1 **Abstract.** This study develops a quantitative climatology of water vapour exchange between
2 the atmospheric boundary layer (ABL) and free troposphere (FT) over eastern China. The
3 exchange flux is estimated for January, April, July, and October over 7 years based on a water
4 vapour budget equation using simulated meteorological data. The spatiotemporal
5 characteristics and occurrence mechanism of ABL-FT water vapour exchange and its
6 relationship with ENSO are revealed: (1) The vertical exchange flux varies regionally and
7 seasonally, with downward transport to maintain ABL moisture during winter and autumn in
8 the northern region and persistent output to humidify FT in the southern region, particularly in
9 summer. Additionally, the vertical exchange flux is also topographic dependent. (2) The
10 vertical motion at the ABL top, which is produced by the dynamic forcing of the terrain on
11 synoptic winds, is the dominant mechanism for the water vapour vertical exchange over the
12 long-term average. The evolution of the vertical exchange flux within one-day scale is driven
13 by the ABL diurnal cycle. (3) The interannual variation of water vapour vertical exchange is
14 correlated with ENSO. A triple antiphase distribution with negative-positive-negative
15 anomalies from north to south exists in La Niña years (and vice versa in El Niño years), which
16 corresponds to the spatial pattern of anomalous precipitation. This phenomenon is mainly due
17 to the alteration of vertical velocity and water vapour content at the ABL top varying with
18 ENSO phases. These results provide new insight into understanding the atmospheric water
19 cycle.

20 **Keywords:** Water vapour; atmospheric boundary layer; free troposphere; vertical exchange

21 **1 Introduction**

22 Water vapour is a significant constituent in the atmosphere. It directly participates in
23 fundamental physical processes, including cloud formation, precipitation, severe weather
24 development and atmospheric circulation (Sodemann and Stohl, 2013; Wong et al., 2018;
25 Wypych et al., 2018). Water vapour also affects important chemical reactions, such as
26 providing OH radicals for gaseous photochemical transformations and serving as a medium in
27 secondary aerosol formations (Pilinis et al., 1989; Tabazadeh 2000; Wu et al., 2019). Moreover,
28 the radiation forcing of water vapour accounts for about 2/3 of the total natural greenhouse
29 effect, which plays a vital role in climate feedback (Kiehl and Trenberth, 1997; Harries et al.,
30 2008; Adebisi et al., 2015).

31 The distribution of water vapour in the atmospheric system depends on its source and
32 transport processes. In general, water vapour evaporates from the Earth's surface into the
33 atmosphere. From the meridional and zonal view, it presents a transport trend from low latitude
34 to high latitude and from ocean to land. The horizontal transport of water vapour has been
35 widely discussed from multiple scales. Hemispheric-scale atmospheric rivers induce large
36 excursions of high vertically integrated water vapour from the subtropics to high latitudes
37 (Newell et al. 1992; Zhu and Newell 1998; Sodemann and Stohl, 2013). Synoptic-scale
38 moisture flux convergence of extratropical cyclones explains the precipitations and cloud
39 structures over the warm front and cold front (Boutle et al., 2010; Wong et al., 2018). Regional-
40 scale transport processes are widely reported in many areas from water vapour advection and
41 dynamical convergence (Zhou and Yu, 2005; Sun et al., 2010; Gvozdikova and Muller, 2021).
42 However, these studies estimate vertically integrated water vapour through the atmospheric
43 layer (usually from the surface to 300 hPa) or only focused on a certain altitude.

44 The water vapour vertical transport, especially within the troposphere, plays a key role in
45 the atmospheric water cycle. All water vapour in the atmosphere originates from surface
46 evaporation and is first confined in the atmospheric boundary layer (ABL, Boutle et al., 2010),
47 which is defined as the lowest layer of the atmosphere influenced by the Earth's surface (Stull,
48 1988). The water vapour is turbulently mixed in the ABL, making it act as a reservoir. Actually,
49 all water vapour entering and transporting meridionally and zonally in the free troposphere
50 (FT) is initially exported through the ABL (Bailey et al., 2013). In other words, the water
51 vapour exchange between the ABL and the FT is a prerequisite for its large-scale transport and
52 redistribution, as well as interaction with other constituents, in the upper atmosphere. Several
53 studies indicate the importance of this key process on precipitation (Liu et al., 2020), cloud
54 systems (Miura et al., 2007), tropical cyclone formation (Fritz and Wang, 2013), Madden–
55 Julian oscillation (Hirota et al., 2018), West African Monsoon Jump (Hagos and Cook, 2007),
56 and O₃ vertical distributions (Andrey et al., 2014). Therefore, it is of great significance to
57 quantify the vertical exchange of water vapour between the ABL and FT.

58 However, the exchange between the ABL and FT is not straightforward, both for water
59 vapour and air mass. Although the diurnal variation of the ABL depth allows air constituents

60 to be entrained into and left out of this layer within its variation range, the actual exchange
61 between ABL and FT is small on the time scale of more than one day due to the cancelling
62 effect (Hov and Flatoy, 1997; Jin et al., 2021). The current studies on water vapour vertical
63 transport are mainly limited to complex terrain areas or special convective events. The
64 local/mesoscale circulation induced by orographic thermal and dynamic effects is considered
65 a key process for ABL ventilation (Kossmann et al., 1999; McKendry and Lundgren, 2000;
66 Dacre et al., 2007). Henne et al. (2005) found that there were elevated moisture layers in the
67 lower free troposphere in the lee of the Alps resulting from mountain venting. On average for
68 the 12-year period, ~30% of the water vapour of the Alpine boundary layer was vented to the
69 FT per hour during the daytime, which makes the total precipitable water within the elevated
70 moisture layer increase by ~1.3 mm. Another simulated study indicates that the moisture
71 exchange between the ABL and FT of mountainous topography can be about 3–4 times larger
72 than the amount of moisture evaporated from the surface in a specific ventilation event (Weigel
73 et al., 2007). The convective system, mainly mesoscale deep and shallow convection, is another
74 important factor leading to the vertical transport of water vapour. The isotope observations
75 show that the moisture transport pathways to the subtropical North Atlantic FT are linked to
76 dry convection processes over the African continent which effectively injects humidity from
77 the ABL to higher altitudes (Gonzalez et al., 2016; Dahinden et al., 2021). The water vapour
78 budget of the free troposphere of the maritime tropics shows that 20% of this source comes
79 from vertical convective transport (Sherwood, 1996). On the other hand, an idealized
80 simulation suggests that the warm conveyor belt ascent and shallow convective processes
81 contributed about equally to FT moisture (Boutle et al., 2010, 2011).

82 Though for these studies, general characteristics of long-term and wide-ranging ABL-FT
83 water vapour exchange are still unknown. These characteristics are closely bound up with the
84 atmospheric energy flow and the entire climate system, affecting clouds, precipitation and
85 radiation (Sodemann and Stohl, 2013; Wong et al., 2018; Wypych et al., 2018). For example,
86 small variations in upper atmospheric humidity over a large space-time scale can cause
87 systemic changes in the hydrological cycle and atmospheric circulation (Minschwaner and
88 Dessler, 2004; Sherwood et al., 2010; Allan, 2012). The climate state of water vapour vertical
89 exchange flux is critical for quantifying these specific effects. To fill this knowledge gap, the
90 present study calculates the water vapour exchange flux between the ABL and FT for 7 years
91 (2011&2014-2019) over eastern China (20-42°N, 108-122°E) to establish the first quantitative
92 climatology view on this issue. The water vapour budget method is used, with the mesoscale
93 meteorological simulation providing input data. January, April, July, and October, respectively
94 representing winter, spring, summer, and autumn, are considered to discuss the seasonal
95 characteristics. Interannual differences are analysed by investigating the impact of El Niño and
96 La Niña events. On the basis of understanding the foundational features, we further attempt to
97 discuss the role of ABL-FT water vapour exchange playing in anomalous precipitation. The
98 arrangement of this paper is as follows. Data and methods are described in Section 2. The
99 seasonal characteristics and mechanism analysis, interannual variability and the relation with

100 anomalous precipitation are presented and discussed in Section 3. Finally, the findings of this
101 study are summarized in Section 4.

