13 **Abstract**

14 Accounting for the condensation of organic vapors along with water vapor (co-condensation) has been shown in
15 adiabatic cloud parcel model (CPM) simulations to enhance the number of aerosol particles that activate to form
16 cloud droplets. The boreal forest is an important source of biogenic organic vapors, but the role of these vapors in
17 co-condensation has not been systematically investigated. In this work, the environmental conditions under which
18 strong co-condensation -driven cloud droplet number enhancements would be expected over the boreal biome are
19 identified. Recent measurement technology, specifically the Filter Inlet for Gases and AEROSOLS (FIGAERO)
20 coupled to an iodide-adduct Chemical Ionization Mass Spectrometer (I-CIMS), is utilized to construct a volatility
21 distribution of the boreal atmospheric organics. Then, a suite of CPM simulations initialized with a comprehensive
22 set of concurrent aerosol observations collected in the boreal forest of Finland during Spring 2014 is performed.
23 The degree to which co-condensation impacts droplet formation in the model is shown to be dependent on the
24 initialization of the updraft velocity, aerosol size distribution, organic vapor concentration and the volatility
25 distribution. The predicted median enhancement in cloud droplet number concentration (CDNC) due to
26 accounting for the co-condensation of water and organics is 20% (interquartile range 29–14%). This corresponds
27 to activating particles 12–16 nm smaller in dry diameter, that would otherwise remain as interstitial aerosol. The
28 highest CDNC enhancements (Δ CDNC) are predicted in the presence of a nascent ultrafine aerosol mode with a
29 geometric mean diameter of ~40 nm and no clear Hoppel minimum, indicative of pristine environments with a
30 source of ultrafine particles (e.g., via new particle formation processes). Such aerosol size distributions are
31 observed 30–40% of the time in the studied boreal forest environment in spring and fall when new particle
32 formation frequency is the highest (six years of statistics). Five years of UK Earth System Model (UKESM1)
33 simulations are further used to evaluate the frequencies to which such distributions are experienced by an Earth
34 System Model over the whole boreal biome. The frequencies are substantially lower than those observed at the
35 boreal forest measurement site (<6% of the time) and the positive values, peaking in spring, are modeled only
36 over Fennoscandia and western parts of Siberia. For the aerosol size distribution regime simulated by UKESM1,
37 offline simulations with the adiabatic parcel model reveal the Δ CDNC to be sensitive to the concentrations of
38 semi-volatile and some intermediate-volatility organic compounds (SVOCs and IVOCs). The magnitudes of
39 Δ CDNC remain less affected by the more volatile vapors such as formic acid and extremely low and low volatility
40 organic compounds (ELVOCs and LVOCs) in the CPM simulations. The reasons for this are that most volatile
41 organic vapors condense inefficiently due to their high volatility below cloud base and the concentrations of
42 LVOCs and ELVOCs are too low to gain significant concentrations of soluble mass to reduce critical

43 supersaturations needed for droplet activation. Suppression of the critical supersaturation caused by organic
44 condensation is the main driver of the modeled Δ CDNC. The results highlight the potential significance of co-
45 condensation in pristine boreal environments close to sources of fresh ultrafine particles. For accurate predictions
46 of co-condensation effects on CDNC, the representation of the aerosol size distribution is of essence. Further
47 studies targeted at finding observational evidence and constraints for co-condensation in the field are encouraged.
48

49 **1 Introduction**

50 Boreal forests emit significant quantities of volatile organic compounds (VOCs, Guenther et al., 1995; Artaxo et
51 al., 2022), such as monoterpenes, that undergo oxidation in the atmosphere. The condensable oxidation products
52 contribute considerably to the secondary organic aerosol (SOA) mass concentrations in the boreal forest air (e.g.,
53 Tunved et al., 2006; Artaxo et al., 2022). The emissions of monoterpenes are strongly temperature-dependent,
54 which leads – together with the higher oxidative potential in the sunlit months – to highest biogenic SOA
55 concentrations in summer (Paasonen et al., 2013; Heikkinen et al., 2020; Mikhailov et al., 2017). This has recently
56 been shown to have implications for cloud properties above the boreal forest through the availability of more
57 cloud condensation nuclei (CCN; Yli-Juuti et al., 2021; Petäjä et al., 2022). Under constant meteorological
58 conditions, an increase in aerosol concentration typically results in an increase in CDNC and smaller average
59 droplet size for a given liquid water content (Yli-Juuti et al., 2021). These effects alter the cloud brightness making
60 clouds scatter incoming solar radiation more efficiently (Twomey effect; Twomey, 1974, 1977). The relationships
61 between the number of aerosol particles, cloud droplet number concentration (CDNC), and their effects on climate
62 are non-linear and complex, which makes aerosol-cloud interactions the largest source of uncertainty in radiative
63 forcing estimates from climate models (e.g., Lohmann and Feichter, 2005; Carslaw et al., 2013; Bellouin et al.,
64 2020). The development of “bottom-up” predictive models is needed for providing accurate, yet robust,
65 simplifications of key processes involved in aerosol-cloud interactions – eventually for inclusion in climate
66 models in computationally efficient parameterizations.

67 Numerous studies have been carried out to understand the role of condensable organic vapors in SOA
68 formation (e.g., Hallquist et al., 2009; Shrivastava et al., 2017) and hence the concentrations of CCN (i.e. particles
69 of at least 50–100 nm in diameter for the water vapor supersaturations typical of the boreal environments; Cerully
70 et al., 2011; Sihto et al., 2011; Paramonov et al., 2013; Hong et al., 2014; Paramonov et al., 2015). The yields of
71 volatile, intermediate-volatility or semi-volatile organic compounds (VOCs, IVOCs, or SVOCs) from
72 monoterpene oxidation, such as those of pinonaldehyde, formic acid, or acetic acid, are generally much higher
73 than those of the readily condensable lower-volatility vapors (low-volatility organic compounds, LVOCs and
74 extremely low volatility organic compounds, ELVOCs). The above-mentioned volatility classes are determined
75 based on the volatilities of individual compounds binned into a volatility basis set (VBS; Donahue et al., 2006):
76 VOCs have a saturation vapor concentration (C^* ; given in units of $\mu\text{g m}^{-3}$ throughout the paper) of at least $10^7 \mu\text{g}$
77 m^{-3} , IVOCs are distributed in the C^* range of $[10^3, 10^6] \mu\text{g m}^{-3}$, SVOCs of $[1, 100]$, LVOCs of $[10^{-3}, 10^{-1}]$ and
78 ELVOCs have a C^* below $10^{-4} \mu\text{g m}^{-3}$ (e.g., Donahue et al., 2011). While VOCs, IVOCs, and some SVOCs are
79 unlikely to produce significant concentrations of SOA at ground level without additional oxidation steps or
80 reactive uptake, some of them can condense at higher altitudes if transported aloft (e.g., Murphy et al., 2015). This

81 work focuses on the role of SVOCs and IVOCs in warm cloud microphysics due to their high abundance in
82 tropospheric air and co-condensation potential.

83 Warm (liquid) clouds can form when air rises and cools, eventually leading to the air being supersaturated
84 with water vapor. The excess water vapor condenses onto aerosol particles, rapidly growing them into cloud
85 droplets. While water vapor represents the most abundant vapor in the atmosphere, also other trace species can
86 influence the cloud droplet activation process as the cooling of the rising air triggers also their condensation. As
87 the trace vapors condense, the molar fraction of water in the swelling droplets increases slower than in the absence
88 of co-condensation, which in turn leads to the condensation of additional water by the time the air parcel reaches
89 lifting condensation level. The co-condensation of water with other vapors eventually leads to a reduction in
90 critical supersaturation (s^*) required for droplet activation of the particles due to an increased amount of organic
91 solute (Topping and McFiggans, 2012) as described by Köhler theory (Köhler, 1936). Topping et al. (2013)
92 studied the impact of organic co-condensation on CDNC using a cloud parcel model (CPM) initialized with a
93 suite of realistic conditions describing the aerosol particle number size distribution (PNSD), composition, and
94 organic aerosol (OA) volatility distribution. They showed significant enhancements in CDNC (Δ CDNC up to
95 roughly 50%) when comparing simulations with organic condensation (CC) to simulations without (noCC). In
96 addition to co-condensing organics and water, also co-condensation of nitric acid and ammonia together with
97 water has been suggested to enhance CDNC in earlier process modeling studies (e.g., Kulmala et al., 1993;
98 Korhonen et al., 1996; Hegg, 2000; Romakkaniemi et al., 2005). Direct experimental studies of co-condensation
99 remain challenging, however, as aerosol particles are typically dried during the sampling process and the loss of
100 liquid water may lead to evaporation of co-condensed organics, too. While direct observational evidence of
101 organic co-condensation in the atmosphere is still lacking, recent laboratory studies show significant water uptake
102 due to co-condensation of propylene glycol and water onto ammonium sulfate particles (Hu et al., 2018).

103 The cloud response to co-condensation in the form of Δ CDNC is the result of a complex interplay
104 between updraft velocity, PNSD and organic compound volatility distribution (Topping et al., 2013). For the same
105 amount of organic vapor, Topping et al. (2013) modelled a non-linear updraft response of Δ CDNC. The highest
106 Δ CDNC were obtained when updrafts were below 1 m s^{-1} , but the peak Δ CDNC was dependent on the initial
107 PNSD characteristics. Under higher updrafts, the modelled Δ CDNC was found to decrease exponentially as a
108 function of updraft, but the asymptote of the curve depended on the initial PNSD – although the dependence on
109 the exact parameters describing multimodal PNSD were not extensively explored. If assumed representative of
110 the global continents, Δ CDNC values of tens of percent could impose a significant impact on predictions of cloud
111 albedo and the Earth's radiative budget. In fact, Topping et al. (2013) suggest accounting for co-condensation
112 could result in up to 2.5% increase in cloud albedo (corresponding to global Δ CDNC = 40%). This albedo increase
113 would translate into a -1.8 W m^{-2} change in the global cloud radiative effect over land. Topping et al. (2013)
114 stress, however, that the impacts of co-condensation will be spatially heterogeneous because of variable surface
115 albedo and variation in VOC sources. For comparison, one should note that the net radiative effect of clouds is
116 approximately -20 W m^{-2} (Boucher et al., 2013). The recent best estimate of the effective radiative forcing from
117 aerosol-cloud interactions is, on the other hand, $-1.0 [-1.7 \text{ to } -0.3] \text{ W m}^{-2}$ (Forster et al., 2021). The potential
118 contribution of co-condensation to estimates on aerosol forcing or to future cloud radiative effects remains unclear.

119 Boreal forests make up about one third of the Earth's forested area, which makes it an important source
120 of biogenic vapors that could affect droplet activation in warm clouds through co-condensation. Δ CDNC due to

121 co-condensation over the boreal forest could reduce the albedo over the dark boreal forest canopy. In a warming
122 climate, temperature-dependent biogenic terpene emissions (Guenther et al., 1993) are expected to rise (e.g.,
123 Turnock et al., 2020). These increasing emissions enrich the ambient pool of organics available for condensation
124 in rising air. As suggested in Topping et al. (2013), through the effects organic co-condensation poses on CDNC,
125 co-condensation could enhance the proposed negative climate feedback mechanism associated with the biogenic
126 SOA (Kulmala et al., 2004; Spracklen et al., 2008; Kulmala et al., 2014; Yli-Juuti et al., 2021), the magnitude of
127 which is currently highly uncertain (Thornhill et al., 2021; Sporre et al., 2019; Scott et al., 2018; Paasonen et al.,
128 2013; Sporre et al., 2020).

