not systematically, some differences arise in terms of amplitude and duration of the strain signal.  
 For example, the lava fountains occurring in February – April 2021 were characterized by strain changes with high  
 amplitudes (hundreds of nstrain) and temporal evolutions ranging from tens of minutes to 8-9 hours. Conversely, the strain  
 changes accompanying the eruptions in May – June 2021 were lower in amplitude (tens of nstrain) and developed in  
 intervals from 1 hour to less than 4 hours.  
 45 In the recent past, attempts to classify the lava fountains at Etna have been made manually by experts by comparing different  
 geophysical and volcanological data (i.e. Andronico et al., 2021; Calvari et al., 2022). However, manual classification is time  
 consuming and prone to subjective biases. With the aim of avoiding a classification biased by experts' belief, we investigate  
 whether an objective cluster analysis on the instrumental dataset could help in discovering group of events with similar  
 characteristics. Clustering analyses of monitoring signals have already been performed in volcanology (Cirillo et al. 2022;  
 50 Corradino et al., 2021; Langer et al., 2009; Nunnari, 2021; Romano et al., 2022; Unglert et al., 2016).  
 Here, we made use of clustering techniques applied on the strain variations recorded concurrently with the eruptive episodes  
 from December 2020 to February 2022 in order to derive the key features that characterize the eruptive process and  
 distinguish the events. In particular, we applied the k-means method, a widely employed unsupervised machine learning  
 algorithm to solve clustering problems in several domains (Lloyd, 1982; MacQueen, 1967). One of the drawbacks of such  
 55 algorithm is that the optimal number of the clusters and also the optimal set of key features which lead to a high-quality  
 clustering are not known *a priori*. We developed a procedure to appropriately identify the features and the number of clusters  
 with high cohesion and separation. Moreover, since the clustering solution could depend on the initial position of the  
 barycenter of the clusters (centroids) chosen to start the algorithm (Fränti and Sieranoja, 2019), we also investigated the  
 influence of the initial position of the centroids on the k-means performance by comparing different initialization techniques.  
 60 Lastly, we discuss the implications that this result entails in the assessment of volcanic activity and the associated eruptive  
 style.