102 **2 Data and methods**

103 **2.1 Observation data**

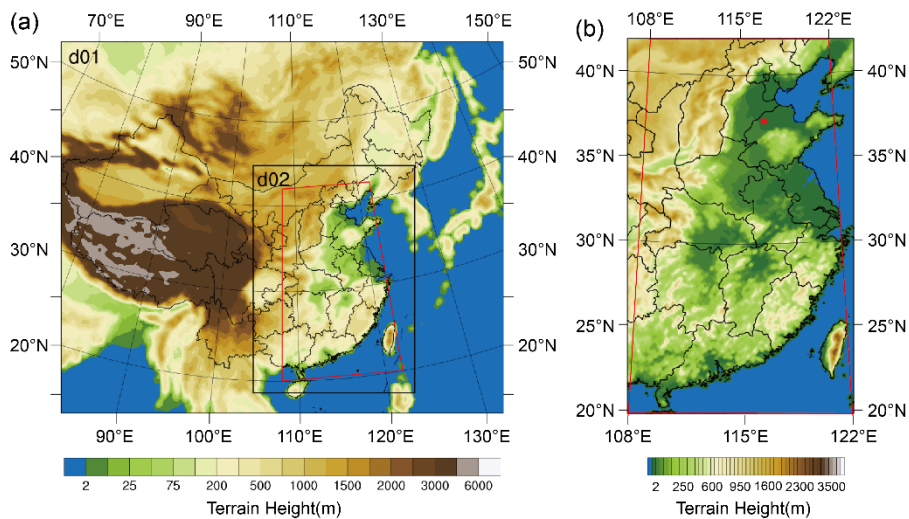

104 Intensive ABL sounding data and routine surface meteorological data were used to
105 evaluate the performance of the Weather Research Forecast (WRF) model that provided the
106 input data for estimating exchange flux.

107 Intensive ABL sounding data: Two field experiments of intensive GPS (Global
108 Positioning System) sounding were carried out in Dezhou (37°16' N, 116°43' E), located in the
109 middle of the North China Plain (NCP) (Fig. 1b), from December 25, 2017, to January 24,
110 2018, and from May 14 to June 14, 2018. Eight soundings were taken for each day, at 02:00,
111 05:00, 08:00, 11:00, 14:00, 17:00, 20:00 and 23:00 LT (i.e., UTC + 8). GPS radiosonde
112 (Beijing Changzhi Sci and Tech Co. Ltd., China) was used to obtain profiles of wind,
113 temperature and humidity with the ascending velocity being about 3-5 m s⁻¹. We eliminated
114 the outliers from the original data and averaged the profiles to an effective vertical resolution
115 of 10 m. ABL heights were determined with these data via the potential temperature profile
116 method (Liu and Liang, 2010). The reliability of the GPS sounding data has been systematically
117 evaluated by Li et al. (2020) and Jin et al. (2020).

118 Routine surface meteorological data: The hourly surface data of 137 routine observatories
119 distributed within the research domain were collected from the Chinese National
120 Meteorological Center. The dataset included information on wind speed and direction, air
121 temperature, relative humidity, air pressure, cloud coverage and precipitation, which was used
122 to evaluate the WRF simulation.

123 **2.2 Three-dimensional meteorological simulation**

124 The WRF model was conducted to provide three-dimensional meteorological data for the
125 estimation of ABL-FT water vapour exchange flux. Two nested domains (Fig. 1a) were
126 employed with horizontal grid lengths of 30 and 10 km, respectively. The inner covered eastern
127 China (20–42°N, 108–122°E), the main research region for the ABL-FT water vapour
128 exchange in the present work (Fig. 1b). Each domain had 37 vertical layers extending from the
129 surface to 100 hPa, with the vertical resolution being about 20-30 m below 200 m, increasing
130 to ~100 m at 750 m, ~250 m at 2000 m, ~350 m at 3000 m, ~600 m at 5000 m, ~900 m at 8000
131 m, ~1300 m at 11000 m and gradually enlarging to the top of the model. There were 24 layers
132 within 3 km to resolve the ABL and its upper FT. The meteorological initial and boundary
133 conditions were set using the US National Center for Environmental Prediction Final Analysis
134 (NCEP-FNL) dataset.

135

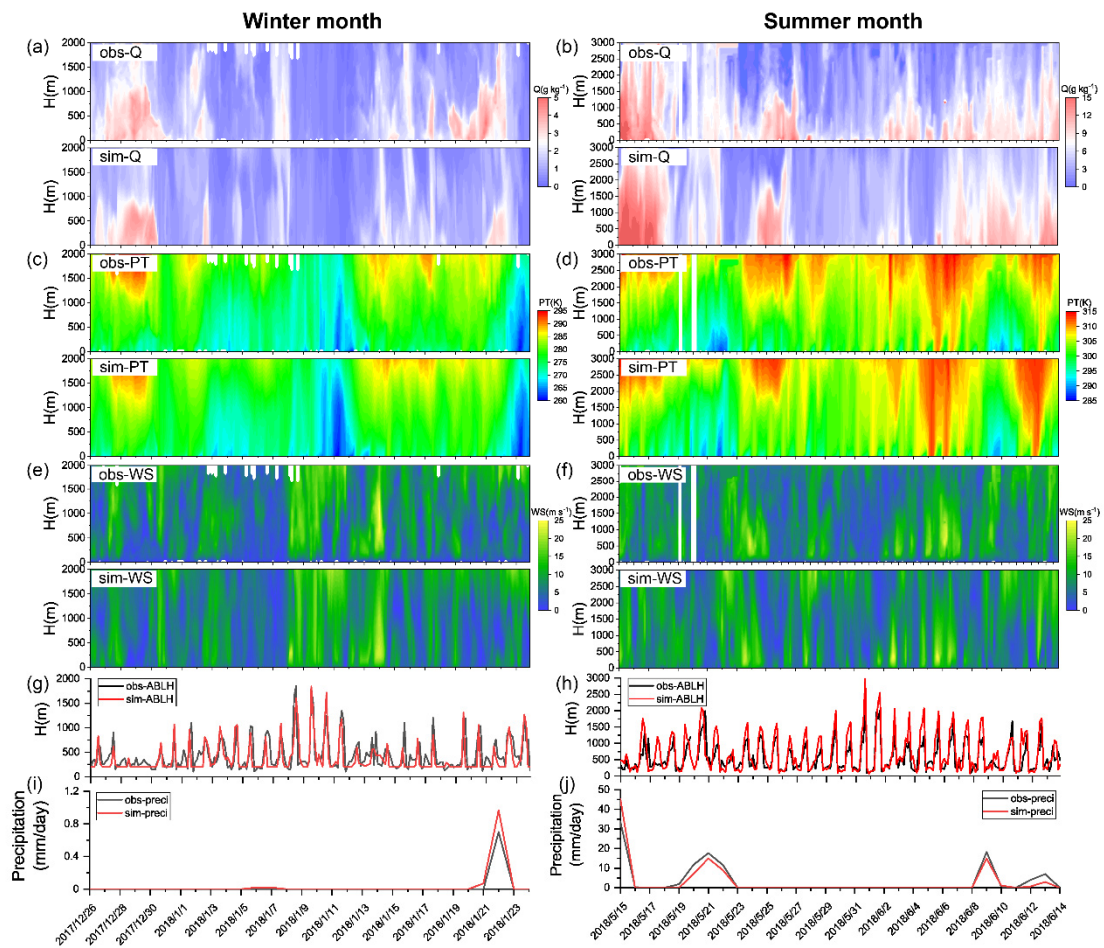

136 Figure 1. Geographical map of (a) the Weather Research and Forecast (WRF) model domains (d01 and
 137 d02) and (b) the amplified research domain (marked with red lines). The map uses the Lambert
 138 projection with the centre meridians of 108°E in (a) and 115°E in (b). The red dot in (b) indicates the
 139 intensive GPS sounding observatory.