129 Since the publication of the Topping et al. (2013) study, improved constraints of the effective volatilities
130 of organic aerosol (e.g., Thornton et al., 2020) can be placed through the application of chemical ionization mass
131 spectrometers (CIMS) providing molecular level information on gas- and particle-phase composition in near-real
132 time. With the up-to-date volatility parameterizations using the molecular formulae retrieved from CIMS data,
133 volatility distributions can be calculated along a volatility scale ranging from ELVOCs to VOCs, while previous
134 techniques could not enable constraints on volatilities exceeding $C^* = 1000 \mu\text{g m}^{-3}$ (SVOC) (Cappa and Jimenez,
135 2010). This means that a notable amount of semi- and intermediate volatility vapors with high co-condensation
136 potential were not included in the early organic co-condensation work (Topping et al., 2013; Crooks et al., 2018).
137 The recent methodological developments motivate revisiting work of Topping et al. (2013), as potentially large
138 concentrations of condensable organic vapors have been so far neglected.

139 In this study, the cloud response to the co-condensation of organic vapors over the boreal forest of
140 Finland is investigated using a CPM. Measurements and parameterization techniques involving FIGAERO-I-
141 CIMS data are utilized to constrain the volatility distribution of organics for these simulations. In addition, to
142 ensure realistic modeling scenarios, simultaneously recorded measurements of PNSD and chemical composition
143 from the Aerosol Chemical Speciation Monitor (ACSM) are used for the CPM initialization. 97 CPM simulations
144 initialized with conditions from boreal spring and early summer following measurement time series recorded
145 during the Biogenic Aerosols – Effects on Clouds and Climate (BAECC) campaign at the Station Measuring
146 Atmosphere–Ecosystem Relationships (SMEAR) II (Hari and Kulmala, 2005) in Finland (Petäjä et al., 2016) are
147 performed, and sensitivity to updraft velocity is studied. These simulations are then used to characterize the
148 environmental conditions (with respect to the size distribution and organic aerosol volatility distribution
149 characteristics) that promote co-condensation-driven CDNC enhancements in the boreal atmosphere. The
150 frequencies to which a strong cloud response to co-condensation can be expected and its spatiotemporal variability
151 over the boreal biome is further investigated using long-term measurements from SMEAR II station and UK Earth
152 System Model (UKESM1) simulations.

153 **2 Methods and Data**

154 **2.1 The adiabatic cloud parcel model (ICPM)**

155 The CPM chosen for this study is the Institute for Marine and Atmospheric research Utrecht (IMAU) entrained
156 pseudo-adiabatic CPM (ICPM, Roelofs and Jongen, 2004). ICPM was further developed so that it could perform
157 simulation of both pseudo-adiabatic and adiabatic ascents of air parcels (Partridge et al., 2011, 2012). ICPM
158 simulates the condensation and evaporation of water vapor on aerosol particles, particle activation to cloud
159 droplet, unstable growth, collision and coalescence between droplets, and aqueous phase sulphur chemistry.

160 The model can be initialized with aerosol populations consisting of one or more internal or external
 161 mixtures of sulfuric acid, ammonium bisulfate, ammonium sulfate, OA, black carbon, mineral dust and sea salt.
 162 The PNSD are presented in a moving-center binned microphysics scheme comprising 400 size bins between 5 nm
 163 and 5 μm in dry radii, which are constructed at model initialization from the three parameters describing log-
 164 normal size distributions for the i number of modes – the geometric mean diameter (D_i), the total mode number
 165 concentration (N_i), and the geometric standard deviation (σ_i). The model can be initialized with up to four log-
 166 normal aerosol modes. The ICPM further provides time evolutions of key thermodynamic and microphysical
 167 parameters e.g., the air parcel temperature (T), pressure (p), supersaturation (s), altitude (z) and the aerosol particle
 168 and hydrometeor size distributions.

169 The dynamical equations used in the ICPM to simulate the adiabatic ascending air parcel equations are
 170 same to those presented by Lee and Pruppacher (1977), where the vertical parcel displacements are determined
 171 by the updraft velocity (w , set to a fixed positive constant value in the ICPM simulations):

$$\frac{dz}{dt} = w. \quad (1)$$

172 The changes in pressure are calculated assuming hydrostatic balance and the temperature decrease along the ascent
 173 follows the dry adiabatic lapse rate while also accounting for the latent heat release due to condensation:

$$-\frac{dT}{dt} = \frac{gw}{c_{p,a}} + \frac{L_e}{c_{p,a}} \frac{dx_v}{dt} + \mu_j \left[\frac{L_e}{c_{p,a}} (x_v - x'_v) + (T - T') \right] w \quad (2)$$

174 where g is the acceleration of gravity, L_e the latent heat of evaporation, $c_{p,a}$ the specific heat capacity of air and x_v
 175 the water vapor mixing ratio of the air parcel. μ_j is the entrainment rate describing mixing of parcel air with
 176 environmental air characterized with x'_v and T' . In this study, in which adiabatic simulations are performed,
 177 entrainment is not considered ($\mu_j = 0$). The water vapor mixing ratio in the air parcel changes with the evolving
 178 ambient supersaturation:

$$\frac{ds}{dt} = \frac{p}{\varepsilon e_s} \frac{dx_v}{dt} - (1 + s) \left[\frac{\varepsilon L_e}{R_a T^2} \frac{dT}{dt} + \frac{g}{R_a T} w \right], \quad (3)$$

179 where $\varepsilon = R_a/R_v = M_w/M_a = 0.622$ i.e., the ratio between the specific gas constants for air and water vapor or
 180 alternatively the molecular weight of water and air. e_s is the saturation vapor pressure of water. To solve the
 181 ordinary differential equations (Eqs. 2–3), the time derivate of the water vapor mixing is approximated as

$$\frac{dx_v}{dt} \approx -\frac{\Delta x_L}{\Delta t} - \mu_j (x_v - x'_v + x_L) w \quad (4)$$

182 where Δt is the model time step (10^{-3} seconds) and the liquid water mixing ratio (x_L) is calculated as a sum of the
 183 liquid water mixing ratio across all the 400 size bins (index i) for each assigned mode composition (index j):

$$\Delta x_L = \frac{4\pi\rho_w}{3\rho_a} \sum_{i=1}^{n_a} \sum_{j=1}^{n_b} n_{ij} (r_{ij}^3 - r_{ij, \text{dry}}^3), \quad (5)$$

184 where ρ_w is density of water, ρ_a is the density of the particle dry mass, n_{ij} is the number of particles within size bin
 185 i and composition j , and finally r_{ij} and $r_{ij, \text{dry}}$ are the wet and dry radii of the particles, respectively. The wet radii
 186 and hence also the particle masses (m) change as water condenses onto the particle (indices dropped for
 187 simplicity):

$$\frac{dm}{dt} = 4\pi\rho_w r^2 \frac{dr}{dt} = \frac{4\pi\rho_w r (S - S_{\text{eq}})}{\frac{\rho_w RT}{\text{DIFF}_v^* e_s} + \frac{L_e \rho_w}{kT} \left(\frac{L_e}{RT} - 1\right)}, \quad (6)$$

188 where k is the thermal conductivity, and DIFF_v^* is size-dependent water vapor diffusivity (from Pruppacher and
 189 Klett, 1997). Eq. (6) is approximated within the ICPM using a linearized form of the condensation equation
 190 (Hänel, 1987). Finally, S is the ambient saturation ratio ($S = s + 1$) and S_{eq} ($S_{\text{eq}} = \text{RH} / 100\%$) the equilibrium
 191 saturation ratio over the (spherical) wet particle surface, the difference of which determines the quantity of excess
 192 vapor for the diffusional growth of the particle. While S depends on the updraft source and condensation sink (Eq.
 193 3), S_{eq} depends on the particle wet radius and composition and it can be calculated using the Köhler equation
 194 (Köhler, 1936), traditionally expressed as:

$$S_{\text{eq}} = \frac{e}{e_s} = a_w \exp\left(\frac{2M_w \gamma}{RT\rho_w r}\right) \quad (7)$$

195 where e is the vapor pressure of water, a_w the water activity, γ the droplet surface tension (assumed to be that of
 196 water; see Table 1), R the universal gas constant, T the droplet temperature and r the droplet radius. Assuming
 197 dilute droplets, Eq. 7 is approximated in ICPM as follows for the equilibrium supersaturation ratio (Hänel, 1987):

$$S_{\text{eq}} \approx \exp\left(\frac{A}{r} - \frac{B}{\left(\frac{r}{r_{\text{dry}}}\right)^3 - 1}\right), \quad (8)$$

198 where

$$A = \frac{2M_w \gamma}{RT\rho_w} \quad (9)$$

199 and

$$B = \frac{3n_s M_w}{4\pi\rho_w}. \quad (10)$$

200 A and B in Eqs. (9) and (10) are the Köhler coefficients, where n_s is the total number of solutes (mol). The Raoult
 201 term (Eq. 10) is reformulated within the ICPM in terms of solute concentrations enabling its adjustments by
 202 dissolving or partially dissolving chemical constituents. For detailed descriptions of the B term, the reader is
 203 directed to Roelofs (1992).

204

2.1.1 Gas–particle partitioning of organics

206 ICPM has been extended to incorporate Köhler and condensation/evaporation equations for organic species of
 207 varying volatilities (Lowe, 2020). The volatility distributions are given using the VBS framework (Donahue et
 208 al., 2006). Initially, each volatility bin q contains the sum of gas ($C_{g,q}$) and particle phase concentrations ($C_{p,q}$;
 209 $C_{g+p,q} = C_{g,q} + C_{p,q}$) of the compounds with a given C^* . The partitioning coefficients for each bin, ζ_q , are defined
 210 as

$$\zeta_q = \frac{C_{p,q}}{C_{p,q} + C_{g,q}}. \quad (11)$$

211 The total particle phase mass concentration across all volatility bins is

$$C_p = \sum_q C_{p,q} = \sum_q C_{g+p,q} \zeta_q \quad (12)$$

212 and the partitioning coefficients depend on C^* as follows

$$\xi_q = \frac{C_p}{C_p + C_q^*}. \quad (13)$$

213 ξ_q are solved iteratively from Equations (12–13) at model initialization. Similarly, as in the work of Topping et
214 al. (2013), C_p is constrained using the initial PNSD and the organic mass fraction in addition to the relative
215 proportions of the various volatility bins (volatility distribution shape).

216 The condensation/evaporation equation for organic species is described in the same manner as in Topping
217 et al. (2013) and as shown for water vapor in Eq (6):

$$\frac{dm_q}{dt} = \frac{4\pi\rho_w r \text{DIFF}_g^* (S_q - S_{\text{eq},q}) e_{s,q}}{\frac{\text{DIFF}_g^* H_q S_{\text{eq},q} e_s \rho_w}{kT} \left(\frac{H_q M_q}{RT} - 1 \right) + \frac{\rho_w RT}{M_w}} \quad (14)$$

218 where DIFF_g^* is the gas phase diffusivity (see details in Topping et al., 2013 supplementary information), H_q the
219 enthalpy of vaporization, $e_{s,q}$ the saturation vapor pressure, and $S_{\text{eq},q}$ the equilibrium saturation ratio of organic
220 species in the q^{th} volatility bin. $S_{\text{eq},q}$ is calculated following the Köhler equation (Eq. 8) analogy:

$$S_{\text{eq},q} = a_q \exp\left(\frac{2v_q \gamma}{RT r}\right) \quad (15)$$

221 where a_q is the activity of $C_{p,q}$ in the bulk condensed phase, which equals the molar fraction of $C_{p,q}$ due to the
222 ideal solution approach of the study. In the model simulations enabling organic phase transitions, the
223 concentrations of the gas and particle phases integrated over all the volatility bins are saved as model output.