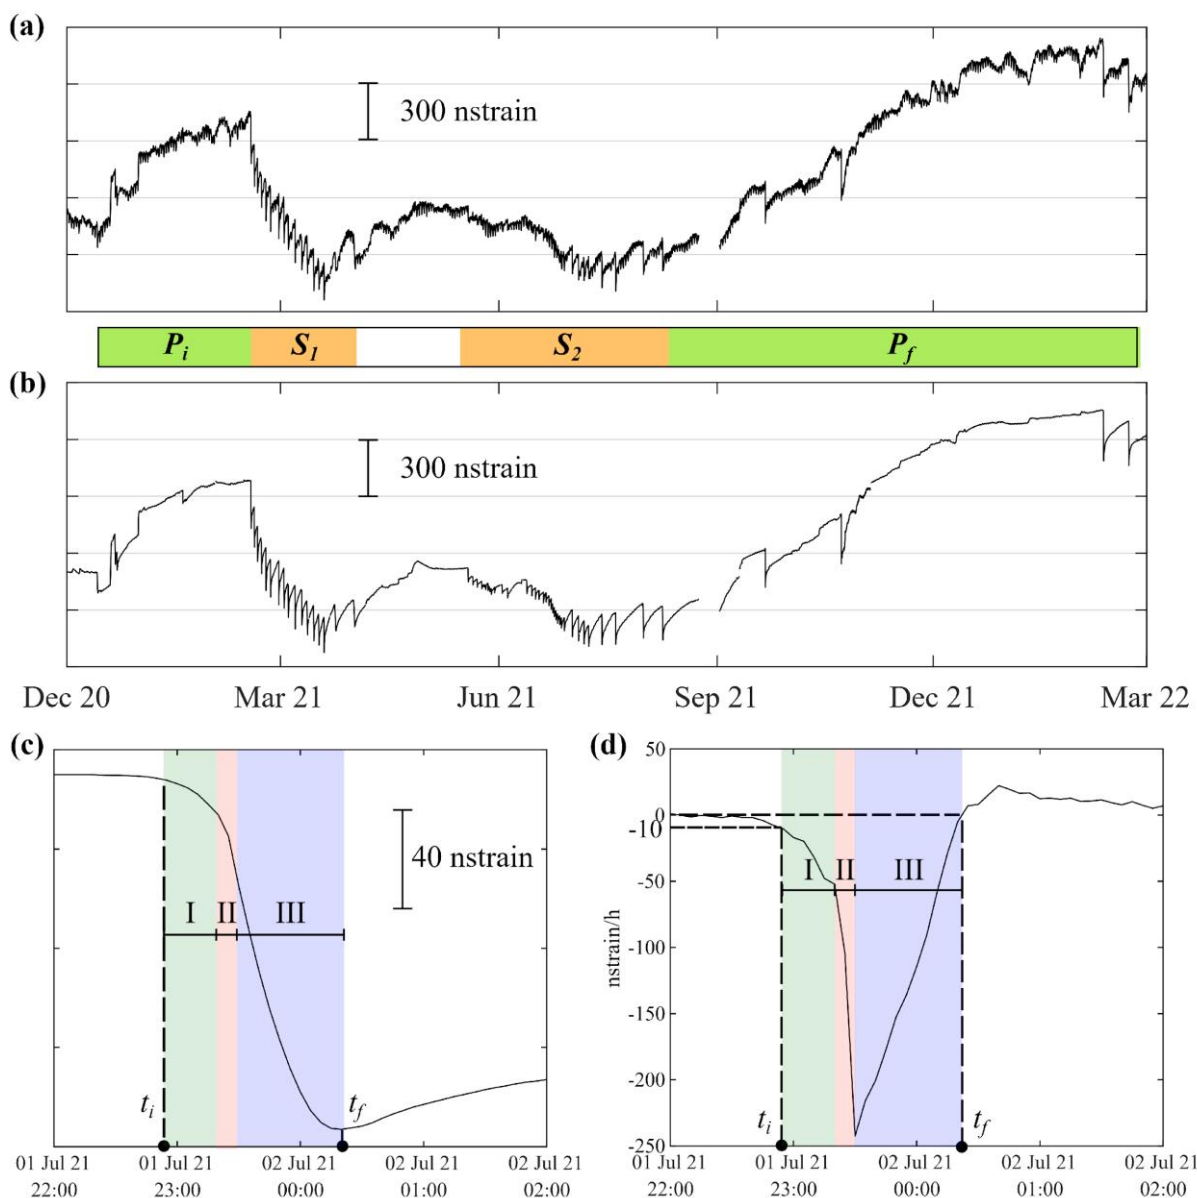

**Figure 1: (a) Location of the borehole strainmeter stations installed at the Etna volcano. The coordinates system is WGS 84 UTM 33. (b) Lava fountain occurring on 23 October 2021 (photo from INGV internal report n° 43/2021).**

## 65 2 Strain changes during the Etna lava fountains in 2020-2022

The December 2020 - February 2022 Etna eruptive activity was extraordinarily intense. It started with four lava fountains from 13 December 2020 to 16 January 2021 (period  $P_i$ ). Successively, a first lava fountain sequence of 17 events took place up to 1 April 2021, with an average frequency of 0.39 events/day (sequence  $S_1$ ). After 49 days of repose, Etna volcano reawakened and a second lava fountain sequence of 34 episodes occurred till 10 August 2021, with a frequency of about 0.42 events/day ( $S_2$ ). Then, the eruptive activity diminished with 5 events occurring from 10 August 2021 to the end of February 2022 ( $P_f$ ).

The borehole strainmeter network, operating at Etna since 2011 (Bonaccorso et al., 2016; Fig. 1), was fundamental in investigating the dynamics of the eruptions (Bonaccorso et al., 2021) and monitoring the eruptive events in near real-time for volcanic surveillance (Carleo et al., 2022b). In this study, we focus on the measurements recorded by the DRUV station, which is located quite far from the summit craters, at ~11 km, and installed in a massive rock layer (at ~180 m depth) guaranteeing high-efficiency in transferring deformation from the rock to the sensor. The strainmeter was calibrated with three different techniques (Bonaccorso et al., 2013a; Bonaccorso et al., 2016; Currenti et al., 2017) that confirmed its high sensitivity ( $\sim 10^{-10}$ ). The DRUV strain signal was filtered from the disturbing effects of both the Earth tides and the barometric pressure to highlight small strain variations related to the volcano activity (Currenti and Bonaccorso, 2019). We used the procedure proposed by Carleo et al. (2022a) to highlight tiny volcano-related strain changes up to  $10^{-10}$  for time scales less than 1 day. Furthermore, we removed the long-term drift component from the strain signal due to the effect of both the curing of the cement and the relaxation of the drilled hole (Canitano et al., 2021).

**Figure 2: The detrended recorded (a) and filtered (b) DRUV signals in the study period. Negative step-like strain variations, clearly detected in the filtered signal, occurred concurrently with the lava fountain episodes. The lava fountains on 29 August and 23 October 2021 were not recorded due to technical problems. The eruptive activity is divided into 4 periods:  $P_i$  (4 events),  $S_1$  (17 events),  $S_2$  (34 events) and  $P_f$  (5 events). The filtered strain signal (c) and the related strain rate signal (d) during the lava fountain on 01 July – 02 July 2021 are shown as an example.  $t_i$  and  $t_f$  indicate the onset and the end of the strain variations. At the beginning of the lava fountain (I), expansion rate gradually increases. In the central part (II), strain rate rapidly reaches its absolute maximum value. The expansion gradually diminishes and the strain rate reaches the pre-event level during the final part of the eruptive event (III).**

In Fig. 2a and 2b, both the recorded and the filtered DRUV signals are presented. Each negative step-like strain variation, clearly visible in the filtered signal, happened concurrently with a lava fountain and correspond to rock expansion around the sensor. The recorded dilatation is the response to the decompression of the magmatic source feeding the lava fountain (Currenti and Bonaccorso, 2019). The near-real time detection algorithm developed by Carleo et al. (2022b) allowed the automatic detection of all the 58 strain variations related to the eruptive episodes in the analyzed period. In Fig. 2c and 2d, the filtered strain signal and its time derivative (strain rate signal) during the lava fountain on 1 – 2 July 2021 are shown as an example of the recorded strain variations. Typically, the strain and the strain rate signals show a sigmoid and a V shape, respectively, which can be described by separating the signals in three parts: in the initial part (I) the strain rate gradually decreases with time and the strain signal shows an elbow with a downward concavity; in the central part (II) the strain rate reaches the absolute maximum value; in the final part (III) the strain rate inverts its trend reaching the pre-event level. We define the onset of the variation  $t_i$  when the strain rate reaches the value of  $-10$  nstrain/h, while the end of the variation  $t_f$  was set when the sign of the strain rate becomes positive.