140 In order to adequately reproduce water vapour distribution and to correctly estimate the
 141 ABL-FT exchange flux, sensitivity simulations were carried out to choose reasonable physical
 142 parameterization schemes. We focused on the microphysical and cumulus parameterizations
 143 that are the most relevant to the moisture simulation. Microphysics in the model includes
 144 explicitly resolved water vapour, cloud and precipitation processes. Cumulus schemes are
 145 responsible for the sub-grid scale effects of convection and/or shallow clouds. Vertical fluxes
 146 due to unresolved updrafts and downdrafts are represented. Lin et al. scheme (Lin et al., 1983)
 147 and WRF Single-Moment 6-class (WSM6) scheme (Hong and Lim, 2006) in microphysics
 148 parameterization, and Grell-Devenyi (GD) ensemble scheme (Grell and Devenyi, 2002) and
 149 Kain-Fritsch (KF) scheme (Kain, 2004) in cumulus parameterization were compared, which
 150 were most commonly used in previous moisture simulation studies (Perez et al., 2010;
 151 Gonzalez et al., 2013; Jain and Kar, 2017; Qian et al., 2020). Other physics parameterization
 152 schemes used in this study included the Yonsei University PBL scheme (Hong et al., 2006),
 153 the Noah land surface Model (Chen and Dudhia, 2001), the Dudhia shortwave radiation scheme
 154 (Dudhia, 1989), and the rapid radiative transfer model (Mlawer et al., 1997) for longwave
 155 radiation. WRF simulations were initialized at 00 UTC on the day and there was a 12-h spin-
 156 up time before the start of each 48-h simulation. Domain outputs were sampled every hour for
 157 the whole simulation period (January, April, July, and October in 2011 and 2014-2019).

158 These schemes were evaluated by comparing simulated and observed specific humidity,
 159 temperature and wind speed, from their near-surface temporal evolution and vertical spatial
 160 structure. Another two key parameters, ABL height and precipitation were also concerned: the
 161 former directly affects the exchange flux results, and the latter characterizes the moisture
 162 budget. The hourly averages of model outputs were extracted from the grid points nearest to
 163 the observed sites for comparison. In the vertical direction, the modelled and sounding data

164 were simultaneously interpolated into the same height with 10 m intervals ranging from 50 m
 165 to 3 km. Note that the ABL height was diagnosed with the potential temperature profile method
 166 both for the simulations and for observation data, rather than using the default bulk Richardson
 167 number method in the YSU scheme.

168 The results of sensitivity experiments showed that there were no appreciable differences
 169 among various microphysical and cumulus parameterization schemes (Table S1 and S2). In
 170 comparison, the combination of the WSM6 scheme and GD scheme performed better in
 171 humidity simulation and was more effective in reproducing temperature, wind speed and ABL
 172 height, especially in summer (Table S2). Therefore, these schemes were used in the present
 173 study. Its simulation performance determines the reliability of the calculated flux results and
 174 thus a comprehensive evaluation is provided here. The spatial-temporal evolutions of modelled
 175 and observed meteorological fields are presented by the height-time cross sections of specific

176
 177 Figure 2. Observed and simulated time-height cross-sections of (a-b) specific humidity, (c-d) potential
 178 temperature, (e-f) wind speed, and temporal evolution of (g-h) ABL height and (i-j) daily cumulative
 179 precipitation at the Dezhou site (37.27°N, 116.72°E) during winter (from December 26, 2017, to
 180 January 24, 2018) and summer (from May 15, 2018, to June 14, 2018) months of intensive GPS
 181 sounding field experiment. The time resolution of sounding data in (a-h) is 3-hr. The Y-axis scales are
 182 different in the winter panel and the summer panel.

183 humidity, potential temperature and wind speed, as well as the ABL height and precipitation
 184 (Fig. 2). During the winter and summer months of the intensive GPS sounding, the simulated
 185 atmospheric thermal and dynamic structures were comparable with observations. The
 186 alternating between dry and wet atmospheric states (Fig. 2a-b), formation and decay of upper
 187 temperature inversion (Fig. 2c-d), and vertical location and temporal transition of the strong
 188 and weak wind layers (Fig. 2e-f) were successfully reproduced. Accordingly, a good
 189 correlation between the simulated and observed ABL height was achieved, both in terms of
 190 diurnal variation and synoptic evolution lasting several days (Fig. 2g-h). The correlation
 191 coefficients were 0.71 and 0.84 during wintertime and summertime, respectively. It should be
 192 mentioned that there was a slight discrepancy in the modelled ABL heights (mean biases are
 193 about -70 m and 120 m in winter and summer), which may further affect the identification of
 194 other parameters (such as the wind component) at the ABL top and lead to uncertainty in the
 195 calculation results. This impact will be quantitatively analysed in the discussion section.
 196 Another concerned meteorological factor, the daily cumulative precipitation was also
 197 evaluated, which showed a consistent evolution in observation and simulation (Fig. 2i-j) with
 198 correlation coefficients as high as 0.99 and 0.91 ($p < 0.05$) in winter and summer respectively,
 199 demonstrating that the moisture budget is accurately captured by the WRF simulations.
 200 Overall, the model showed the ability to capture the major variation of observed atmospheric
 201 thermal-dynamical structures reasonably, which ensures the validity of the meteorological
 202 inputs for the ABL-FT exchange flux calculation.

203 **2.3 ABL-FT water vapour exchange flux**

204 Similar to mass vertical exchange (Sinclair et al. 2010; Jin et al., 2021), the estimation of
 205 ABL-FT water vapour exchange flux in this study was based on an ABL water vapour budget
 206 equation established by Boutle et al. (2010):

$$\begin{aligned}
 207 \quad \frac{\partial}{\partial t} \left(\int_0^h \rho q dz \right) = & - \left(\frac{\partial}{\partial x} \int_0^h \rho q u dz + \frac{\partial}{\partial y} \int_0^h \rho q v dz \right) + (\rho q)_h \left(\frac{\partial h}{\partial t} \right) \\
 208 \quad & - (\rho q)_h (\vec{U} \cdot \vec{n})_h - (\overline{\rho w' q'})_h + (\overline{\rho w' q'})_0 + P, \quad (1)
 \end{aligned}$$

209 where ρ is air density, q is water vapour mixing ratio, h is the ABL height, $\vec{U} = (u, v, w)$ is
 210 wind vector, $\vec{n} = \left(-\frac{\partial h}{\partial x}, -\frac{\partial h}{\partial y}, 1\right)$ is the unit normal vector perpendicular to the ABL top
 211 surface, w' and q' are the fluctuation values of vertical velocity and water vapour content
 212 respectively. P is the precipitation. Subscripts h and 0 indicate quantities at the ABL top and
 213 the surface. The first term on the right side of Eq. (1) represents horizontal
 214 convergence/divergence within the ABL, the second term indicates the local change in ABL
 215 depth, the third term indicates vertical advection across the ABL top, the fourth and fifth terms
 216 are turbulent transport at the ABL top and the surface respectively, and the last term indicates
 217 the net precipitation falling through the ABL.

218 Denoting the water vapour vertical exchange flux between the ABL and FT as F (positive
 219 values represent upward transport), it can be further written as:

$$\begin{aligned}
220 \quad F &= -((\rho q)_h \left(\frac{\partial h}{\partial t} \right) - (\rho q)_h (\vec{U} \cdot \vec{n})_h - (\overline{\rho w'q'})_h) \\
221 \quad &\approx -((\rho q)_h \frac{\partial h}{\partial t} + (\rho q)_h \left(u_h \frac{\partial h}{\partial x} + v_h \frac{\partial h}{\partial y} \right) - (\rho q)_h w_h). \quad (2)
\end{aligned}$$

222 Since turbulent transport between the ABL and FT is typically related with dryer air that does
223 not affect the total moisture content, $(\overline{w'q'})_h$ is usually considered to be a negligible
224 contribution to the ABL-FT water vapour exchange flux (Boutle et al., 2010). Specifically, the
225 finite difference method was adopted for calculation with the time step being 1 hr, and the
226 horizontal dimensions of the model grid being 10 km. The ABL heights were obtained from
227 the hourly output of the WRF model. Other variables at the ABL top were extracted from the
228 nearest model level above the ABL height (there is no significant difference between these
229 extracted values and those interpolated to the ABL top). It is clear that the water vapour vertical
230 exchange flux between the ABL and FT is determined by i) the local temporal variation of
231 ABL height, $\frac{\partial h}{\partial t}$, allowing the water vapour entrained into the ABL or left in the upper
232 atmosphere; ii) the spatial variation of the ABL, making water vapour horizontally advected
233 across an inclined ABL top; and iii) the vertical advection motion, carrying water vapour
234 downward/upward through the interface between the ABL and FT. These three flux
235 components are denoted as F_{local} , F_{hadv} , and F_{vadv} , and their contributions and evolutions will
236 be discussed in the following.