224

225 2.2 Measurement data from SMEAR II used for ICPM initialization

226 The observational data used for the ICPM initialization were collected during the Biogenic Aerosols – Effects on
227 Clouds and Climate (BAECC) campaign which took place in 2014 at the Station Measuring Ecosystem–
228 Atmosphere Relationships (SMEAR) II in Hyytiälä, Finland (Petäjä et al., 2016). SMEAR II is a well
229 characterized atmospheric measurement supersite located within a boreal forest in Southern Finland (61°51'N,
230 24°17'E; Hari and Kulmala, 2005). The surroundings of the measurement site are mostly forested (80% within a
231 5 km radius and 65% within a 50 km radius; Williams et al., 2011). The atmospheric composition measured at the
232 site suggests strong influence of biogenic emissions on aerosol and aerosol precursor (i.e., biogenic VOCs,
233 BVOCs) concentrations (e.g., Hakola et al., 2012; Yan et al., 2016; Allan et al., 2006; Heikkinen et al., 2021).
234 Anthropogenic influence is pronounced when air masses arrive from heavily industrialized areas such as St
235 Petersburg, Russia (Kulmala et al., 2000).

236 The PNSD for the ICPM initialization are obtained from the Differential Mobility Particle Sizer (DMPS)
237 measurements from SMEAR II performed within the forest canopy (Aalto et al., 2001; Petäjä et al., 2016). Since
238 ICPM takes in the log-normal parameters that the size distribution comprises (N , D , σ), also the fitting of the
239 PNSD is performed. This is done using the Hussein et al. (2005) algorithm that allows fitting 1–4 modes into the
240 measured distributions and decides the optimal number of modes. For the BAECC data set, the optimal number
241 would always be between three and four modes, with a higher number of modes generally yielding a better fit to
242 the observational data as expected. Despite the optimal number of 3–4 modes, the maximum number of modes is
243 restricted to two as the agreement between the fitted and measured distributions remained good considering the
244 experimental uncertainties, and including two modes only instead of four considerably sped up the simulations.

245 Moreover, the DMPS is suitable for sampling aerosol particles of ca. 3–1000 nm in size (electrical mobility
246 equivalent diameter) and hence does not capture the coarse mode. In addition, the Aitken mode at SMEAR II
247 typically originates from a growing nucleation mode. In more polluted environments, where small particles have
248 sources other than new particle formation, simplifications like this might not be appropriate. The PNSD time
249 series measured during BAECC is shown in Fig. 1a. It shows clearly the growth of nucleation mode to Aitken
250 mode on several occasions. Statistics regarding the log-normal parameters of the fitted data during BAECC are
251 provided in Table 1. The bimodal fits are also calculated for the years 2012–2017. These data are used later to
252 evaluate the frequency of times size distributions yielding high Δ CDNC appear in long-term data.

253 The aerosol chemical composition for ICPM initialization are obtained from Aerosol Chemical
254 Speciation Monitor (ACSM; Ng et al., 2011) measurements performed within the forest canopy (Heikkinen et al.,
255 2020). The ACSM measures the non-refractory (NR) sub-micrometer particular matter (PM_i) chemical
256 composition, which means that the reported composition is restricted to organics, sulfate, nitrate, chloride and
257 ammonium. The salts measured by the instrument do not include sea salt, because it typically exists in the coarse
258 mode and does not fully evaporate at the ACSM vaporizer temperature of 600°C. The latter reason restricts the
259 instrument also from detecting black carbon (BC). The composition from the ACSM measurements is shown in
260 Fig. 1b. Statistics regarding the organic mass fractions (f_{org}) are shown in Table 2. The ACSM data are further
261 used to derive volatility distributions similar to those utilized by Topping et al. (2013; see Sect. 2.3.1 for details).

262 An iodide FIGAERO-I-CIMS, sampling above the forest canopy in a ca. 30 m tower, is used to retrieve
263 molecular composition and volatility distributions of gas- and particle-phase species during BAECC (Mohr et al.,
264 2017, 2019; Schobesberger et al., 2016; Lee et al., 2018, 2020; see Sect. 2.3.2 for details). The Filter Inlet for
265 Gases and AEROsols (FIGAERO; Lopez-Hilfiker et al., 2014) coupled with a CIMS (the coupling of these
266 instruments hereafter referred to as FIGAERO-I-CIMS) stands as one of the very few instruments capable of
267 performing near-simultaneous measurements of both gas and particle phases. The FIGAERO inlet allows the gas
268 phase to be sampled while aerosol particles are collected on a Teflon filter, and after sufficient particle deposition
269 time the sample is heated and the evaporated molecules are measured similarly to the gas phase. The heating
270 procedure, which typically reaches a maximum temperature of around 200°C can, however, cause thermal
271 fragmentation of molecules (Lopez-Hilfiker et al., 2015). This leads to the detection of small molecular fragments,
272 which get assigned a higher C^* than that of the parent molecule, which can be seen in the FIGAERO-I-CIMS
273 thermograms when compounds with high C^* vaporize at exceptionally high temperatures. In addition to the
274 indistinguishable isomers from any of the phases from online FIGAERO-I-CIMS measurements (or any other
275 mass spectrometer for that matter), thermal fragmentations add to the uncertainty of volatility distributions
276 retrieved from these data.

277 The parcel model simulations are initialized at 90% RH, which is most of the time higher than that
278 measured at ground level. An interpolated radiosonde data product from the BAECC campaign (ARM Data
279 Center, 2014) is used to find temperatures matching 90% RH. Both the temperature measured near ground level
280 (8.4 m above ground level) and the temperature corresponding to 90% RH are shown in Fig. 1c. While these
281 temperatures show similar temporal behavior at times, major differences exist, which can arise from instable
282 temperature profiles as well as sudden changes in air masses that the interpolated data product built from sondes
283 sent three times a day fails to capture. The PNSD and aerosol chemical composition measured near ground level
284 are assumed to be identical to those at 90% humidity, because measurement data at higher altitudes is not

285 available. The volatility distributions retrieved from the FIGAERO-I-CIMS and ACSM data are adjusted to the
286 temperatures obtained from the interpolated radiosonde data product (see Sects 2.3.1 and 2.3.2 for details).

287

288 **2.3 Volatility distributions**

289

290 The total organic (gas + particle phase) volatility distributions are provided as inputs for the ICPM (see Sect.
291 2.1.1). To compare the results from this work to those of Topping et al. (2013), and to assess the changes in co-
292 condensation driven Δ CDNC due to volatility distribution updates from the old particle-phase derived
293 distributions (denoted with CJ; see Sect. 2.3.1) to FIGAERO-I-CIMS-derived distributions (here denoted with F;
294 see Sect. 2.3.2), both approaches are used. The term “volatility distribution shape” refers to the relative proportions
295 of organic mass in each volatility bin, which remain fixed when the partitioning coefficients are iterated (see Eqs.
296 11–13 in Sect. 2.1.1).

297

298 **2.3.1 Volatility distributions based on ACSM measurements (CJ distributions)**

299

300 Previous to the development of the FIGAERO-I-CIMS, organic volatility distributions were probed only through
301 particle phase measurements (e.g., Huffman et al., 2009b), which enabled volatility constraints of relatively low
302 volatility species (Cappa and Jimenez, 2010). More precisely, these early generation OA volatility distributions
303 were obtained from e.g. Aerosol Mass Spectrometer (AMS; Canagaratna et al., 2007) measurements coupled with
304 a thermal denuder (TD; e.g., Huffman et al., 2009a, b). The TD-AMS measurements provide thermograms (mass
305 fractions remaining in the particle phase as a function of TD temperature of ca. 25–250 °C) that could be assigned
306 to individual OA components i.e., low-volatility oxygenated organic aerosol (LV-OOA), semi-volatile
307 oxygenated organic aerosol (SV-OOA), hydrocarbon-like OA (HOA) and biomass burning OA (BBOA). Cappa
308 and Jimenez (2010) then reproduced such thermograms using a kinetic evaporation model (Cappa, 2010) through
309 fitted OA volatility distributions. In this paper, volatility distributions of this kind are referred to as CJ
310 distributions. It is important to keep in mind that the general CJ volatility distribution shape (i.e., the relative
311 proportions of the volatility bins) is assumed to be of the form $C_{i, \text{tot}} = a_1 + a_2 \exp [a_3 (\log_{10} C^* - 3)]$, which was
312 motivated by previous studies on organic aerosol volatility distribution shapes retrieved from chamber
313 experiments (Presto and Donahue, 2006; Robinson et al., 2007), with a_1 , a_2 and a_3 as fitting parameters. Later
314 theoretical work on OA volatility distribution retrievals from TD data states, however, that due to uncertainties
315 associated with the enthalpy of vaporization (ΔH_{vap}), mass accommodation coefficients, and volatility distribution
316 shapes, the attained distributions can be reproduced with several combinations of the three (Karnezi et al., 2014).

317 To calculate the CJ distributions for the BAECC OA types, the LV-OOA, SV-OOA and primary organic
318 aerosol (POA; taken as a mix of HOA and BBOA) from the SMEAR II ACSM long-term data set are utilized
319 (Heikkinen et al., 2021). During BAECC, the organic aerosol comprised 63% LV-OOA, 32% SV-OOA and only
320 5% POA on average. Using the time-dependent mass fractions of each OA type, mass-weighted average CJ
321 volatility distributions for each of the model initialization scenarios (97 of them) are calculated. The HOA
322 volatility distribution is used for POA (due to the low abundance of levoglucosan in the ACSM mass spectrum;
323 Heikkinen et al., 2021). Topping et al. (2013) utilized the $\log_{10} C^*$ range of [-6, 3] in their simulations and their
324 example is followed in this work. The CJ volatility distributions have been reported for 298.15 K (Cappa and
325 Jimenez, 2010). As the ICPM simulations are initialized at different temperatures, accounting for the impact these

326 temperature changes had on the volatility distributions is necessary. The relationship between temperature, ΔH_{vap} ,
327 and C^* is accounted for through an Arrhenius-type Clausius-Clapeyron relation:

$$C^* = C^*(T_{\text{ref}}) \exp\left(\frac{\Delta H_{\text{vap}}}{R} \left(\frac{1}{T_{\text{ref}}} - \frac{1}{T}\right)\right), \quad (16)$$

328 where R is the universal gas constant and T is the ambient temperature in Kelvin (the ICPM initialization
329 temperature), and T_{ref} is 298.15 K. For the relationship between ΔH_{vap} (in J mol^{-1}) and C^* the semi-empirical
330 parameterization under 300 K provided in Epstein et al. (2010) is used:

$$\Delta H_{\text{vap}} = -11 \log_{10} C^*(T_{\text{ref}}) + 129, \quad (17)$$

331 where ΔH_{vap} is the change in heat (enthalpy) of vaporization in kJ mol^{-1} . A lower limit of 20 kJ mol^{-1} is set to the
332 ΔH_{vap} , which is close to the ΔH_{vap} determined for formic acid (NIST Chemistry WebBook, 2022). Eq. (17) would
333 otherwise provide too low, unphysical and even negative values. After the temperature adjustments, the volatility
334 distributions are binned to ranges between $\log_{10} C^* = [-8, 3]$ spaced by one decade in C^* as after adjustments with
335 Eqs. (16–17). The lower limit is reduced by two orders of magnitude, but the upper limit remains as the
336 initialization temperatures did not exceed 300 K. The campaign average CJ volatility distribution is shown with
337 black bars in Fig. 2a. However, each simulation utilizes a unique distribution constructed using the LV-OOA, SV-
338 OOA, and POA time series.