We characterized each lava fountain event by extracting the main features from both the strain and strain rate signals. In particular, we focused on parts I and II of the signals. Feature extraction transforms each eruptive event into a strain data point in the feature domain which forms a dataset that is going to be clustered.

### 3 Clustering the lava fountain events through the related strain variations

We used the k-means algorithm to characterize the 2020-2022 lava fountain events using the associated strain changes. We varied the inputs of the algorithm, namely the  $k$  number of clusters, the employed set of features and the initial centroid positions. We analyzed the quality of the different clustering solutions by employing two methods, both described in Appendix A: the “Elbow method”, based on the Sum-of-Squared Errors (SSE), and the Silhouette value ( $Sil$ ; Kaufman and Rousseeuw, 2009). An iterative procedure (Appendix B) was developed to find the optimal number of clusters,  $k_{opt}$ , and the optimal subset of features,  $C_{opt}$ , from a set of 15 potential features (Table B1) whose values were previously normalized to warrant a balanced weight in the clustering process (Langer et al., 2020). We compared two different initialization techniques to evaluate the effects of the initial centroid position on the k-means performance: the random centroid (RC) position (MacQueen, 1967) and the method proposed by Yelda et al. (2010) (YC). We repeated the k-means clustering  $n$  times by varying the RC and the YC positions randomly and took the solution with the lowest SSE value. We tested the influence of different values of  $n$  for the quality of the clustering.