237 **3 Results and discussion**

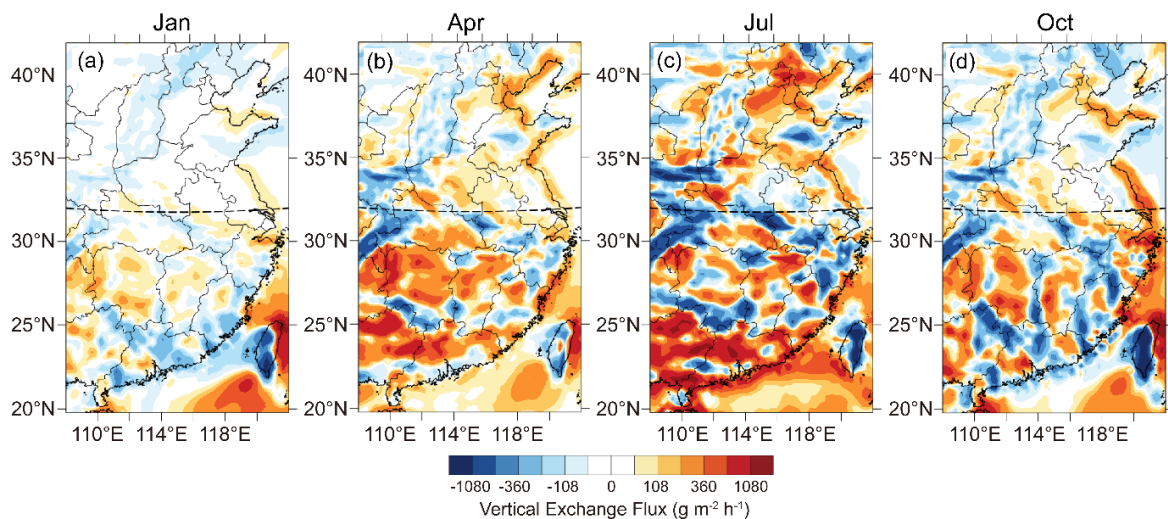

238 The present study is based on a 7-year flux calculation. The years 2011&2014-2019 are
239 selected for analysis, which includes typical La Niña, El Niño, and neutral years (Marchukova
240 et al., 2020; You et al., 2021; Felix Correia Filho et al., 2021), and are considered to be valid
241 and concise datasets to reflect the characteristics of water vapour exchange between the ABL
242 and FT. Their climatic representativeness is demonstrated using a long-term historical dataset
243 provided by the fifth generation ECMWF (European Centre for Medium Range Weather
244 Forecasts) reanalysis (Hersbach et al., 2023, download from the website
245 <https://cds.climate.copernicus.eu/cdsapp#!/dataset/reanalysis-era5-pressure-levels?tab=form>).
246 We compare the features of key meteorological elements during the study period (2011&2014-
247 2019) and over the past 30 years (1990-2019) by the Kolmogorov-Smirnov test (K-S test) and
248 histogram analysis. Temperature, three-dimensional wind component, specific humidity both
249 near the surface and at the upper level, as well as the ABL height and precipitation, are
250 concerned. The K-S test indicates that there is no significant difference (with a confidence level
251 of 95%) between the 7-year sample period and the 30-year historical dataset for these variables
252 (Table S3). The histogram analysis further illustrates that their normalized frequencies in the
253 research samples are similar to those in the long-term historical data (Fig. S1). Also, the annual
254 variation of the two sets of data presents a high consistency, with similar mean values and
255 standard deviations (Fig. S2). The above analysis verifies that the 7-year samples adopted in

256 this study can represent the long-term climatology, and be promising to obtain climatic features
 257 of water vapour exchange between the ABL and FT. The basic temporal and spatial patterns,
 258 influencing mechanism, and relationship with ENSO and extreme precipitation are revealed as
 259 follows.

260 3.1 Seasonal generality and variability

261 3.1.1 Spatial distribution

262 Figure 3 shows the spatial distribution of water vapour exchange flux between the ABL
 263 and FT in the research domain (20-42°N, 108-122°E, marked by red lines in Fig.1), averaged
 264 over all 7-year (2011, 2014-2019) for January, April, July, and October. It is obvious that the
 265 ABL-FT water vapour exchange in the south and north of the research domain is different,
 266 because they are affected by subtropical and temperate climates, respectively (Domroes and
 267 Peng, 1988; Zheng et al. 2013; Zhang et al., 2020). Therefore, the southern (20-32°N, 108-
 268 122°E) and northern (32-42°N, 108-122°E) regions are divided for analysis (the boundary is
 269 marked in Fig. 3). The water vapour exchange is more active in the southern region with more

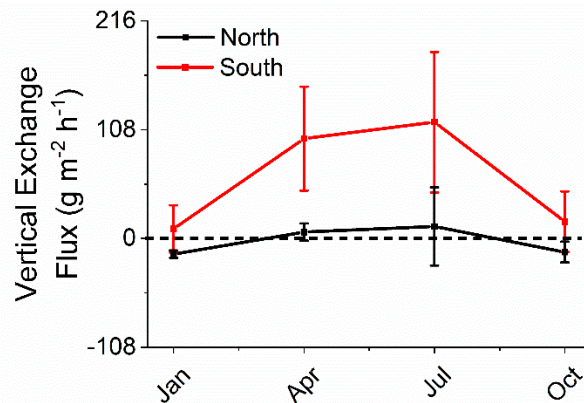

270 Figure 3. Spatial distribution of ABL-FT water vapour exchange fluxes in eastern China, averaged over
 271 7 years for (a) January, (b) April, (c) July, and (d) October. Black dashed lines mark the boundary
 272 between the northern (32-42°N, 108-122°E) and southern (20-32°N, 108-122°E) regions. Positive and
 273 negative fluxes (warm and cool colours) represent water vapour upward and downward transport at the
 274 ABL and FT interface.
 275

276 pronounced spatial variability, and tends to output from the ABL. In the northern region,
 277 vertical exchange fluxes and spatial differences are relatively small. From another perspective,
 278 the vertical exchange of water vapour is closely related to the topographic distribution (Fig.
 279 1b), which is manifested as strong exchange activities usually occurring around mountainous
 280 or coastal areas, both in the northern and southern regions. This feature is similar to the spatial
 281 pattern of the air mass exchange flux between the ABL and the FT indicated by Jin et al. (2021).
 282 It is the result of the dynamical interaction of topography on the synoptic system, and thermal

283 property difference over the heterogeneous underlying surface (Kossmann et al., 1999; Dacre
 284 et al., 2007; Jin et al., 2021). These phenomena will be detailedly explained in the mechanism
 285 analysis in Sect. 3.2.

286 3.1.2 Seasonal difference

287 Corresponding to Fig. 3, the spatial means of ABL-FT water vapour exchange flux and
 288 their seasonal evolutions for northern and southern regions are shown in Fig. 4. They are
 289 obtained by grid averaging in the ranges of 32-42°N, 108-122°E and 20-32°N, 108-122°E,
 290 respectively. Obviously, the exchange flux varies from season to season in both regions. For
 291 the northern region, winter and autumn (represented by January and October, respectively) are
 292 characterized by water vapour transport downward from the FT into the ABL, with the spatial
 293 mean fluxes of -15.6 and $-18.8 \text{ g m}^{-2} \text{ h}^{-1}$ ($1 \text{ g m}^{-2} \text{ h}^{-1} = 10^{-3} \text{ mm h}^{-1}$) and the standard deviation
 294 of 3.6 and $8.6 \text{ g m}^{-2} \text{ h}^{-1}$ over 7 years. While in spring and summer (represented by April and
 295 July, respectively), the northern region as a whole presents an upward export of water vapour
 296 from the ABL to the FT, with the regional mean fluxes being 6.4 and $11.9 \text{ g m}^{-2} \text{ h}^{-1}$. They are
 297 characterized by more significant inter-annual variations than the exchange fluxes in the cold
 298 seasons. In the southern region, the water vapour vertical exchange is featured with ABL output
 299 in all seasons, with a winter minimum and a summer maximum. The mean upward fluxes vary
 300 greatly, showing one order of magnitude greater in April and July (99.1 and $115.51 \text{ g m}^{-2} \text{ h}^{-1}$)
 301 than in January and October (9.6 and $16.7 \text{ g m}^{-2} \text{ h}^{-1}$), accompanied by the larger standard
 302 deviation (50.4 and $68.4 \text{ g m}^{-2} \text{ h}^{-1}$). The notable interannual variability in the warm season may
 303 be related to the ENSO phenomenon, which will be discussed in the following section.