339

340 2.3.2 Volatility distributions based on FIGAERO-I-CIMS measurements (F distributions)

341 Organic aerosol volatility distributions from FIGAERO-I-CIMS measurements conducted during BAEEC (Mohr
342 et al., 2017, 2019; Schobesberger et al., 2016; Lee et al., 2018, 2020) are also derived. It can be assumed that the
343 FIGAERO-I-CIMS detected most of the OA measured with the ACSM. This is because with the iodide adduct-
344 ionization, FIGAERO-I-CIMS is most sensitive to oxidized organic species, such as organic acids (Lutz et al.,
345 2019), but not sensitive to non-oxidized hydrocarbons (dominating AMS-derived HOA) and as mentioned in Sect.
346 2.3.1. The OA measured with the ACSM comprised on average 95% oxygenated organic aerosol (LV-OOA +
347 SV-OOA), which is generally thought to represent organic acids (Yatavelli et al., 2015). The agreement between
348 the two measurements is supported by the comparison between the daytime FIGAERO-I-CIMS particle phase
349 signal (of identified ions) and the OA mass concentration retrieved from ACSM measurements provided in Fig.
350 S.1. While the quantification of the FIGAERO-I-CIMS measurements remains challenging and therefore a
351 quantitative comparison between the concentrations is uncertain, the high correlation between measurement data
352 (Pearson $R = 0.79$) proves that the instruments generally sample the same aerosol population. Notably, the ICPM
353 simulations obtain OA mass fraction (f_{org}) only from the ACSM measurements. The volatility distributions are
354 derived from FIGAERO-I-CIMS data using molecular formula parameterizations derived under 300 K in Li et al.
355 (2016):

$$\log_{10} C^*(T_{\text{ref}}) = (n_C^0 - n_C) b_C - n_O b_O - 2 \frac{n_C n_O}{(n_C + n_O)} b_{\text{CO}} - n_N b_N, \quad (18)$$

356 where n_C^0 is a reference carbon number; b_C , b_O , and b_N are the contributions of each carbon, oxygen, and nitrogen
357 atom to the $\log_{10} C^*$, respectively; b_{CO} is a so-called carbon-oxygen non-ideality parameter (Donahue et al., 2011);
358 n_C , n_O , and n_N are the numbers of carbon, oxygen, and nitrogen atoms in the molecular formulae assigned for the
359 FIGAERO-I-CIMS data during high resolution peak fitting of the measured mass spectra. The b -values utilized
360 are listed in Li et al. (2016). In their recent work, Huang et al. (2021) derived volatility distributions from various

361 organic vapor measurements from SMEAR II. They adjusted the Li et al. parameterization for organic nitrates.
362 As shown in Isaacman–VanWertz and Aumont (2021), the utilization of the Li et al. parameterization for OA rich
363 in organic nitrates leads to biased vapor pressure estimates. Organic nitrates are known to form in the boreal air
364 as a result of nitrate radical chemistry, which is pronounced during night, along with daytime oxidation of
365 monoterpenes in the presence of nitric oxide (e.g., Yan et al., 2016; Zhang et al., 2020). To account for these
366 nitrates, Huang et al. (2021) followed the suggestions presented in Daumit et al. (2013) and treated all the nitrate
367 functional groups as hydroxyl (—OH) groups. Given that the focus of this study is on the same measurement site
368 as Huang et al. (2021), their methodology for deriving a volatility distribution from the FIGAERO-I-CIMS is
369 followed here. Once the volatility distributions are constructed using Eq. (18) for 300 K (reference temperature),
370 their adjustments to the parcel model simulation initial temperatures using Eqs. (16–17) are performed.

371 The volatilities are calculated for the 1596 ions identified by the FIGAERO-I-CIMS measurements and
372 afterwards binned with one decadal spacing so that all the extremely low volatility organic compounds (ELVOC)
373 are summed into one bin at $C^* = 10^{-4} \mu\text{g m}^{-3}$. This is assumed to be appropriate as ELVOCs contain little or no
374 gas phase signals post-initialization (See Sect. 2.1.1). The highest volatilities reached $C^* = 10^7 \mu\text{g m}^{-3}$, which is
375 therefore set as the upper limit of the volatility distribution. Following from this, the volatility span is $\log_{10}C^* =$
376 $[-4, 7]$. The campaign average volatility distribution is shown in red bars in Fig. 2a. The average CJ distribution
377 exhibits generally higher fractions in the ELVOC region as compared to the F distribution (Fig. 2a). This mostly
378 results from the low or non-existent SVOC and IVOC concentrations in the CJ distribution. The F distributions
379 show a remarkable agreement with the organic volatility distributions from the BEACHON-RoMBAS field
380 campaign conducted at the Manitou Experimental Forest Observatory in the Colorado Rocky Mountains in
381 summer 2011 (Hunter et al., 2017, see Fig. 2a). Hunter et al. (2017) derived a volatility distribution for the total
382 atmospheric reactive carbon (other than CH_4 , CO_2 and CO) using six different types of measurements and
383 assuming minimal overlap among the measured species. This volatility distribution is displayed in Fig. 2a after
384 shifting it to the mean ICPM initialization temperature (280 K) using Eqs. (16–17) and subtracting VOC signals
385 from it for comparison.

386 In Figs. 2b and c the partitioning coefficients ξ_q (see Eq. 11) from the ICPM initialization (see Sect. 2.1.1)
387 against the partitioning suggested by the measurements is compared, after accounting for the temperature
388 differences between ground level and ICPM initialization temperatures using Eqs. (16–17). The concentrations in
389 volatility bins with $\log_{10}C^* \leq 1$ agree, suggesting that the majority of the organics in these bins are in the particle
390 phase. Similarly, the agreement in the highest volatility bin ($\log_{10}C^* = 7$) suggests the presence of gas-phase
391 compounds only in both distributions. The estimations of the gas phase vary between $\log_{10}C^* 1$ and 7, showing a
392 higher gas-phase fraction for the modelled partitioning coefficients. This variability can result from numerous
393 reasons, which apart from uncertainties related to measurements and parametrizations include viscous particle
394 coatings inhibiting equilibration between gas and particle phases, and therefore showing high particle-phase
395 concentrations of high-volatility compounds in the observations. Alternatively, these concentrations can also
396 result from thermal decomposition of lower volatility products during the FIGAERO-I-CIMS heating process
397 (Lopez-Hilfiker et al., 2015) or from the tendency of the Eq. (18) parameterization to underestimate (despite
398 treating the $-\text{NO}_3$ groups at $-\text{OH}$ groups) the volatility of organic nitrates (Graham et al., 2022), shown to be
399 abundant in the BAEC FIGAERO-I-CIMS data set (Fig. 2e). Understanding these differences is important and
400 requires further analysis.

401 The molecular composition of the gas-phase compounds detected by the I-CIMS during BAECC are
402 analyzed and presented in detail in Lee et al. (2018). In the following, the average composition of each volatility
403 bin during daytime is briefly described. Except for the highest volatility bin, nitrogen-containing species (CHON),
404 which are prominently organic nitrates at SMEAR II (Huang et al., 2021), make up significant mass fractions of
405 each bin in the gas phase (Fig. 2e). Fig. 2f shows the concentration of the gas-phase compounds as a function of
406 the compound carbon and oxygen atom numbers. The figure shows how ELVOCs and LVOCs have the highest
407 numbers of both carbon and oxygen atoms. IVOCs and SVOCs comprise compounds with highly variable carbon
408 skeleton lengths, but the number of oxygen atoms per compound remains low, notably always lowest for IVOCs
409 and VOCs. Formic acid (HCOOH) makes up most of the gas phase signal. It is distributed in the most volatile
410 volatility bin ($C^* = 10^7 \mu\text{g m}^{-3}$). HCOOH is one of the most abundant carboxylic acids in the atmosphere and rain
411 water (e.g., Galloway et al., 1982; Millet et al., 2015 and references therein) and is known to have various sources
412 and precursors (Millet et al., 2015). The I-CIMS measurements discussed here were also performed as part of an
413 eddy covariance flux measurement setup during BAECC (Schobesberger et al., 2016). These flux measurements
414 provided insight into the high HCOOH concentrations possibly due to high emissions from the boreal forest
415 ecosystem. More details from these results can be found in Schobesberger et al. (2016).

416

417 **2.4 ICPM simulation setup**

418 97 daytime scenarios are simulated with ICPM initialization data from BAECC (see Fig. 1a, red crosses). The
419 configuration of ICPM used in this study only considers the adiabatic ascent of an air parcel, without treatment of
420 droplet collision and coalescence, aqueous phase sulfur chemistry or entrainment. Each modelled scenario has
421 log-normal parameters describing a bimodal aerosol size distribution from DMPS measurements followed by
422 Hussein et al. (2005) fitting algorithm. Also, the organic mass fraction from ACSM measurements is given as an
423 input. Organics are present in the simulations as an internal mixture with ammonium sulfate as nitrate is assumed
424 to be organic nitrate (Lee et al., 2018) and the measured sulfate is assumed to be ammonium sulfate, which is
425 generally a good approximation at SMEAR II (Heikkinen et al., 2020). For the simulations performed here, BC
426 is not included given its small (about <5%) contribution to PM_{10} mass from late spring to summer (Luoma, 2021).
427 The ICPM initialization temperature is taken from interpolated radiosonde data that represents the 90%
428 initialization RH. The atmospheric pressure was set to 980 hPa in all simulation scenarios. The simulations are
429 performed for updraft velocities of 0.1 m s^{-1} , 0.3 m s^{-1} , and 1.0 m s^{-1} , with and without co-condensation for the F
430 distribution. Additional 97 simulations are performed using the 0.3 m s^{-1} updraft with the CJ volatility distribution.
431 Only daytime data (local time between 10:00 and 19:00) are used for the model initializations. Table 1 contains a
432 summary of the simulation input data, which also contains the values used for accommodation coefficient, surface
433 tension, the effective soluble fraction of organics as well as the model time step and number of PNSD size bins.
434 The simulation output, discussed later in the results section of the paper (Sect. 3), is summarized in Table 2. The
435 output data are averaged to a fixed height output grid spaced with a two-meter resolution.

436

437 **2.5 UK Earth System Model (UKESM1) simulations**

438 To evaluate the frequency of times size distributions yielding high ΔCDNC (which is the percent-change in CDNC
439 due to co-condensation) during BAECC would become evident over the boreal biome in an ESM if a
440 parameterization of co-condensation was implemented, the United Kingdom Earth System Model (UKESM1,

441 Sellar et al., 2019; Mulcahy et al., 2020) is utilized. The simulations performed with UKESM1 are configured for
442 Atmospheric Model Intercomparison Project (AMIP) style simulations, where UKESM1 is run in its atmosphere-
443 only configuration with time-evolving sea surface temperature and sea ice as well as prescribed marine biogenic
444 emissions from fully coupled model simulations. In addition to the HadGEM3-GC3.1 core physical dynamical
445 model of the atmosphere, land, ocean and sea ice systems (Ridley et al., 2018; Storkey et al., 2018; Walters et al.,
446 2017), UKESM1 also contains additional component models for atmospheric chemistry and ocean and terrestrial
447 biogeochemistry for carbon and nitrogen cycle representation. A N96L85 horizontal resolution structure ($1.875^\circ \times$
448 1.25° longitude–latitude, which corresponds roughly a horizontal resolution of 135 km) is chosen for the
449 simulations and the vertical space is split to 85 levels (50 levels between 0 and 18 km and 35 levels between 18
450 and 85 km). In this study the model is run in a nudged configuration (horizontal wind nudging (but not
451 temperature) between model levels 12 and 80 with a constant 6-hour relaxation time), for the years 2009–2013
452 inclusively. External forcing and emission datasets are consistent with the Coupled Model Intercomparison Project
453 Phase 6 (CMIP6) implementation as described in Sellar et al. (2020). The simulation setup is same as in the
454 Aerosol Comparisons between Observations and Models (AeroCom) Phase III GCM Trajectory experiment
455 (AeroCom, 2022; Kim et al., 2023, in prep.).