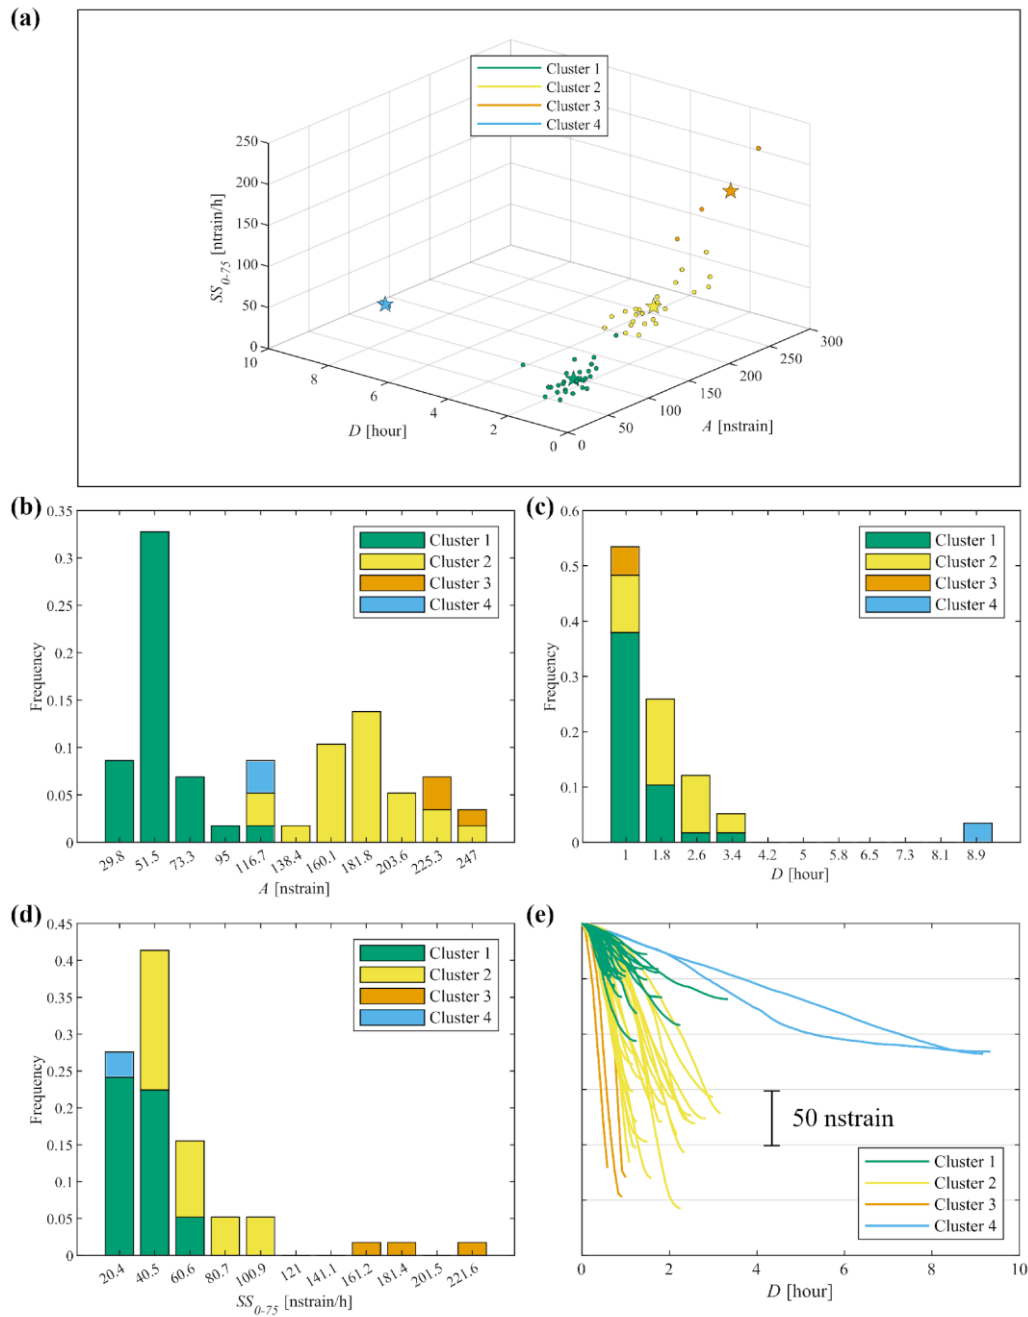

The iterative procedure converged in two steps and provided an optimal subset of features composed by the amplitude  $A$  and the duration  $D$  of the strain variation and the average strain rate in the time window ranging from  $t_i$  to the time when the strain rate reaches the 75% of the minimum strain rate,  $SS_{0.75}$ . The results are presented in Fig. B1. In the  $k - SSE$  plot (Fig. B1a), the elbow of most of the curves is found at  $k = 4$  which can be selected as the optimal number of clusters,  $k_{opt}$ .

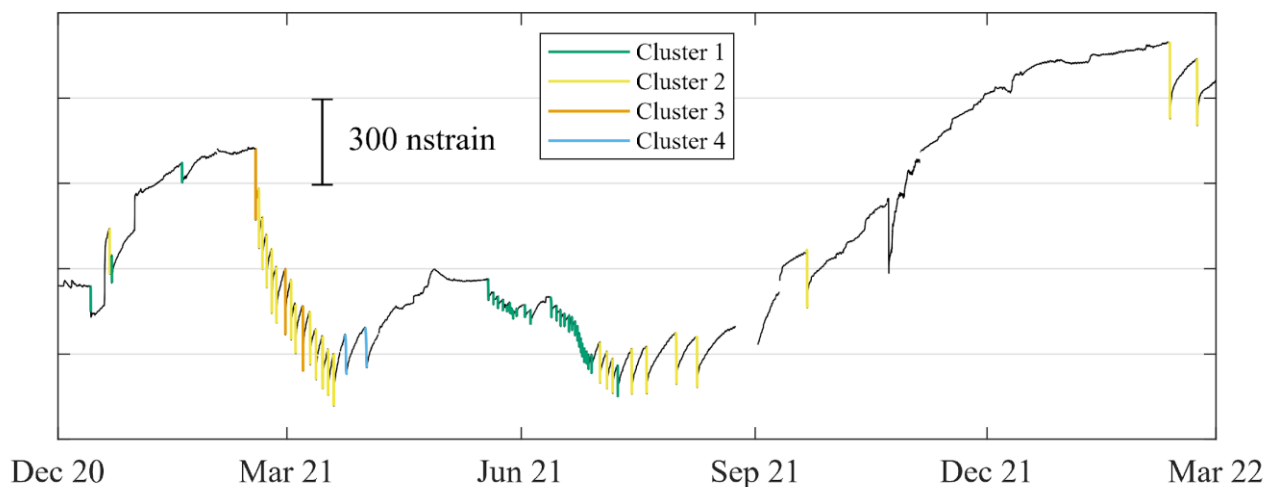

**Table 3: Coordinates of the cluster centroids and mode values of the optimal features for each cluster.**

Clusters	Amplitude $A$ [nstrain]		Duration $D$ [hour]		Strain rate $SS_{0.75}$ [nstrain/h]	
	Centroid	Mode	Centroid	Mode	Centroid	Mode
<b>Cluster 1</b>	50.0	51.5	1.15	0.98	32.5	20.4
<b>Cluster 2</b>	177.5	181.8	1.92	1.78	59.1	40.5
<b>Cluster 3</b>	232.7	225.3	0.83	0.98	187.6	181.4
<b>Cluster 4</b>	116.8	116.7	9.25	8.94	12.3	20.4