304
 305 Figure 4. Seasonal variation of average ABL-FT water vapour exchange fluxes and their standard
 306 deviations over the northern region (32-42°N, 108-122°E) and southern region (20-32°N, 108-122°E)
 307 during 7 years. Positive and negative fluxes represent water vapour upward and downward transport
 308 between the ABL and FT.

309 In order to better understand the magnitude of water vapour exchange between the ABL
 310 and FT, we compare the transport flux with the surface evaporation rate (Table 1). It indicates
 311 the “emission intensity” of water vapour from the surface, which varies in different regions and
 312 seasons. The surface evaporation rates in the northern and southern regions have maximums in

313 summer ($122.4 \text{ g m}^{-2} \text{ h}^{-1}$ and $194.4 \text{ g m}^{-2} \text{ h}^{-1}$) and minimums in winter ($21.6 \text{ g m}^{-2} \text{ h}^{-1}$ and 108.0
314 $\text{g m}^{-2} \text{ h}^{-1}$). Obviously, the evaporation in the north is weaker than that in the south, especially
315 in winter, it is only one-fifth of that in summer. Consequently, for the northern region, during
316 the cold seasons with the dry land surface, the ABL-FT water vapour exchange is downward
317 and the input flux is 37%-72% of the surface evaporation rate. Although the specific humidity
318 decreases with height, counter-gradient transport still occurs reasonably because the ABL-FT
319 exchange is a typically non-local mixing process (Stull 1988; van Dop and Verver, 2001;
320 Ghannam et al., 2017). This suggests the ABL is a net moisture sink of upper layer FT air,
321 which plays a role in maintaining water vapour within this layer. As surface evaporation
322 intensifies in the warm months, water vapour is exported from the ABL in April and July, and
323 the upward flux accounts for 10% of the evaporation rate. In the southern region with relatively
324 strong evaporation, the ABL water vapour is always transported upward to the FT. The output
325 flux is about 10% of the evaporation rate in January and October, and this ratio is as high as
326 60%-80% in April and July, indicating that the ABL acts as an effective water vapour source
327 to the upper atmosphere.

328 Table1. Comparison of ABL-FT water vapour exchange flux ($\text{g m}^{-2} \text{ h}^{-1}$, positive for upward, negative
329 for downward) and surface evaporation rate ($\text{g m}^{-2} \text{ h}^{-1}$, positive for upward) in the northern and southern
330 regions.

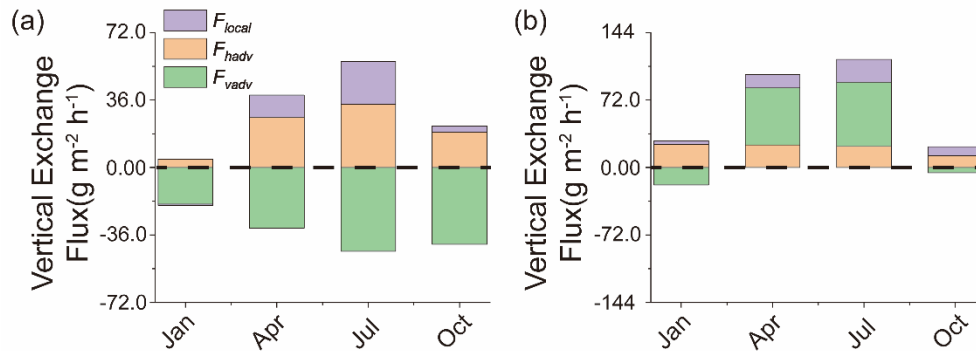

Region	Process	Jan	Apr	Jul	Oct
North	ABL-FT exchange	-15.6	6.4	11.9	-18.8
	Surface evaporation	21.6	61.2	122.4	50.4
South	ABL-FT exchange	9.6	99.1	115.5	16.7
	Surface evaporation	108.0	115.2	194.4	144.0

331 3.2 Main influential mechanism

332 As shown in Eq. (2), three physical terms contribute to the total ABL-FT exchange, i.e.,
333 the local temporal variation of ABL height (F_{local}), the horizontal advection across the spatial
334 inclined ABL top (F_{hadv}), and the vertical motion through the ABL-FT interface (F_{vadv}). It is
335 of interest to clarify the specific effects of these factors on water vapour vertical exchange and
336 their seasonal characteristics. Results of the monthly mean and diurnal cycle over the 7 years
337 are presented below respectively.

338 The monthly mean results show that the term F_{vadv} is the most significant to total ABL-
339 FT moisture exchange flux (Fig. 5, green bar). In the northern region, this term produces
340 persistent downward flux ($-19.5 \sim -44.7 \text{ g m}^{-2} \text{ h}^{-1}$, Fig. 5a), which substantially offsets the
341 upward flux caused by the other two terms, so that the ABL water vapour presents net input
342 during cold months (i.e., January and October) and weak output in warm seasons (i.e., April
343 and July). For the southern region, it induces small downward fluxes in January and October
344 (-18.6 and $-5.5 \text{ g m}^{-2} \text{ h}^{-1}$) while large upward flux in April and July (60.7 and $68.6 \text{ g m}^{-2} \text{ h}^{-1}$),

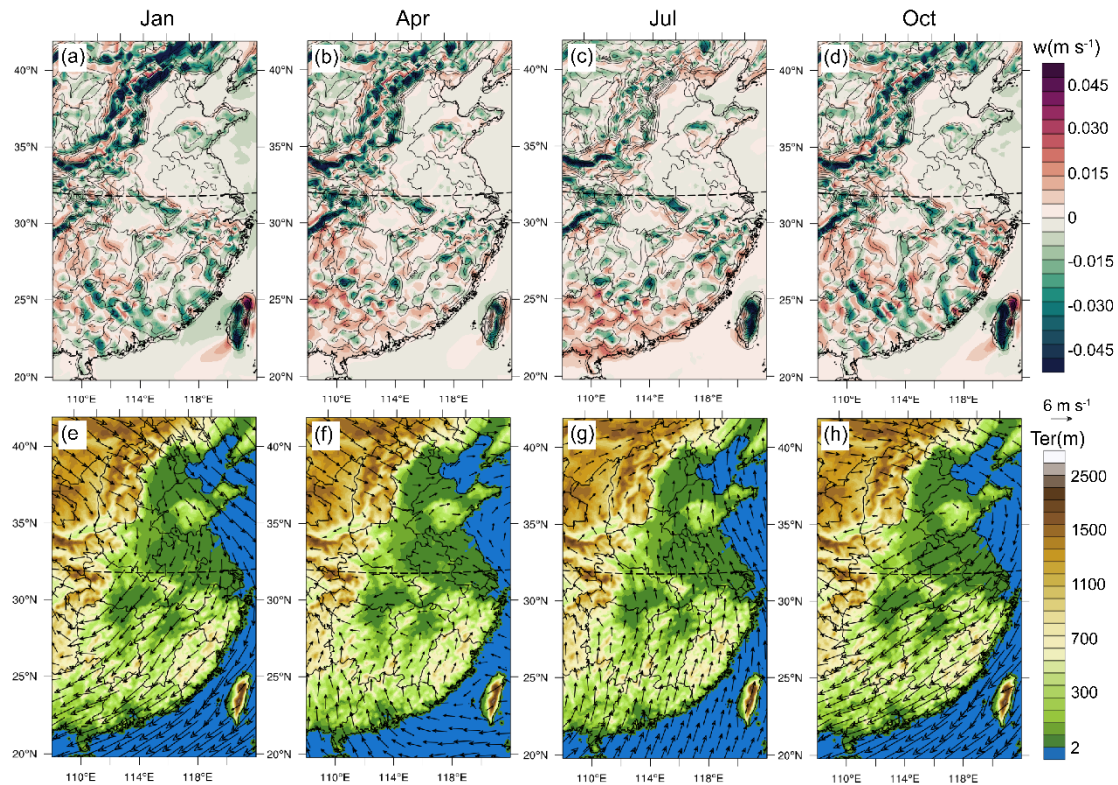

345 which results in the total water vapour exchange as weak and strong output from the ABL
 346 during cold and warm months, respectively (Fig. 5b).