456 The UKESM1 aerosol scheme represents the particle size distributions with five log-normal modes: the
457 nucleation soluble mode, Aitken soluble and insoluble modes, accumulation soluble mode, and coarse soluble
458 mode (Mulcahy et al., 2020). The aerosol microphysical processes of new particle formation (NPF), condensation,
459 coagulation, wet scavenging, dry deposition and cloud processing are handled with GLOMAP (Global Model of
460 Aerosol Processes; Mann et al., 2010; Mulcahy et al., 2020). The UKESM1 NPF mechanism follows the
461 parameterization derived in Vehkamäki et al. (2002) for binary homogeneous nucleation of H_2SO_4 and water.
462 Separate boundary layer NPF is not included in the simulations (Mulcahy et al., 2020). The soluble aerosol size
463 distribution lognormal aerosol modal parameters (nucleation mode, soluble Aitken mode and soluble
464 accumulation mode) and updraft velocities with a 3-hour time resolution at cloud base of stratiform clouds are
465 used. These diagnostics are subsequently masked to include only data in which activated aerosol particles exceeds
466 zero and the temperature exceeds 237.15 K in keeping with criteria used by the droplet activation scheme. The
467 PNSD modal parameters are used to construct aerosol size distributions. In UKESM1 the geometric standard
468 deviations are fixed parameters. The same values are used for consistency for the modes that are accounted for in
469 this work. The geometric standard deviation for UKESM1 Nucleation soluble mode and the Aitken soluble mode
470 is 1.59, and for the accumulation soluble mode it is 1.40. UKESM1 outputs for the Aitken insoluble mode and
471 coarse mode are not used in analysis performed in this study because they do not contribute to CCN in the model
472 representation of cloud droplet activation.

473 **3 Results and discussion**

474 **3.1 Organic condensation: time and volatility dependencies**

475 The first cloud parcel model simulation results (Fig. 3) correspond to initializing the model with data collected on
476 May 11, 2014 at 11:30 EET (East European winter time). This simulation is identified from the full dataset as one
477 that represents a strong cloud response to co-condensation of organics and water. Fig. 3a shows the vertical
478 evolution of total SVOC and IVOC concentrations in the gas phase for the three different updraft scenarios ($w =$
479 0.1, 0.3, or 1 m s^{-1} , respectively). Both SVOC and IVOC concentrations decrease significantly along the adiabatic

480 ascent in subsaturated conditions below cloud base (CB, $RH_{CB} = 100\%$). “Below CB” is defined as the ascent
481 from $RH = 90\%$ upwards as long as $RH < 100\%$. SVOCs and IVOCs are further scavenged inside the cloud in
482 saturated conditions. This result is in line with Bardakov et al. (2020), who modelled complete gas removal of
483 volatility bins up to roughly $\log_{10}C^* = 9$ within convective clouds.

484 When considering all 97 simulations, the net mass fractions of organics condensed below CB are on
485 average 91, 72 and 35% for the 0.1, 0.3 and 1.0 $m\ s^{-1}$ updraft, respectively, which in absolute concentrations means
486 additions of 1.8, 1.4, and 0.7 $\mu g\ m^{-3}$ to the aerosol particle soluble mass (Table 2). The yielded mass concentrations
487 are in the same order of magnitude of the PM_{10} mass concentrations measured during BAEC (interquartile range,
488 IQR: 0.95, 1.95, and 3.22 $\mu g\ m^{-3}$ from ACSM data), which means that such organic condensation along the
489 adiabatic ascents simulated here would yield roughly a doubling of the soluble mass due to SVOC and IVOC
490 condensation below CB. These numbers should, however, be assessed with caution as an ideal liquid phase, as
491 well as partitioning being determined by mole fractions of water-soluble organics are assumed in this work (Sect.
492 2.1.1).

493 Topping et al. (2013) looked into the assumption of ideality in their supplementary material. They found
494 it to enhance the amount of modelled organic condensate as compared to a non-ideal case. However, their
495 simulations exploring non-ideality with organic activity coefficients predicted with the UNIFAC method
496 (UNIQUAC Functional-group Activity Coefficients; Fredenslund et al., 1975) or solubilities still led to significant
497 amounts of condensed organic mass. The impact of the ideality assumption was shown to be most significant in
498 their highest volatility bin ($C^* = 1000\ \mu g\ m^{-3}$). Activity coefficients and solubilities of organics should in the future
499 be better constrained to assess the impact on volatility bins of $\log_{10}C^* > 3$, which was not explored in Topping et
500 al. (2013). As discussed in the Topping et al. (2013) supplementary information, it is likely that solubility
501 decreases towards the higher volatility bins.

502 Further investigation on how efficiently different volatility bins condensed along the adiabatic ascents
503 across all the 97 simulation scenarios repeated with the three fixed updraft velocities is also performed (Fig. 4).
504 In the 0.1 $m\ s^{-1}$ updraft scenario, almost all organic vapor condenses up to $\log_{10}C^* = 5$ and the condensation
505 capability of the highest volatility bin ($\log_{10}C^* = 7$) shows the highest variability (30–100% condensed below CB;
506 Fig. 4a). The same features can be observed with the 0.3 $m\ s^{-1}$ and 1.0 $m\ s^{-1}$ updraft simulations, although the
507 fraction of organic vapor condensed per volatility bin is reduced (in the $w = 1\ m\ s^{-1}$ scenarios only ca. 40% of the
508 vapor condenses below CB (Figs. 4b–c). The results from these simulations reveal that there is enough time under
509 slow adiabatic ascents for most of the organic vapor to condense.

510 Figures 4d–f show the simulated organic condensate concentrations for each volatility bin. While the
511 fraction condensed for the highest volatility bin is lowest (Figs. 4a–c), the absolute concentrations are amongst
512 the highest due to the high availability of organic vapor in the highest volatility bin (mostly HCOOH; Sect. 2.3.2).
513 The condensation efficiency of the highest volatility bin shows a high ICPM initialization temperature
514 dependence. If the model initialization takes place at 270 K, up to 100% of the organic vapor in the bin condenses,
515 while if the ascent starts at 290 K, only 40% of the mass concentration is transferred to the condensed phase below
516 CB (Figs. 4g–i). A closer look into Figs. 4g–i reveals that under similar temperature, the condensation of the
517 $\log_{10}C^* = 7$ bin is most efficient in the presence of a high concentration of accumulation mode particles. This
518 suggests that these organic vapors are likely to condense onto larger particles, which are susceptible to be activated
519 into cloud droplets regardless of co-condensation. Similar correlations are observed to a lesser extent with the

520 $\log_{10}C^* = 6$ volatility bin (not shown). In this work, the information of the size ranges of particles which the high-
521 volatility IVOCs condense onto is lacking. Therefore, more systematic studies should be conducted to better
522 understand whether the condensation of the high-volatility IVOCs onto ultrafine particles is sufficient enough to
523 lead to droplet activation.

524 As the results from Figure 4 underline the time-dependence of co-condensation, it is worth remembering
525 that the ICPM initialization RH is set to 90% (see Sect. 2.4). If the initial RH was set to a lower value, more time
526 would be available for co-condensation before reaching CB, and if the initial RH was set to a higher value, less
527 time would be available. While the decision of maintaining a fixed initial RH for the different simulations is
528 proven useful for this study as it eases the data interpretation process, it should be acknowledged that the initial
529 RH could be better constrained in future simulations.

530

531 3.2 Impact of updraft velocity on the sensitivity of cloud microphysics to organic vapor condensation

532 As explained previously in Topping et al. (2013), the CDNC enhancements associated with co-condensation arise
533 from the enhancement in organic solute concentration, which decreases the critical supersaturation (s^*) needed for
534 a given particle to activate. The s^* reductions from 0.15% to 0.10% for the May 11, 2014 at 11:30 EET case are
535 shown in Fig. 3b, and correspond to a dry radius of 71.9 nm (i.e., the smallest activated dry radius when co-
536 condensation is disabled, r_{noCC}^* , and $w = 0.1 \text{ m s}^{-1}$; Table 2). Fig. S.2 shows the development of the wet particle
537 size as a function of altitude in the ICPM simulation summarized in Fig. 3. It clearly demonstrates the differences
538 introduced by co-condensation through the activation of new size bins (4 size bins in total when $w = 0.1 \text{ m s}^{-1}$)
539 that remain as interstitial aerosol particles in the simulations, where co-condensation is turned off. The enhanced
540 growth of more particles due to co-condensation enhances the water vapor condensation sink, which leads to a
541 reduction in the achieved maximum ambient supersaturations (s_{max} ; see Fig. 3c for the May 11 case and Table 2
542 summarizing all the 97 simulations). As the updraft is the same in simulations performed with and without co-
543 condensation, the condensation sink dictates the changes in s_{max} (Eq. 3). A reduced s_{max} would typically lower the
544 number of aerosol particles activating into cloud droplets, but here the suppressions in s^* are greater than the
545 reductions in s_{max} , which therefore leads to an enhanced CDNC (see Fig. 3b–c for the May 11 case). This can be
546 interpreted as a competition effect between the s_{max} and s^* reductions, respectively, which the s^* reduction wins.
547 When examining the 0.1 m s^{-1} updraft case in the May 11th simulation shown in Fig. 3, the s_{max} is reduced 12.5%
548 (from 0.16% to 0.14%), which is less significant than the s^* reduction of about 33% (from 0.15% to 0.10%; Fig.
549 3b). This leads to a 22% enhancement in CDNC (Fig. 3d) as r^* reduces from 72 nm to 66 nm ($\Delta r^* \approx 6 \text{ nm}$). Fig.
550 3e finally shows the droplet spectrum for the May 11 case, which highlights the consistent shift of droplet sizes
551 to smaller diameters due to organic co-condensation (see also Fig. S.2, which displays the same May 11th
552 simulation with $w = 0.1 \text{ m s}^{-1}$).

553 The modelled BAECC campaign median CDNC values (over the 97 simulations) without co-
554 condensation are on average 161, 300 and 530 cm^{-3} in modeling scenarios utilizing 0.1 m s^{-1} , 0.3 m s^{-1} , and 1.0 m s^{-1}
555 updrafts, respectively (Table 2). CDNC is shown to correlate well with the accumulation mode number
556 concentration (N_2), and at times with the Aitken mode number concentration (N_1) if the Aitken mode particles are
557 large enough in size and accompanied with strong enough updrafts and a low N_2 (Fig. S.3). The reductions in the
558 smallest activated critical radii due to co-condensation are on average 8.2, 6.6, and 5.9 nm for the modeling
559 scenarios utilizing 0.1 m s^{-1} , 0.3 m s^{-1} , and 1.0 m s^{-1} updrafts, respectively, and the corresponding median ΔCDNC

560 are 16.8, 23.3 and 20.6%, respectively (Table 2 and Fig. 5a). The swarm plot on Fig. 5a shows that Δ CDNC and
561 CDNC do not correlate i.e., high susceptibility is in this case not predicted specifically for low CDNC.

562 On average during the BAECC simulation period (97 simulations), the highest Δ CDNC are found when
563 initializing the model with a 0.3 m s^{-1} updraft velocity (also visible in Fig. 3d for the May 11 case) followed by
564 Δ CDNC predictions for the 1 m s^{-1} case. In the latter, high supersaturations are achieved leading to the formation
565 of many cloud droplets, yet the effects of co-condensation remained less pronounced as the high ascent speed
566 poses kinetic limitations for organic condensation (see Sect. 3.1 and Fig. 4). Despite the highest organic uptake in
567 the 0.1 m s^{-1} updraft simulations (Fig. 4a, d), the Δ CDNC remains the lowest. This can be explained by the low
568 s_{max} , which remains insufficient for the activation of small particles and kept the smallest activated dry diameter
569 on average at 63.7 nm (Table 2). As the Aitken mode possesses most particles in terms of number (Table 1), the
570 few nm reductions in r^* affect Δ CDNC the most when taking place at the steep slopes between the Aitken and
571 accumulation mode, which does not happen in the simulations performed with 0.1 m s^{-1} updraft.