The  $Sil$  values are all positives indicating a good clustering for all the strain data points. Moreover, the average Silhouette values for the four clusters are very high and equal to 0.90, 0.71, 0.82 and 0.99, denoting both a high cohesion in the same cluster and a high separation among the clusters (Text B1). The results of the analysis on the influence of the initial centroid position and on the number of repetitions of the k-means algorithm are summarized in Fig. B2. We reported the  $k - SSE$  and the  $k - Sil$  plots related to both the RC and YC positions with value of  $n$  equal to 10,  $10^4$  and  $10^6$ . The  $k - SSE$  plots for the different values of  $n$  (Fig. B2a,c,e) showed notably overlapped curves, indicating that the analyzed initial centroid positions do not affect the shape of the curves and, hence, the choice of  $k_{opt}$  can be easily identified at  $k = 4$ . In Fig. B2b,d,f the number of cluster  $k$  is plotted against the  $Sil$  value for  $n$  equal to 10,  $10^4$  and  $10^6$ , respectively. The figures highlight that a high number of repetitions is necessary to make the clustering independent from the analyzed initialization techniques. Indeed, the  $k - Sil$  curves overlap with  $n$  values higher than  $10^4$  and up to  $k = 4$  which corresponds to  $k_{opt}$ . Therefore, the outputs of the procedure,  $k_{opt}$  and  $C_{opt}$ , can be considered reliable. The mode values of the frequency distributions of the  $C_{opt}$  features are presented together with their centroids locations in Table 1. In Fig. 3a, the strain changes are presented in the  $C_{opt}$  feature domain. A very good clustering can also be observed visually confirming the reliability of the procedure in providing high-quality results. The frequency distribution of the values of the  $C_{opt}$  features,  $A$ ,  $D$  and  $SS_{0.75}$ , are presented in Fig. 3b-d, respectively. In Fig. 3e, all the strain changes are plotted by aligning them with their initial time  $t_i$  for a further visual comparison. The analysis of the distributions of the cluster features allows us to identify the main characteristics of the events. Cluster 1 gathers lava fountain episodes of low strain amplitude and duration and characterized by small initial strain rate changes. All the features of Cluster 1 are located in the lower range of variations. Cluster 2 groups events whose features cover more the intermediate part of their ranges. Cluster 3 gathers events characterized by high deformations evolving in a very short time window, less than 1 hour. Furthermore, the mode value of the  $SS_{0.75}$  feature for Cluster 3 (181.4 nstrain/h; Table 1) is 4.5 to 9 times higher than for the others. Cluster 4 groups the episodes with the highest mode value for the duration feature  $D$ , which is 5 to 11 times higher with respect to the ones related to the other clusters. The mode of the  $SS_{0.75}$  feature in the Cluster 4 shows the lowest value among the clusters.

150 **Figure 3: (a) All the clustered strain data points plotted as circles in the domain of the optimal features: amplitude  $A$ , duration  $D$  and strain rate  $SS_{0.75}$ . Stars represent the cluster centroids. Frequency distribution of  $A$  (b),  $D$  (c) and  $SS_{0.75}$  (d) for the different clusters. Mode values of the distributions are reported in Table 1. In (e), all the clustered strain variations are aligned with the initial time  $t_i$ .**

155 **Figure 4: Temporal distribution of the clusters in the analyzed time period plotted together with the filtered DRUV signal.**

## 4 Discussions and Conclusion

We studied the eruptive activity occurring at Etna in the period December 2020 - February 2022, where a variability in the characteristics of the lava fountain events has been observed (Andronico et al., 2021; Calvari and Nunnari, 2022). A signature of this variability is found in the diversity of the ground deformation response imprinted in the strain signal  
 160 (Calvari et al., 2022). Using the extraordinary 2020-2022 strain dataset, we investigated the use of an automated clustering analysis to provide an objective quantitative measure of similarities and differences of the lava fountain events.

The clustering analysis allows us to methodically identify three key features ( $A$ ,  $D$  and  $SS_{0.75}$ ) that grouped the events in four distinct and coherent clusters. In particular, all the three features are required to distinguish Cluster 1 and 2 from the other clusters, while the  $SS_{0.75}$  and the duration features sharply identify Cluster 3 and Cluster 4, respectively.

165 The clustered events do not occur randomly but are grouped over time as shown in Fig. 4, denoting a transition in the eruptive dynamic. It appears that the clusters have an intimate relationship with the volcanic eruption style. In the period  $P_i + S_I$  (December 2020 – March 2021), Andronico et al. (2021) manually identified three eruption styles classified as transitional activity (TA), sustained lava fountain (LF) and large-scale lava fountain (LSLF). Comparing the strain clustering and the eruption style classification reported in Andronico et al. (2021), we observed an interesting correspondence. The first  
 170 events recorded in  $P_i$  and classified as TA are all grouped in Cluster 1, except the 21 December lava fountain which falls into Cluster 2. Then, in the  $S_I$  lava fountain sequence, the eruptive style turned into LF with episodic LSLF events. As well, the clustering highlights a transition, grouping the  $S_I$  events in Cluster 2 and 3. The three events, that belong to Cluster 3, are all classified as LSLF in Andronico et al., (2021) and occurred closely in time on 16 February, 28 February and 7 March 2021. At the end of  $S_I$  on 23 March and 31 March, two lava fountains belonging to Cluster 4 occurred. Although classified as LF

175 by Andronico et al. (2021), their eruptive behavior, in terms of long duration, large effusive volume emitted (Calvari and Nunnari, 2022) and very low strain-rate, is quite different from other lava fountain events. The clustering analysis on the strain signal is able to distinguish them and highlights the duration as their distinctive feature (Fig. 3a). Indeed, also the analysis of the thermal camera images (Calvari and Nunnari, 2022; in Fig. 13) evidenced their very long duration, well above the average value observed for the others. After a period of repose, the new sequence  $S_2$  restarted in May 2021 with events  
180 belonging to Cluster 1 that slowly over time turned into events belonging to Cluster 2. This transition is in agreement with a variation in the parameters estimated from the thermal camera images (Calvari and Nunnari, 2022).