347
 348 Figure 5. Contributions of three components (F_{local} , F_{hadv} , and F_{vadv}) to the total ABL-FT water
 349 vapour exchange flux. Results are spatial mean over the (a) northern (32-42°N, 108-122°E) and (b)
 350 southern (20-32°N, 108-122°E) regions of eastern China respectively. F_{local} : local temporal variation
 351 of ABL height (purple bar); F_{hadv} : advection across the spatial inclined ABL top (yellow bar); F_{vadv} :
 352 vertical motion through the ABL-FT interface (green bar). Positive and negative fluxes represent water
 353 vapour upward and downward transport between the ABL and FT. The Y-axis scales are different in
 354 (a) northern and (b) southern regions.

355 The upward/downward transport of water vapour caused by the term F_{vadv} depends on
 356 the direction of the vertical motion. The spatial distributions of the vertical velocity are
 357 presented in Fig. 6, accompanied by horizontal wind fields at the ABL top, as well as terrain
 358 heights. The upward motions usually occur on the windward of the mountains, while the
 359 descending velocities appear on the leeward side, in each season. This is attributed to the
 360 dynamic forcing of the terrain on seasonal mean winds. Due to the alternation of winter and
 361 summer monsoons throughout the year, the vertical motion pattern varies accordingly in four
 362 representative months (Fig. 6a-d). In the winter, the Siberian high invades from the northwest
 363 and forms strong northerly winds (Fig. 6e). In the northern region, the prevailing northwest
 364 airflows overcome the obstruction of Taihang Mountain and intensely descend on its leeward
 365 side (Fig. 6a). As the air migrates south, the dominant airflow deflects northeasterly (Fig. 6e),
 366 and the vertical motion manifests more upward velocities in front of the major mountainous
 367 region, and more downward velocities behind these mountains (Fig. 6a). During the summer,
 368 southerly air flows dominate eastern China and gradually weaken from south to north (Fig. 6g).
 369 The southern region is characterized by obvious forced uplift on the windward side of the major
 370 mountains (Fig. 6c). The onshore airflow convergence of the prevailing southerly winds in
 371 coastal areas also produces upward motions (Fig. 6c). These factors are conducive to the
 372 vertical output of ABL water vapour in the southern region during warm months. The northern
 373 region is less invaded by the summer monsoon: only the eastern part of the NCP is affected by
 374 southerly winds to induce upward motion in the piedmont, while the western part is still
 375 dominated by westerly winds leading to systematic subsidence (Fig. 6c, g). The general
 376 patterns of vertical velocity fields provide an explanation for the water vapour exchange fluxes
 377 caused by the term F_{vadv} . It is noticed that, although the ABL-FT water vapour exchange fluxes

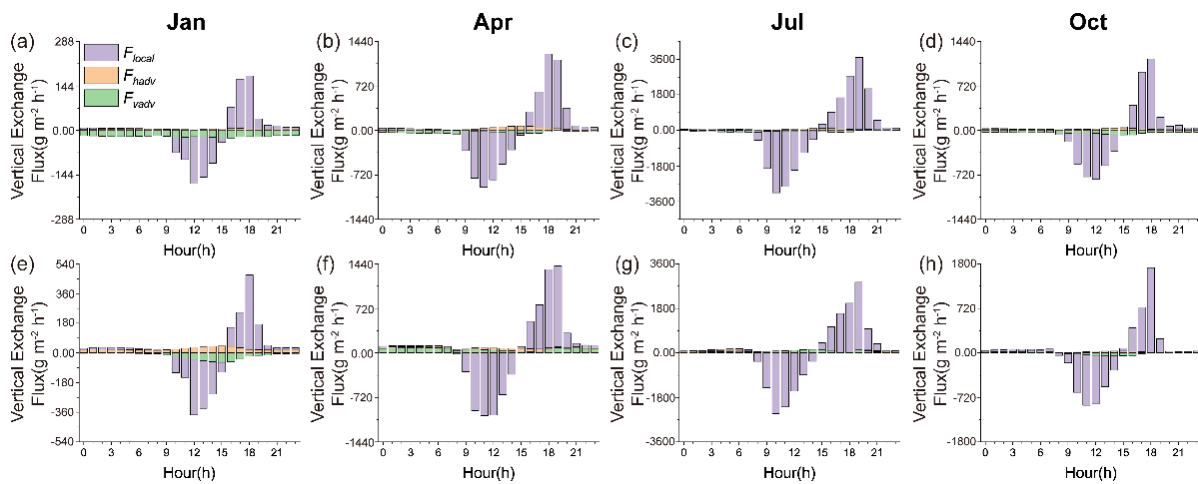

378 in Fig. 3 are averages over 7 years, there still exists obvious spatial heterogeneity. Smooth
 379 variations in both the mean wind field (Fig. 6e-h) and mean ABL height (Fig.S5) indicate these
 380 two factors are not related to the flux heterogeneity. But there indeed exists discontinuous
 381 structures in the vertical velocity fields at the ABL top (Fig.6a-d), which is significant to water
 382 vapour exchange flux. There can be smaller-scale secondary vertical motion being stimulated
 383 when prevailing airflows encounter diverse terrains (Fig. S4). Multiscale dynamical
 384 interactions between complex terrain and synoptic processes should be of great significance to
 385 the water vapour exchange between the ABL and FT.

386
 387 Figure 6. Spatial distribution of (a-d) vertical velocities at the ABL top and (e-h) terrain height
 388 superposed with horizontal wind vectors averaged over 7 years for January, April, July, and October.
 389 Positive values represent upward motions and the contours in (a-d) represent the terrain height. Black
 390 dashed lines mark the boundary between the northern (32-42°N, 108-122°E) and southern (20-32°N,
 391 108-122°E) regions.

392 The horizontal advection term F_{hadv} tends to allow water vapour to be out of the ABL
 393 and the magnitude increases in spring and summer (Fig. 5, yellow bar). This water vapour
 394 exchange component mainly occurs in the mountain-plain transition zone and the land-ocean
 395 boundary (Fig. S3e-h), where the ABL is unevenly distributed due to the heterogeneous surface
 396 properties (Fig. S5). During the warm season, the thermal difference is more obvious with the
 397 solar radiation strengthening and thereby with larger spatial variation of the ABL, especially
 398 in the northern region. This explains the seasonal variation of the water vapour exchange flux
 399 caused by the term F_{hadv} .

400 The temporal ABL height variation term F_{local} contributes relatively less to the total water
 401 vapour exchange (Fig. 5, purple bar). Noticeably, this average flux component is positive,
 402 being negligible in autumn and winter ($0.7\sim 3.3\text{ g m}^{-2}\text{ h}^{-1}$), but becoming relatively pronounced
 403 in spring and summer ($12.0\sim 24.5\text{ g m}^{-2}\text{ h}^{-1}$). This is inconsistent with the air mass exchange
 404 between the ABL and FT, in which the monthly average flux caused by this term is always
 405 insignificant because the ABL entrainment and detrainment of the air mass cancel out each
 406 other in a diurnal cycle (Jin et al., 2021). To understand more details of the term F_{local} in the
 407 ABL-FT water vapour exchange, the mean diurnal variation of the exchange flux is derived
 408 and shown in Fig. 7.

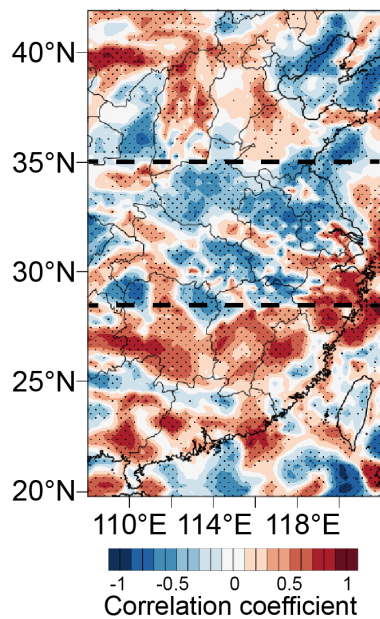

409
 410 Figure 7. Diurnal variation of the three exchange flux components (F_{local} , F_{hadv} , and F_{vadv}) over the
 411 (a-d) northern region (32-42°N, 108-122°E) and (e-f) southern region (20-32°N, 108-122°E) averaged
 412 for (a, e) January, (b, f) April, (c, g) July, and (d, h) October. F_{local} : local temporal variation of ABL
 413 height (purple bar); F_{hadv} : advection across the spatial inclined ABL top (yellow bar); F_{vadv} : vertical
 414 motion through the ABL-FT interface (green bar). Positive and negative fluxes represent water vapour
 415 upward and downward transport between the ABL and FT. The Y-axis scales are different in different
 416 months and different regions.