572 An additional set of simulations using the CJ volatility distribution with the 0.3 m s^{-1} updraft velocity are
573 performed to assess the comparability of our simulations to Topping et al. (2013) and to evaluate the impact of
574 the volatility distribution upgrade from CJ to F. Results from these simulations are summarized in Table 2, but
575 also visualized in black in Figs. 3 and 5a. The Δ CDNC predicted in the simulations using CJ volatility distributions
576 are lower (Δ CDNC = 12.4%) than those predicted using the F distribution, but fall within the variability reported
577 in Topping et al. (2013; Δ CDNC of ~5–55%). The difference between the simulations performed with CJ and F
578 volatility distributions, respectively, can be explained by the lower organic vapor concentration in the CJ
579 distribution at model initialization, leading to a lower amount of soluble mass at CB (Table 2; Fig. S.4). This result
580 highlights that significant quantities of co-condensable organic vapors are distributed in the higher volatility bins
581 and these concentrations should not be neglected in further co-condensation studies.

582

583 **3.3 Impact of initial aerosol size distribution and organic vapor concentration on the sensitivity of CDNC** 584 **to organic vapor condensation**

585

586 The importance of Aitken mode in Δ CDNC associated with turning co-condensation on in ICPM is exemplified
587 in Fig. 5b for the 0.3 m s^{-1} updraft simulations. In this figure, the initial dry PNSD are averaged from the
588 simulations with the highest 50% and lowest 50% modelled Δ CDNC, respectively. The PNSD corresponding to
589 the highest 50% of the modelled Δ CDNC has a very minor accumulation mode and a large Aitken mode (with
590 respect to the mode total number concentrations i.e., N_2 and N_1 , respectively). It is therefore named as PNSD_{NUM},
591 where NUM refers to a strong nascent ultrafine mode characteristic of the shown size distribution. The PNSD
592 corresponding to the lowest 50% of the modelled Δ CDNC is strongly bimodal, where the Aitken and accumulation
593 modes are almost equal in terms of N . Moreover, the two modes are separated by a clear Hoppel minimum (Hoppel
594 and Frick, 1990). Hoppel minimum is characteristic for particulate matter, which has undergone cloud processing.
595 This result underlines that environments rich in particles from a local source would be more susceptible to high
596 Δ CDNC due to co-condensation while regions with aged and cloud processed size distributions are affected less
597 (Δ CDNC < 20% in our simulations; Fig. 5a).

598 Interestingly, a nascent ultrafine aerosol particle mode (NUM) was found to be important when looking
599 into suitable conditions for large increase in CDNC caused by surface active organics (Lowe et al., 2019;
600 Ovadnevaite et al., 2017). Lowe et al. (2019) utilized the same CPM as used in this study (notably without co-

601 condensation), but enabled a fraction of the particulate organics to form a thin, max. 0.2 nm thick film around the
602 particle. The film was characterized by a surface tension of 40 mN m^{-1} as opposed to the surface tension of pure
603 water (72.8 mN m^{-1}). The idea of this compressed film (CF) approach was to simulate the surface tension
604 reductions caused by organic species leading to the activation of smaller particles to cloud droplets at the coastal
605 Mace Head site (Ovadnevaite et al., 2017). Through sensitivity studies, Lowe et al. (2019) found that the largest
606 percent change in CDNC due to surface active organics (>10%) took place in Mace Head when $N_2 < aN_1^b + c$ ($a =$
607 602 , $b = 0.0884$, $c = -766$). The increase in CDNC in the Lowe et al. (2019) study was also attributed to the
608 reduction in s_c when comparing against simulations where the surface tension was that of water. Moreover, the
609 same competition effect between s_{max} and s_c reductions – as described here in Sect. 3.2 – was demonstrated in
610 their study, but just triggered by different chemical parameters. The sensitivity of the CDNC enhancements to
611 PNSD_{NUM} in this study as well as in Lowe et al. (2019) demonstrates that the activation of fresh and non-cloud-
612 processed aerosol particles is susceptible to small reductions in s_c that can be triggered e.g., by organic surfactants
613 or co-condensation. Importantly, potential surface activity also affects the CCN activation behavior of
614 atmospheric organics (Ruehl et al., 2012, 2016; Lowe et al., 2019), correlating with volatility and solubility. The
615 combined effect of all these three properties needs to be thoroughly investigated, because of the potential of the
616 organic film to suppress the solute effect (Sorjamaa et al., 2004) and thereby co-condensation and its effects on
617 ΔCDNC .

618 In conjunction with the ΔCDNC susceptibility to PNSD_{NUM}, this study most critically highlights the
619 importance of incorporating multimodal, and representative size distributions in process modeling studies
620 examining the cloud response to surface active organics, or co-condensation. Topping et al. (2013), for example,
621 used monomodal distributions (with varying log-normal parameters) in their study, which could lead to
622 overestimation of ΔCDNC as size distributions with Hoppel minima are not explored. Multimodal distributions
623 were used later by Crooks et al. (2018), but further explanation of the cloud response of the update remained
624 lacking. In summary, our results suggest that in clean environments with a local source of ultrafine particles, such
625 as the boreal forest or marine environments, organic species in the presence of a NUM-featured PNSD can have
626 significant impact on cloud properties either via co-condensation or through surface tension reductions.

627 Subsequently, a dry PNSD-based criteria for identifying regimes (conditions) in which co-condensation
628 has the highest impact on CDNC are defined. It is found that restricting the ratio between the accumulation and
629 Aitken mode geometric mean diameters in the initial dry PNSD to below six (i.e., $D_2/D_1 < 6$) and the Aitken mode
630 number concentration to exceed 1000 cm^{-3} (i.e., $N_1 > 1000 \text{ cm}^{-3}$) would yield $\Delta\text{CDNC} > 20\%$ in our simulations.
631 By using the diameter ratio criterion, size distributions without a distinguishable Hoppel minimum are selected,
632 which is characteristic in the simulations yielding the highest ΔCDNC (Fig. 5b) and the high N_1 ensures a high
633 concentration of aerosol particles potentially activating into cloud droplets. Fig. 5d shows the ΔCDNC as a
634 function of D_2/D_1 , N_1 and the Pearson correlation coefficient with PNSD_{NUM} (0.3 m s^{-1} updraft case). The
635 simulations with the initial dry PNSD fulfilling the criteria are highlighted with white crosses. Most of the high
636 ΔCDNC are well captured, and at those times the correlation with the PNSD_{NUM} is high (Pearson $R > 0.7$). The
637 simulations fulfilling the dry PNSD-based criteria are marked also in Fig. 5c showing that most of the high
638 ΔCDNC are captured, which again highlights the critical role of the aerosol size distribution representation in
639 capturing the co-condensation driven ΔCDNC .

640 In addition to the PNSD_{NUM} features, also the initial organic vapor concentration (C_g^{INIT}) influences the
641 modeled ΔCDNC . This relationship is depicted in Fig. 5c using the ICPM simulations corresponding to 0.3 m s^{-1}
642 updrafts. The y -axis represents the modeled ΔCDNC and the x -axis the organic vapor concentration distributed
643 in $\log_{10}C^*$ bins within $[-4, 4]$ (denoted as $C_{g,-4:4}^{\text{INIT}}$) i.e., in bins that do not show high dependency on N_2 or initial
644 temperature (see Sect. 3.2 for details). The relationship is not straightforward, but linear increases in ΔCDNC as
645 a function of $C_{g,-4:4}^{\text{INIT}}$ can be seen under constant, yet sufficiently high s_{max} (here $>0.2\%$). Under the modelled
646 scenarios where $s_{\text{max}}>0.2\%$, the $C_{g,-4:4}^{\text{INIT}}$ remains low, mostly below $2 \mu\text{g m}^{-3}$, and the highest enhancements are
647 achieved when $C_{g,-4:4}^{\text{INIT}}$ is $\lesssim 1 \mu\text{g m}^{-3}$ because the soluble organic mass is distributed to more particles. The markers
648 in Fig. 5c are color-coded by the initial PNSD surface area, which under a constant updraft anticorrelates with
649 s_{max} (see Eq. 3). ΔCDNC shows high sensitivity to $C_{g,-4:4}^{\text{INIT}}$ when the dry PNSD surface area stays below a $100 \mu\text{m}^2$
650 cm^{-3} threshold. Based on this analysis, it can be concluded that in the presence of a NUM-featured PNSD enabling
651 the formation of high supersaturations (the dry PNSD surface area stays below $100 \mu\text{m}^2 \text{cm}^{-3}$), an adiabatic ascent
652 with an updraft of 0.1 or 0.3 m s^{-1} can yield ΔCDNC of $>40\%$ if $1 \mu\text{g m}^{-3}$ of co-condensable organic vapor is
653 present in the rising air. This is a likely occurrence in the spring and summertime boreal forest (Huang et al.,
654 2021). The simulations performed with the highest updraft velocity ($w = 1.0 \text{ m s}^{-1}$) yield lower ΔCDNC under
655 these clean conditions (ΔCDNC does not exceed 40%) even though the simulated s_{max} increase as opposed to the
656 results obtained with lower updrafts (e.g. Table 2), because of the kinetic limitations hindering co-condensation
657 (see Sect. 3.1).

658

659 3.4 Expected seasonality in the impact of co-condensation on CDNC at SMEAR II

660 In the following, the seasonality of the dry PNSD surface area at SMEAR II (6-year-long time series, 2012–2017)
661 is investigated to estimate how often it stays below the previously mentioned threshold of $100 \mu\text{m}^2 \text{cm}^{-3}$ i.e., times
662 when only $1 \mu\text{g m}^{-3}$ of co-condensable organic vapor present in the rising air could yield significant ΔCDNC . This
663 is followed by an investigation of the frequency of the PNSD criteria ($D_2/D_1<6$ and $N_1>1000 \text{ cm}^{-3}$) fulfillments in
664 the long-term size distribution measurements at SMEAR II.

665 Fig. 6a shows the seasonality of the dry surface area at SMEAR II. During daytime (9–19 EET) the
666 surface area stays below the previously mentioned threshold 86% of the time during the 2012–2017 measurement
667 period (Fig. S.5), which suggests that under 0.3 m s^{-1} updraft velocities, generation of $s_{\text{max}}>0.2\%$ at this site is
668 likely. During summer months, the likelihood of surpassing the dry PNSD surface area threshold of $100 \mu\text{m}^2 \text{cm}^{-3}$
669 increases to 22% from 10% (Fig. S.5) due to biogenic SOA formation (Tunved et al., 2006), which grows the
670 accumulation mode in the PNSD. Biogenic SOA formation depends on the SOA precursor i.e., BVOC emissions
671 and concentrations. Monoterpene concentrations are highest at SMEAR II in summer (Kontkanen et al., 2016;
672 Hakola et al., 2012) as their emissions are strongly temperature-driven (Guenther et al., 1993). The organic vapor
673 concentration available for co-condensation is therefore also highest in summer, but due to the enhanced surface
674 area, the soluble organic mass is distributed to more particles dampening the cloud response to co-condensation.
675 However, the monoterpene emission period is longer than just summer, and elevated monoterpene concentrations
676 can be observed throughout the thermal growing season (when the daily average temperature is above 5°C ;
677 Kontkanen et al., 2016; Hakola et al., 2012). Therefore, monoterpene emissions take place also at times when the
678 dry PNSD surface area stays below the $100 \mu\text{m}^2 \text{cm}^{-3}$ threshold.