Summarizing, the automatic clustering on the strain signal recognizes and identifies four classes of lava fountains confirming the three classes manually identified and adding a further class of longer events in Cluster 4. Moreover, the time occurrence of the clustered events is closely linked to the eruptive style evolution observed by the experts. Changes in the eruptive style  
185 are regulated by many interrelated magmatic properties and processes (Cassidy et al., 2018). The exsolved and dissolved gas content, overpressure at depth, magma composition and conduit geometry of the plumbing system, all control the speed at which magma ascends, decompresses and outgasses, and hence, determine eruptive style and evolution. Our findings demonstrate that the clustering analysis on the strain signal may contribute in discovering persistence and transition in the eruptive style and thus may give indirect insights into the evolution of the magmatic plumbing system. A joint analysis,  
190 together with other geophysical, geochemical, volcanological and petrophysical data, may help in confirming the persistence and transition of the magmatic system conditions and in identifying the most likely magmatic properties and/or processes that regulate the lava fountain behavior at Etna volcano.

## Appendix A

The quality of the clustering solutions was evaluated using both the “Elbow method” and the Silhouette value (Kaufman and  
195 Rousseeuw, 2009). The “Elbow method” is one of the most widely used techniques to find the optimal number of the clusters. The key quantity is the *sum-of-squared errors* (SSE), defined as the sum of the squared Euclidean distances between the data points and the centroids to which the data points belong. The k-means algorithm clusters data so that the SSE are as little as possible. Therefore, the less the SSE, the better the clustering. Normally, the higher the number of the clusters  $k$ , the lower the SSE. In a  $k$  - SSE plot, the elbow in the curve represents the optimal number of clusters for the  
200 analyzed dataset and corresponds to the most effective clustering solution in terms of  $k$  and SSE.

The Silhouette value,  $Sil$ , for a single data point is defined as:

$$Sil = \frac{b-a}{\max\{b,a\}}, \quad (A1)$$

where  $b$  is the average distance between the datum and the data of another cluster minimized over the clusters, and  $a$  is the  
205 average distance between the datum and the data within the cluster to which the datum belongs. The  $Sil$  value is a measure of

how much a data point is cohesive within its own cluster (distance  $a$ ) and, at the same time, separated from the other clusters (distance  $b$ ). It ranges from -1 to 1, where -1 corresponds to a completely wrong clustering while 1 to an optimal clustering.

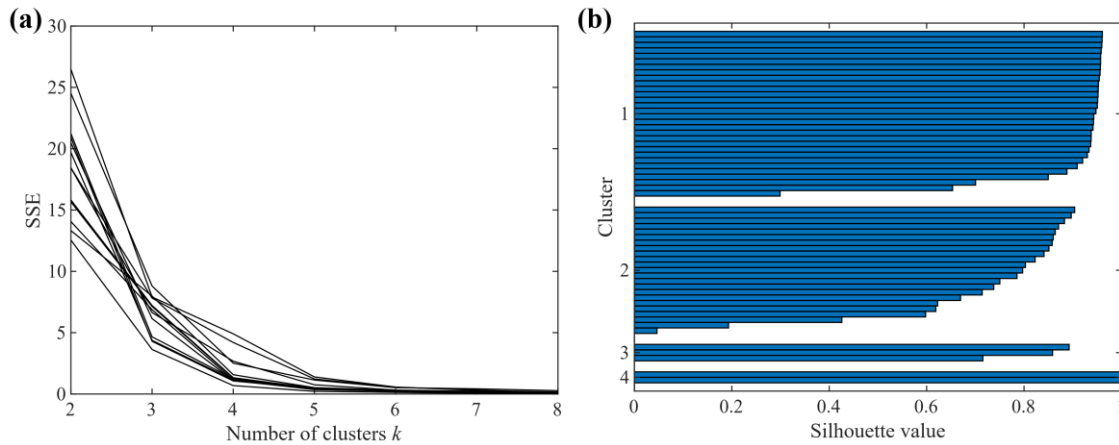

## Appendix B

We developed an iterative procedure to extract an optimal subset of features,  $C_{opt}$ , from a set of 15 potential features  $X = \{X_1, X_2, \dots, X_j\}$ , where  $j$  represents the  $j$ -th feature of  $X$ , (Table B1), and to determine the optimal number of clusters,  $k_{opt}$ . Both the “Elbow method” and the Silhouette value  $Sil$  are used to evaluate the quality of the clustering solutions. The procedure is organized in the following steps:

- 1) create the most basic subset of features  $C_{start}$  composed by the amplitude  $A$  and the duration  $D$  of the strain variation;
- 2) if it is the first iteration of the procedure, the starting subset of feature related to the  $i$ -th iteration,  $C_i$ , is  $C_{start}$  otherwise  
 $C_{i-1,j\_max}$ , defined at point 7);
- 3) consider a new set of features  $X_{left} = X - C_i$ . Create all the possible subsets of features,  $C_{i,j}$ , composed by  $C_i$  plus one feature from  $X_{left}$ ;
- 4) cluster the dataset using  $C_i$  and all the  $C_{i,j}$ ;
- 5) find the optimal number of clusters for the  $i$ -th iteration of the procedure,  $k_{opt,i}$ , by comparing all the  $k - SSE$  curves;
- 6) at  $k_{opt,i}$ , calculate the Silhouette values averaged over the clusters related to  $C_i$  and all the  $C_{i,j}$ ,  $Sil_{a,C_i}$  and  $Sil_{a,C_{i,j}}$  respectively;
- 7) if  $\max\{Sil_{a,C_{i,j}}\} > Sil_{a,C_i}$  then define a new subset of features  $C_{i,j\_max}$  composed by  $C_i$  plus the feature that provides  $\max\{Sil_{a,C_{i,j}}\}$ ; repeat from point 2) to point 7) updating  $C_i$  with  $C_{i,j\_max}$ . If  $\max\{Sil_{a,C_{i,j}}\} \leq Sil_{a,C_i}$ , stop the procedure and take  $C_i$  as the optimal set of features,  $C_{opt}$ , and  $k_{opt,i}$  as the optimal number of clusters,  $k_{opt}$ .

Before proceeding with the analysis, since the features are in different units and ranges, we normalized them in the range [0 1] to ensure a balanced weight in the clustering process (Langer et al., 2020). The initial centroid position was chosen randomly. To have more robust results, for each clustering solution, we performed  $n = 10^4$  repetitions of the k-means, setting different random initial seeds and keeping fixed the other inputs. Then, we chose the solution with the lowest SSE value. The robustness of the choice of  $n$  and of the RC initialization in providing reliable results was then tested.