417 At a first sight of the daily cycle, F_{local} is the absolutely dominant term in all seasons and
 418 both northern and southern regions (Fig. 7, purple bar), corresponding to the diurnal variation
 419 of the ABL height (shown in Fig. S6). When the unstable ABL develops in the morning, the
 420 water vapour in the residual layer is entrained into the ABL; while as the daytime ABL
 421 collapses in the later afternoon, a large part of water vapour is left aloft the newly formed stable
 422 ABL. Note that, unlike the air mass exchange at the ABL top, the water vapour entrained
 423 (input) flux is less than the output flux, especially in spring and summer. This difference can
 424 be attributed to the fact that the surface is, in general, a continuous evaporation source
 425 throughout a diurnal cycle. Turbulent mixing brings water vapour upward in the ABL depth,
 426 and forms a net upward flux across the ABL top. This is also the reason why a larger magnitude
 427 of F_{local} exists in the warm seasons when there is stronger surface evaporation. Although the
 428 ABL temporal variation term F_{local} dominates the diurnal variation of the total ABL-FT

429 moisture exchange flux, it contributes only a weak net output of water vapour in a monthly
430 average flux, in comparison with the vertical motion term F_{adv} , as mentioned above.

431 3.3 Interannual variability and its relation with ENSO

432 A climatic mean of the ABL-FT water vapour exchange over eastern China is presented
433 above. Critically linked to the atmospheric water cycle, the exchange flux and its interannual
434 variation are of great interest. It is well known that the atmospheric water cycle is significantly
435 affected by El Niño and southern oscillation (ENSO), which is a joint phenomenon of the ocean
436 and the atmosphere appearing as a recurring anomaly of the sea surface temperatures in the
437 tropical Pacific and a seesaw of sea level pressure anomalies between Tahiti and Darwin. The
438 El Niño (warm phase) and La Niña (cold phase) are the two extremes of ENSO (Walker and
439 Bliss, 1932, 1937; Kousky et al., 1984; Wolter and Timlin, 2011). Considerable work has been
440 conducted on the relationship between ENSO and wet and dry variability, water vapour
441 horizontal transport, and precipitation events (Diaz, 2000; Knippertz and Wernli, 2010; Felix
442 Correia Filho et al., 2021). However, little is known about the ABL-FT water vapour exchange
443 during ENSO events. Here we take July as the research object, the month with the largest
444 variability (shown in Fig. 4), to investigate the interannual difference of ABL-FT water vapour
445 exchange fluxes affected by the ENSO phenomenon.

446
447 Figure 8. Spatial distribution of correlation coefficient between the water vapour exchange flux
448 anomalies and Niño-3.4 index in July for 7 years. The dots indicate statistically significant grids and
449 the black dashed lines indicate the triple distribution.

450 The correlation between the water vapour exchange flux anomalies and the Niño-3.4 index
451 during the study period (2011&2014-2019) is quantitatively calculated. The former (anomaly
452 or variability) is derived from the difference of each year with the 7-year average, and the latter
453 is obtained from the website https://psl.noaa.gov/gcos_wgsp/Timeseries/Nino34/, representing

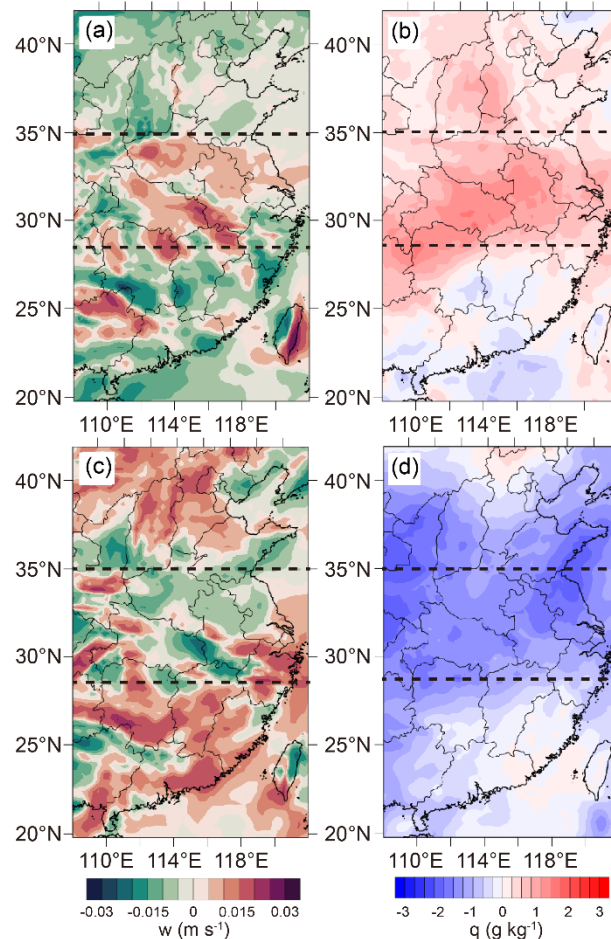

454 the average equatorial sea surface temperature across the Pacific from about the dateline to the
 455 South American coast (5°N-5°S, 170°W-120°W), which is the most commonly used indices to
 456 define El Niño and La Niña event. The statistical result shows that there is a significant
 457 correlation between the two factors, with about 65% of the grids meeting the 95% confidence
 458 level. A positive-negative-positive triple distribution is presented in the correlation map (Fig.
 459 8). On this basis, the sensitive areas are identified, in which the water vapour exchange fluxes
 460 are further analysed. The central region (28-35°N, 108-122°E) has the most obvious
 461 significance, where the proportion of significant grids is as high as 70%. This area shows a
 462 negative correlation, i.e., the mean vertical output flux of water vapour is enhanced by about
 463 57.6~151.2 g m⁻² h⁻¹ in cold phase La Niña years (2011 and 2016, blue boxes in Fig. 9a), and
 464 vice versa in warm phase El Niño years (2015 and 2019, red boxes in Fig. 9a), and the flux
 465 anomalies are close to 0 in neutral years (2014, 2017, and 2018, black boxes in Fig. 9a). In
 466 south (20-28°N, 108-122°E) and north (35-42°N, 108-122°E) areas with positive correlation
 467 coefficients, the trend is reversed. That is, the ABL moisture ventilation flux weakens
 468 79.2~140.4 g m⁻² h⁻¹ in La Niña years and increases 108~194 g m⁻² h⁻¹ in El Niño years (figure
 469 not shown). This provides an explanation for the interannual variation of the water vapour
 470 exchange flux mentioned in Sect. 3.1.2.

471
 472 Figure 9. Anomalies of (a) water vapour exchange flux and (b) precipitation in July over the central
 473 region (28-35°N, 108-122°E, indicated in Fig. 8) during 2011&2014-2019. Blue, red and black indicate
 474 La Niña years, El Niño years and neutral years, respectively. Upper and lower sides of the box are the
 475 75th and 25th percentile, and whiskers are the 90th and 10th percentile. Hollow squares and black lines
 476 in the box are mean and median.

477 In order to elucidate why the water vapour vertical exchange flux varies with ENSO, we
 478 further analyse three exchange components anomalies in El Niño and La Niña years (Fig. S7).
 479 Among them, the term F_{vadv} presents the most obvious correspondence with the correlation
 480 pattern (Fig.8), demonstrating that vertical motion and water vapour content at the ABL top
 481 are crucial influencing factors. We select the central region (with the most significant
 482 correlation) for detailed analysis. As shown in Fig.10, in La Niña year (represented by 2016),
 483 the upward vertical velocity strengthened and the water vapour mixing ratio increased in the
 484 central area, while the opposite trend was observed in El Niño year (represented by 2015). This

485 phenomenon is attributed to the stronger East Asian monsoon that brings more water vapour
 486 from the south and facilitates convergence to uplift during the cold phase period of ENSO,
 487 while in the warm phase, the weaker southerly wind reduces water vapour transport and is not
 488 conducive to convergence within the ABL (Zhou et al. 2012; Xue et al., 2015; Gao et al., 2018),
 489 which explains the increase or decrease of ABL water vapour output affected by ENSO.