679 Fig. 6b shows the dry PNSD surface area derived from the long-term PNSD measurements at SMEAR
680 II as a function of temperature. When the ambient temperature exceeds 5°C, the dry PNSD surface area starts to
681 increase with increasing temperature. The dry PNSD surface areas and ambient temperatures (from 8.4 m height;
682 Fig. 1c) from the BAECC simulation period are also shown to highlight the fact that the BAECC sample represents
683 well the long-term statistics of the thermal growing season, providing confidence in the representativity of the
684 BAECC sampling period for this boreal environment. The BAECC samples are color-coded by the modelled
685 ΔCDNC . The highest ΔCDNC (i.e., $\Delta\text{CDNC} > 40\%$) are modeled when the dry PNSD surface areas are below
686 the $100 \mu\text{m}^2 \text{cm}^{-3}$ threshold. Importantly, most of these model scenarios yielding $\Delta\text{CDNC} > 40\%$ coincide with
687 ambient temperatures between 5 and 8°C i.e., at times when the monoterpene concentrations are not at their
688 highest yet sufficient concentrations of organic vapor are still present to cause a large cloud response. It can
689 thereby be concluded that the highest ΔCDNC due to co-condensation can be expected in thermal Spring and Fall.
690 However, due to the seasonality in hygroscopicity and the slightly higher κ in spring and autumn (as opposed to
691 summer; Fig. 6a) the likelihoods of obtaining s_{max} exceeding 0.2% to yield significant ΔCDNC can be somewhat
692 buffered due to hygroscopic growth.

693 Next, the frequency to which the PNSD criteria ($D_2/D_1 < 6$ and $N_1 > 1000 \text{ cm}^{-3}$) are fulfilled in the long-
694 term size distribution measurements is examined. For this purpose, the same 6-year PNSD data set collected at
695 SMEAR II fitted with two log-normal size distributions (Hussein et al., 2005) is utilized. The percentage of times
696 the criteria are met is shown in Fig. 7a. The highest frequencies (30–40% of the time) are observed in April, May
697 and September, which correlates with the new particle formation (NPF) frequency at the site (Nieminen et al.,
698 2014; Dada et al., 2017). The monthly median size distributions fulfilling the criteria are shown in Fig. 7c. They
699 all clearly exhibit the lack of a Hoppel minimum, similarly to PNSD_{NUM} , and suggest a potentially high impact of
700 newly formed particles on cloud properties through co-condensation. The results again clearly emphasize the need
701 of accurate representation of aerosol size distributions and lifecycle in models (such as other CPMs or global
702 circulation models, GCMs) to account for the impacts of co-condensation and the strong seasonality to be expected
703 in the magnitudes in ΔCDNC .

704

705 3.5 Expected spatiotemporal variability in the impact of co-condensation on CDNC over the boreal biome

706 In this section the SMEAR II results are compared against a 5-year UKESM1 simulation (see Sect. 2.5; analysis
707 restricted to the boreal biome). While the SMEAR II PNSD data are retrieved at ground level, utilization of the
708 UKESM1 modal parameters (only soluble modes considered) from CB is chosen, because these PNSD log-normal
709 parameters would actually meet the cloud droplet activation scheme in the model. The monthly averages of the
710 percentage of times the criteria ($D_2/D_1 < 6$ and $N_1 > 1000 \text{ cm}^{-3}$) are fulfilled in the boreal grids are shown in Fig. 7b.
711 Here, the Aitken mode geometric mean diameter and total number concentration (D_1 , N_1) and accumulation mode
712 geometric mean diameter (D_2) are obtained from the soluble Aitken and accumulation modal parameters (see Sect.
713 2.5 for more details regarding the UKESM1 modes). The frequencies, which remain roughly well below 6%, are
714 in general much lower than observed at SMEAR II. This can be explained by the lack of the boundary layer NPF
715 process in the UKESM1 simulations (Sect. 2.5). Therefore, the UKESM1 results can be taken as the lower estimate.
716 Fig. 7d displays the monthly median PNSD in the boreal grid cells fulfilling the criteria ($D_2/D_1 < 6$ and $N_1 > 1000$
717 cm^{-3}), which are constructed from the soluble Nucleation, soluble Aitken and soluble accumulation mode modal
718 parameters from the UKESM1 simulations when the criteria are fulfilled (criteria only uses soluble Aitken and
719

720 soluble accumulation modes). The size distributions calculated using these UKESM1 modal parameters are in
721 general less similar to the PNSD_{NUM} than the monthly median SMEAR II size distributions are (Fig. 7c), because
722 they have more distinguished multimodal shapes. However, they still feature a minor accumulation mode in the
723 presence of a large Aitken mode (with respect to N).

724 The UKESM1 results suggest strong spatiotemporal variability in the co-condensation driven Δ CDNC
725 should be expected if this process were to be represented in GCMs. Consistently with the SMEAR II observations
726 (Fig. 7a), spring months stand out as the times when the criteria are most likely to be met, but the other peak in
727 the frequency, expected in September at SMEAR II, cannot be seen. Another interesting feature is the large spatial
728 variability in the frequency. In March and April, a very evident hotspot can be seen in the southern parts of the
729 boreal forest, more precisely in the north of Kazakhstan. When the whole northern hemisphere is displayed, it is
730 clear that the hot spot region extends over Europe during Spring (Fig. S.6) when the conditions favor the
731 formation, growth and survival of small particles (Kerminen et al., 2018) as shown in Fig. S7 in terms of nucleation
732 mode number concentration. The result therefore suggests high co-condensation potential in areas rich in ultrafine
733 particles. The cloud response of co-condensation in an extended domain covering most of Eurasia could be an
734 interesting follow-up study. However, such a study should incorporate also the condensation of nitric acid and
735 ammonia, the concentrations of which are presumably abundant in the regions, where the co-condensation PNSD
736 criteria are met (Kakavas et al., 2022). As this “Kazakhstan hotspot” is connected to aerosol phenomenology
737 outside the boreal biome, the analysis is not continued further. Another evident springtime hot spot is located in
738 North America, near the Rocky Mountains, but the updraft velocities at the area are not within the desired range
739 ($[0.2, 0.5] \text{ m s}^{-1}$) to yield significant cloud response from co-condensation (Fig. 7b).

740 Aside from these hotspots, it is notable that the overall background of the frequency of the times the
741 criteria are met in the latitude range of $[0, 75]^\circ\text{E}$ increases from $<2\%$ to $2\text{--}6\%$ when moving from March to April.
742 This background stays elevated until June. Smaller hotspots within this area are visible and they correspond to
743 regions known with high sulfur dioxide (SO_2) emissions, such as the Kola peninsula. The Kola peninsula SO_2
744 emissions have shown to trigger NPF events measured at SMEAR I in Finnish Eastern Lapland (e.g., Kyrö et al.,
745 2014). An interesting next step would be to see how Fig. 7b changes with UKESM1 simulations incorporating
746 boundary layer NPF and whether the percentage of times the criteria are met increases to values comparable with
747 the SMEAR II observations and whether the frequency becomes larger also in Fall. Another interesting
748 observation to be made from Fig. 7b is that no significant impact of co-condensation would be expected in
749 UKESM1 in most of Siberia (East and Northeastern Siberia), which can be explained by the lack of nucleation
750 mode particles in the UKESM1 simulations over the region (Fig. S.7).

751 4 Conclusions

752 This study focuses on the role of the co-condensation of organic vapor and water on warm cloud microphysics in
753 a boreal forest environment. Co-condensation has been proposed as a potentially significant process contributing
754 to the feedbacks between VOC emissions, SOA loadings, cloud formation and climate. Boreal forests account for
755 about a third of the Earth’s forested area and are potentially significant sources of such co-condensing species.
756

757 First, ICPM model is used to perform simulations for the BAECC measurement campaign which took
758 place at the SMEAR II station in Southern Finland during 2014 (Petäjä et al., 2016). The measurement setup
759 during BAECC was very advanced, enabling the initialization of ICPM with state-of-the art data describing the

760 ambient aerosol physical and chemical properties. The measurements conducted with the FIGAERO-I-CIMS
761 (e.g., Mohr et al., 2017) are of high importance for this study due to the simultaneous measurements of organic
762 particle and vapor species. These data enable the incorporation of organic vapors from a broad volatility range
763 into the ICPM simulations. The previous modeling work on this topic used volatility distributions based on
764 particle-phase measurements only, resulting in overall lower volatility and contributions of semi- and intermediate
765 volatility organic vapor.

766 The results from the ICPM simulations reveal that a competition effect exists between the reductions in
767 maximum supersaturations and critical supersaturations needed for aerosol particle activation into cloud droplets.
768 The reductions in critical supersaturations are greater than the reductions in maximum supersaturation, which
769 results in the simulated CDNC enhancements (simulations with co-condensation are compared against simulations
770 without it under same meteorological conditions). The CDNC enhancements are of the order of 20% under
771 realistic updraft velocities (0.1, 0.3, and 1 m s⁻¹) and correspond to reductions of 12–16 nm in the smallest activated
772 dry diameters (144 to 126 nm, 102 to 88.6 nm, 72 to 61 nm for the 0.1, 0.3, and 1 m s⁻¹ updraft scenarios,
773 respectively). The activation of smaller particles into cloud droplets results, as expected, in the formation of more
774 numerous smaller cloud droplets. The critical supersaturation suppressions result from the additions of soluble
775 organic mass below cloud base along the simulated air parcels' adiabatic ascents while the reductions in maximum
776 supersaturation are caused by the increasing condensation sink provided by more cloud droplets (the source of
777 supersaturation is fixed as the meteorological conditions between simulations with and without co-condensation
778 are kept constant).

779 The predicted CDNC enhancements are highest for the 0.3 m s⁻¹ updraft velocities and depend on several,
780 at least partly, interlinked parameters (see also Lowe et al., 2019). One parameter affecting the modelled CDNC
781 is the availability of the co-condensable organic vapors, which in turn depend on the updraft velocities and the
782 features of the organic volatility distribution. Most organic vapor condenses under the slowest adiabatic ascents
783 and least in the highest due to kinetics. The organic volatility bins spanning from ELVOCs to the lower-volatility
784 IVOCs condense in a similar, updraft-dependent, degree prior reaching the cloud base. Organic vapors of higher
785 volatility involving species such as formic acid condense less efficiently and their condensation is sensitive to the
786 model initialization temperature and the presence of large particles, which are likely to activate regardless of co-
787 condensation. Therefore, small enhancements in particularly SVOC and lower-volatility IVOC concentrations
788 lead to significant enhancements in CDNC, while increases in the most volatile IVOCs and formic acid do not
789 affect CDNC much.

790 The simulations performed with 0.3 m s⁻¹ updrafts are repeated using volatility distributions from
791 previous co-condensation studies (Cappa and Jimenez, 2010; Topping et al., 2013; Crooks et al., 2018). By doing
792 so, the BAEC campaign median CDNC enhancement decreased from 23.3 to 12.4%. This result is explained by
793 the lower SVOC and IVOC concentrations in previous studies, highlighting the added value of capturing these
794 higher volatility bins within the VBS representations of atmospheric organic species. On the other hand, adding
795 information on the LVOC and ELVOC range do not significantly influence the CDCN enhancements due to co-
796 condensation.

797 The sensitivity of the modelled Δ CDNC to organic vapor concentrations is strongest when high
798 maximum supersaturations ($s_{\max} > 0.2\%$ for the 0.3 m s⁻¹ updraft scenarios) are reached. Such conditions are
799 achieved when the dry PNSD surface area (a proxy for the condensation sink) remains below 100 $\mu\text{m}^2 \text{cm}^{-3}$. Under

800 those conditions, CDNC enhancements exceeding 40% are predicted for conditions in which roughly $1 \mu\text{g m}^{-3}$ of
801 co-condensable organic vapor is present.

802 Besides the updraft velocities and the availability of co-condensable vapors, the CDNC enhancements
803 depend critically on the size distribution of the initial aerosol population. Highest CDNC enhancements are
804 generally achieved when the model is initialized with a relatively weak accumulation mode combined with a large
805 nascent ultrafine particle mode with a geometric mean diameter of ca. 40 nm, with no visible Hoppel minimum
806 present in the distribution. Such conditions are observed most frequently in Spring and September (about 30–40%
807 of the time in years 2012–2017), when new particle formation events take place at SMEAR II.