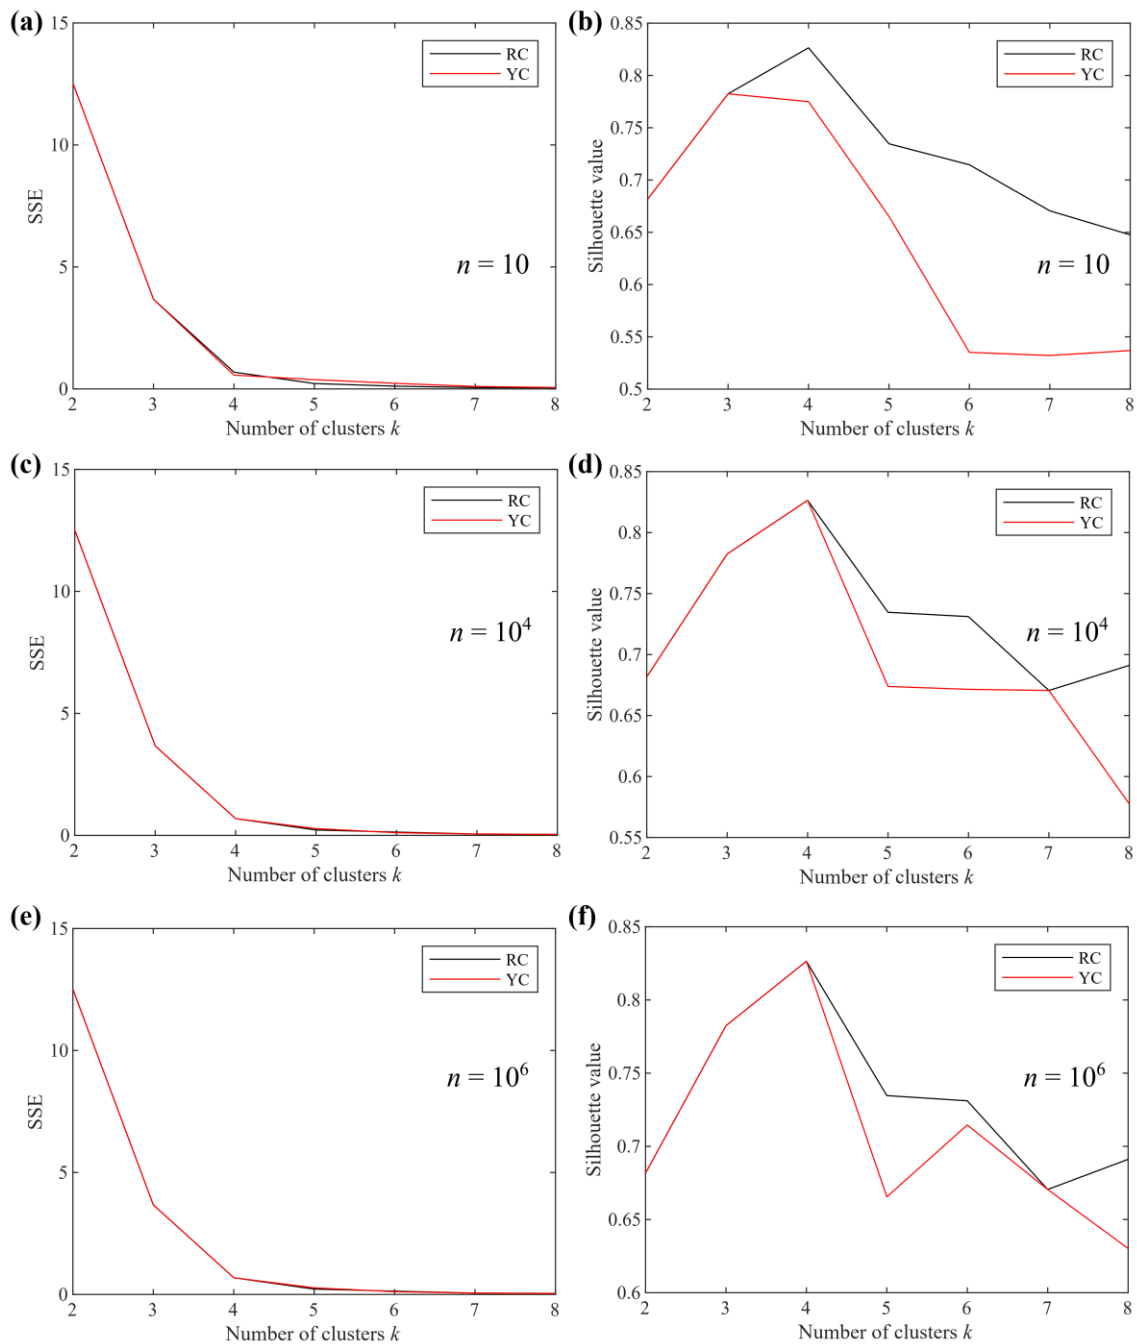

The influence of the initialization was also investigated by comparing two seeding techniques: the random centroid (RC) position (MacQueen, 1967) and the method proposed by Yelda et al. (2010) (YC). The former method is the most popular and consists of locating the centroids randomly in the range of variation of the features, namely, in our case, between 0 and 1. The latter method involves first sorting data points in accordance with their distance from the origin and, then, partitioning them in  $k$  clusters with equal number of sorted points. Yelda et al. (2010) proposed to locate the initial centroid position in the barycenter of each cluster. We introduced more randomness by locating the centroids randomly in each cluster. The tests were performed using the optimal set of features  $C_{opt}$ . To investigate the importance of performing repetitions, we repeated k-means by considering  $n$  in the range [10 10<sup>6</sup>].

240 **Figure B1: (a)  $k$  – SSE curves related to all the clustering solutions analyzed in the last step of the procedure. (b) Silhouette values for the clustering solution obtained with the optimal set of features  $C_{opt}$  and the optimal number of clusters  $k_{opt} = 4$ .**

**Table B1: Features considered in the cluster analysis**

Symbol	Description
$A$	Amplitude of the strain change from $t_i$ to $t_f$
$D$	Duration of the strain change from $t_i$ to $t_f$
$Sr_{min}$	Minimum strain rate from $t_i$ to $t_f$
$SA_{0.75}$	Amplitude from $t_i$ to the instant when 75% of $Sr_{min}$ is reached
$SA_{0.100}$	Amplitude from $t_i$ to the instant when 100% of $Sr_{min}$ is reached
$SD_{0.75}$	Length of the time window from $t_i$ to the instant when 75% of $Sr_{min}$ is reached
$SD_{0.100}$	Length of the time window from $t_i$ to the instant when 100% of $Sr_{min}$ is reached
$SS_{0.75}$	Average strain rate from $t_i$ to the instant when 75% of $Sr_{min}$ is reached
$SS_{0.100}$	Average strain rate from $t_i$ to the instant when 100% of $Sr_{min}$ is reached
$AS_{0.50}$	Average strain rate from $t_i$ to the instant when 50% of $A$ is reached
$AS_{0.75}$	Average strain rate from $t_i$ to the instant when 75% of $A$ is reached
$ASr_{min,0.50}$	Minimum strain rate from $t_i$ to the instant when 50% of $A$ is reached
$ASr_{min,0.75}$	Minimum strain rate from $t_i$ to the instant when 75% of $A$ is reached
$AD_{0.50}$	Length of the time window from $t_i$ to the instant when 50% of $A$ is reached
$AD_{0.75}$	Length of the time window from $t_i$ to the instant when 75% of $A$ is reached

**Figure B2:**  $k$  – SSE and  $k$  –  $Sil$  plots obtained using the optimal set of features  $C_{opt}$ . The SSE and Silhouette values are presented considering the random initial centroid (RC) positions and centroids located as proposed by Yelda et al. (2010) (YC). The results obtained performing a number of repetitions  $n$  equal to 10 (a and b),  $10^4$  (c and d) and  $10^6$  (e and f) are shown as an example.

255 administrated the funding acquisition for conducting the research. All Authors contributed to the writing of the manuscript  
and the discussion of the results.

## Competing interests

The authors declare that they have no conflict of interests.

## Acknowledgements

260 This research benefited from funding provided by the 2019–2021 Agreement between INGV and Italian Presidenza del  
Consiglio dei Ministri, Dipartimento della Protezione Civile (DPC), All. B2 - WP2 - Task 9 and also from the EC H2020-  
FET OPEN project “SiC nano for picoGeo”, grant agreement No. 863220.