490

491 Figure 10. Spatial distribution of anomalies of vertical velocities (left) and water vapour mixing ratio
 492 (right) at the ABL top in July of (a-b) 2016 (La Niña year) and (c-d) 2015 (El Niño year).

493 Previous observation climatological studies have indicated that the summer precipitation
 494 anomalies in La Niña/ El Niño years are characterized by a tripolar distribution over eastern
 495 China (Wang et al., 2020), similar to water vapour exchange flux anomalies revealed in this
 496 work. It is of interest to investigate the relationship between water vapour vertical exchange
 497 and precipitation under the influence of ENSO. Taking the central region (28-35°N, 108-
 498 122°E) as an example, the precipitation anomalies present a good correspondence with the
 499 variations of the ABL-FT water vapour exchange flux (Fig. 9). Specifically, precipitation
 500 increases (decreases) about 3.2-6.9 mm (2.8-3.5 mm) when the vertical output of water vapour
 501 intensifies (weakens) in La Niña (El Niño) years. That is, enhanced water vapour output flux
 502 from the ABL to the FT tends to produce increased precipitation and vice versa. These results
 503 imply that, upper layer FT water vapour supplement from the ABL can also be a significant
 504 factor in changing regional precipitation, in addition to horizontal transport.

505 It should be stated that the above results are preliminary and rough, due to the limitations
506 of the sample. The response of the ABL-FT water vapour exchange to ENSO, and its impact
507 on precipitation, are complicated. The isolated patches in Fig. 8 and Fig. 10, as well as the box
508 and whisker in Fig. 9 (being 75th-25th and 90th-10th percentile of the flux/precipitation
509 anomalies), reflect the complex spatial variability over the research domain, which is not
510 thoroughly analysed in the current work. Nevertheless, this general result points to an
511 association among ABL-FT water vapour exchange, ENSO, and extreme precipitation, which
512 should be paid more attention to in future research.

513 **3.4 Discussion**

514 The present results are based on numerical simulations. Although reasonable
515 parameterization schemes are chosen according to sensitivity experiments, and the model
516 performance is also evaluated by observational data, there are inevitable uncertainties in the
517 modelled meteorological fields, which may directly affect the estimate of ABL-FT water
518 vapour exchange flux. For example, the difference between the simulated ABL height and the
519 observed value (~70 m and 120 m in winter and summer) brings ~30% uncertainty to the
520 acquisition of vertical velocity at this level, which may affect the accuracy of the flux results
521 in a similar magnitude. In addition, ignoring the turbulence term in this study may also reduce
522 the accuracy of the results. Nevertheless, this work presents a general view of long-term and
523 large-scale ABL-FT water vapour exchange over eastern China.

524 The water vapour exchange in the climatological sense presents a significant regional
525 division of north and south China, due to their quite distinct climatic features. In addition to
526 this general pattern, the spatial heterogeneity associated with the topographic distribution is
527 also noteworthy. We try to sort out the vertical exchange fluxes of water vapour over the ocean,
528 plain and mountain, roughly by the altitude below 0m, between 0-200m and greater than 200m.
529 The statistical results show that the ocean and plain are characterized by the upward output of
530 water vapour from the ABL, while the mountainous regions are dominated by downward
531 transport. This mode reflects the important role of the complex terrain in causing ABL-FT
532 vertical exchange. As described in Sect. 3.2, the prevailing airflow is obstructed by the
533 mountains to forcingly ascend on the windward and densely descend on the leeward slope, then
534 it decelerates and converges to induce upward motion when reaching the plain area. This
535 vertical motion pattern makes the water vapour upward export from the ABL in the plain, and
536 downward transport in mountainous areas due to the intensity and effect of the leeward side
537 subsidence being larger than that of the uplift in the windward side. For the ocean area,
538 horizontal wind crossing the inclined boundary layer top is responsible for the ABL water
539 vapour output, especially in the nearshore region. We admit the current analysis is preliminary,
540 but it does indicate the characteristics of vertical exchange flux distribution with topography,
541 and the significance of the interaction between mountain/sea and synoptic airflow. This finding
542 suggests that topographic ventilation is not only caused by mesoscale circulations such as
543 daytime upslope winds/sea breezes around mountains/coasts (Henne et al., 2004; Weigel et al.,

544 2007) or convective activities on a relatively small scale or a specific time (Gonzalez et al.,
545 2016; Dahinden et al., 2021). Dynamical forcing of terrain on seasonal airflow or synoptic
546 winds is more essential, which induces vertical motion and leads to systematic water vapour
547 exchange. The topographic-dependent feature of water vapour vertical exchange should also
548 be of general meaning to other complex terrain regions around the world.

549 Moreover, the climatology of water vapour exchange flux between ABL and FT provides
550 a quantitative background for investigating weather processes, radiation feedback and climate
551 changes. Water vapour entering the FT may provide more latent heat to the energy flows and
552 further affect synoptic systems. It is also involved in the radiative budget to influence climate.
553 Previous model simulations and observations indicate that small yet systematic changes in the
554 humidity of the upper atmosphere modulate the magnitude of the hydrological cycle and
555 radiative feedback, including clouds and precipitation (Minschwaner and Dessler, 2004;
556 Sherwood et al., 2010; Allan, 2012). Our results also demonstrate a notable relation between
557 precipitation anomalies and ABL-FT water vapour exchange patterns. Based on the
558 quantitative results in this study, the specific role of ABL - FT water vapour exchange in
559 Earth's energy flows and climate system might be studied further in the future.

560 **4 Conclusions**

561 In this study, we developed a climatology of water vapour exchange flux between the
562 ABL and FT, based on 7-year meteorological modelling data. The ABL water vapour
563 conservation method was used to estimate the vertical exchange flux across the ABL-FT
564 interface. Spatial distribution and seasonal characteristics of the water vapour exchange were
565 presented, and the influential mechanisms were analysed. The interannual difference was
566 simply discussed through its variations with ENSO events. The major findings of this work are
567 as follows:

568 (1) The spatiotemporal distribution of the ABL-FT water vapour exchange was
569 characterized by regional division and seasonal variation. During January and October in the
570 northern part (32-42°N), water vapour transport was downward to maintain ABL moisture,
571 while in the southern region (20-32°N) it was persistently exported to moisture the FT, with
572 the output flux from 10% to 80% of the surface evaporation rate.

573 (2) Vertical motion at the ABL-FT interface played a key role in the long-term (monthly
574 or seasonal) average state of water vapour vertical exchange, which was caused by the dynamic
575 forcing of the complex terrain on large-scale airflow. The temporal evolution of the vertical
576 exchange flux over the course of one day was primarily driven by the diurnal cycle of the ABL
577 height.

578 (3) Interannual variability of ABL-FT water vapour exchange was related to ENSO. Their
579 correlation was shown as a triple anti-phase distribution, with exchange strengthening in the
580 central zone and weakening in the north and south in La Niña years (and vice versa in El Niño
581 years). It was mainly attributed to the alteration of vertical velocity and water vapour content

582 at the ABL top varying with ENSO phases. Moreover, this pattern presented a good
583 correspondence to the distribution of precipitation anomalies.

584 This work is the first trial to quantitatively reveal the climatological state of ABL-FT
585 water vapour exchange flux over eastern China. Though for this specific research domain, the
586 method and results derived in the present study may provide reference to other regions of the
587 world. Through this study, the moisture linkage between the earth's surface and the upper layer
588 atmosphere is more clearly described. This may help us to obtain a better understanding of the
589 atmospheric water cycle.

590 **Data availability**

591 The data in this study are available from the corresponding author (xhcai@pku.edu.cn).

592 **Author contribution**

593 XHC and XPJ designed the research. LK and HSZ collected the data. XPJ performed the
594 simulations and wrote the paper. XHC reviewed and commented on the paper. QQH, YS, XSW
595 and TZ participated in the discussion of the article.

596 **Competing interests**

597 The authors declare that they have no conflict of interest.