808 Further on, UKESM1 simulations (years 2009–2013) are utilized to investigate the potential impact of
809 including the process of co-condensation on droplet formation in this model over the whole boreal biome using
810 the criteria developed from the SMEAR II case to identify most susceptible PNSD conditions. Aside from two
811 hotspots (one near the Rocky Mountains in North America, one over northern Kazakhstan, which are not analyzed
812 further), the presence of suitable PNSD is most frequent over Fennoscandia and western parts of Siberia in spring,
813 yet the frequencies at which those PNSD are modelled remained much lower than those obtained from the long-
814 term SMEAR II PNSD measurements (2–6% in UKESM1). It is likely that the incorporation of boundary layer
815 NPF in UKESM1 will increase this frequency. Perhaps surprisingly, suitable PNSD are never modeled over most
816 of Siberia, suggesting that for the model configuration of UKESM1 used in this study, the process of co-
817 condensation would not be expected to have an influence on droplet formation in this area. This is due to the low
818 concentration of ultrafine particle particles modeled in the area.

819 In summary, these results highlight the potential significance of co-condensation in pristine boreal
820 environments with a nascent ultrafine particle mode present. Such conditions are met over Fennoscandia and
821 Western parts of Siberia in Spring and to a lesser extent in the Fall, when NPF takes place. For future modelling
822 purposes, it is vital to stress the importance of the accurate representation of PNSD for capturing the role of co-
823 condensation of organics on CDNC enhancements. Because the modelled CDNC enhancements are so significant,
824 further research focus especially regarding observations of the co-condensation should be targeted in the future to
825 motivate future assessments of co-condensation-driven radiative forcing. Perhaps this work inspires aircraft
826 measurements (of the relevant parameters discussed in this paper) to take place over the Fennoscandia in the future
827 to finally narrow down the importance of co-condensation.

828

829

830 **Data availability**

831 The ICPM input and outputs for reproducing the figures will be available on the Bolin Centre database.

832 **Competing interests**

833 The authors have the following competing interests: Some authors are members of the editorial board of
834 Atmospheric Chemistry and Physics. The peer-review process will be guided by an independent editor. On or
835 more authors have received funding from European Union's Horizon 2020 research and innovation programme,
836 European Research Council, Knut and Alice Wallenberg foundation, Academy of Finland and US Department of
837 Energy, and/or support from ACTRIS Translational Access and ACTRIS-HY. The authors have no other
838 competing interests to declare.

839 **Author contributions**

840 LH, IR, DGP and CM conceptualized the idea of the study. LH prepared the model input data performed the
841 simulations, analyzed the simulation output, made the figures and wrote the manuscript with contributions from
842 the coauthors. TP designed and led the BAECC campaign. CM performed the FIGAERO-I-CIMS measurements,
843 WH processed and delivered the FIGAERO-I-CIMS data and gave input on the volatility distribution calculation.
844 RR assisted with the radiosonde data and provided the hygroscopicity seasonal cycle data. ET and DGP performed
845 the UKESM1 simulations and DGP designed and processed the data for analysis input parameters to droplet
846 activation parameterization. SB visualized the UKESM1 data and gave input on the data interpretation. LH wrote
847 the paper with input from all co-authors.

848 **Acknowledgements**

849 We gratefully acknowledge Samuel Lowe for developing the unified framework for organics onto the ICPM
850 (Lowe, 2020), the useful discussions, code and support. We acknowledge Ellie Duncan for useful discussions and
851 support regarding the UKESM data. We acknowledge Pasi Aalto and SMEAR II staff for their efforts during the
852 BAECC campaign and Dmitri Moisseev for useful discussions regarding updraft velocities. We thank Federico
853 Bianchi for useful discussion regarding NPF in the Northern Hemisphere. We acknowledge the Atmospheric
854 Radiation Measurement (ARM) Program for their inputs during BAECC, the interpolated radiosonde data were
855 obtained from the ARM Program sponsored by the U.S. Department of Energy, Office of Science, Office of
856 Biological and Environmental Research, Climate and Environmental Sciences Division. We acknowledge use of
857 the Monsoon2 system, a collaborative facility supplied under the Joint Weather and Climate Research Programme,
858 a strategic partnership between the Met Office and the Natural Environment Research Council. We also thank all
859 the people responsible for the development of UKESM1. DGP would like to extend a personal thanks to Dr
860 Alistair Sellar, who provided support for the configuration of the UKESM1 simulations performed as part of the
861 AeroCom GCM Trajectory experiment on which these simulations are based.

862 **Funding**

863 Financial support from the European Union's Horizon 2020 research and innovation programme (project FORCeS
864 under grant agreement No 821205, project FOCI under grant agreement No101056783, project CRiceS under
865 grant agreement No 101003826), European Research Council (Consolidator grant INTEGRATE No 865799,
866 starting grant CHAPAs No 850614), and Knut and Alice Wallenberg foundation (Wallenberg Academy
867 Fellowship projects AtmoRemove No 2015.0162 and CLOUDFORM No 2017.0165), Academy of Finland via a
868 Flagship programme for Atmospheric and Climate Competence Center (ACCC, No 337549) and projects No
869 353386, 334792, 340791, 325681 are gratefully acknowledged. The BAECC campaign was supported by US
870 Department of Energy (Petäjä, No DE-SC0010711) and additional measurements were supported via ACTRIS
871 Transnational Access. University of Helsinki is acknowledged for supporting the SMEAR II station via ACTRIS-
872 HY.

Figure 2 (a) The normalized volatility distributions ($C_g + C_p$) from Cappa and Jimenez (2010; CJ) and the BAECC FIGAERO-I-CIMS measurements (F) using the modified Li et al. (2016) molecular formulae-based parameterizations. A volatility distribution from Hunter et al. (2017) constructed from the BEACHON-RoMBAS measurement campaign is shown in the dashed bars. The volatility ranges for ELVOC, LVOC, SVOC and IVOC/VOC are shown in color scales. These C^* limits apply throughout the paper. (b–c) The partitioning predicted based on the FIGAERO-I-CIMS gas- and particle-phase measurements and the ICPM, respectively. (d) A scatterplot drawn between the FIGAERO-I-CIMS derived partitioning coefficients ($\zeta_{\text{meas}}^{90\% \text{ RH}}$) and ICPM derived coefficients ($\zeta_{\text{mod}}^{90\% \text{ RH}}$) for the 12 different volatility bins. Panels (e–f) represent the gas phase molecular composition from the FIGAERO-I-CIMS: panel (e) the distribution between organic nitrates and non-nitrates and panel (f) the degree of oxygenation in the form of oxygen and carbon numbers. The marker size in panel f corresponds to the concentration of signal for the given n_C and n_O combination.

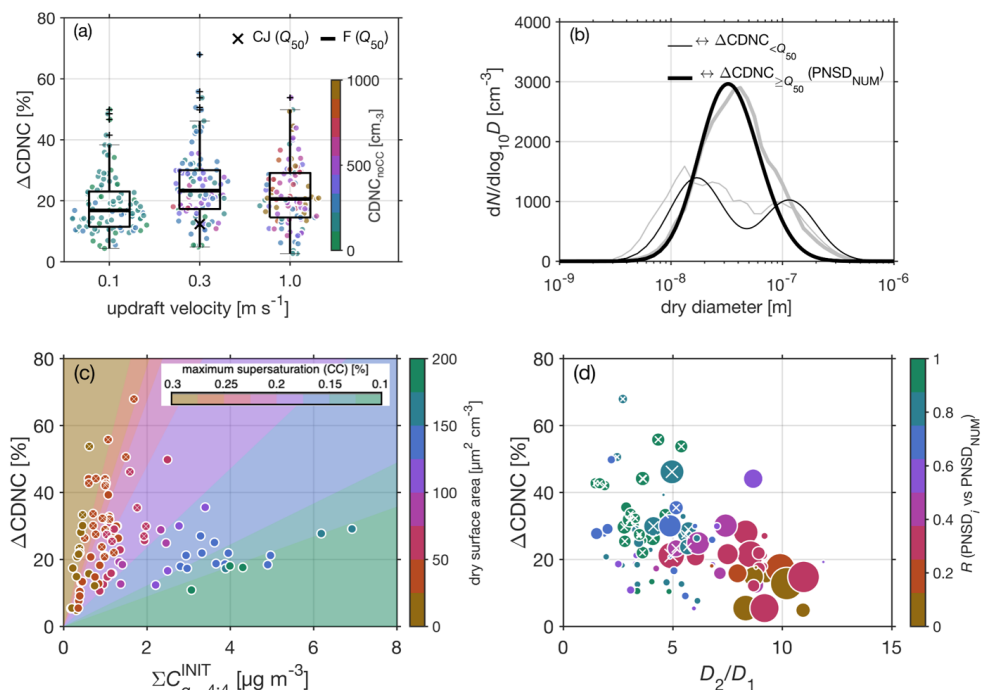

915

916 **Figure 3** A summary of simulated cloud microphysics on May 11, 11:30 EET during the BAECC campaign. Simulations are
 917 performed both with and without organic condensation (red and blue lines, respectively) for three different updraft velocities
 918 (see line styles from panel a). The initial temperature is 279 K, pressure 980 hPa and supersaturation -0.1% ($RH = 90\%$). (a)
 919 The concentration of SVOCs and IVOCs in the gas phase as a function of distance from cloud base (CB). (b) The absolute
 920 change in critical supersaturation as a function of soluble mass added along the ascent by condensing organics. The markers
 921 represent the reductions at the maximum supersaturation (s_{\max}). (c–d) The evolution of the s_{\max} and CDNC with altitude,
 922 respectively. (e) The droplet spectra 50 meters above CB. Size bins exceeding the critical diameter as predicted by Köhler
 923 theory are calculated as cloud droplets. The red lines are obtained with F volatility distributions and the black with CJ (**Fig.**
 924 **2a**). The line type specifications in panels d–e follow those shown in panel a and the colors used in panels d–e are documented
 925 in the panel c legend.

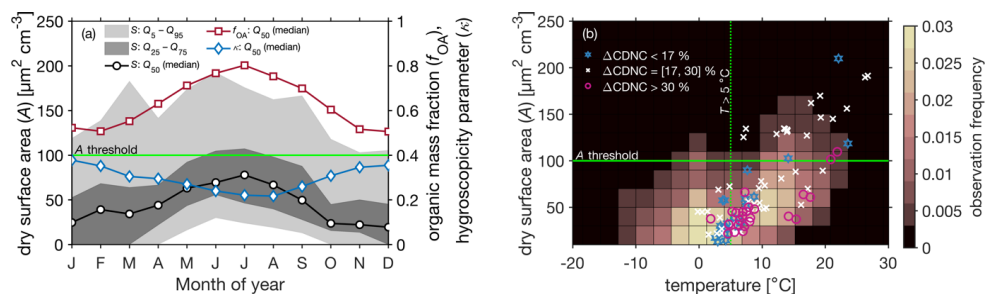

926

927 **Figure 4** Box plots showing the fractions (a–c) and absolute concentrations (d–f) of vapor condensed below cloud base per
 928 volatility bin for the 0.1, 0.3 and 1.0 m s⁻¹ updraft scenarios, respectively. The volatility ranges in panels a–f start from log₁₀C*
 929 = 0 because of the negligible gas-phase concentrations in the lower volatility bins. The final row (g–i) shows how the fraction
 930 of vapor condensed from the highest volatility bin (y-axis) behaves as a function of ICPM initialization temperature (x-axis),
 931 accumulation mode number concentration (marker size) and total initial organic vapor concentration (marker color).

Figure 5 (a) Box plots showing the predicted ΔCDNC (using F volatility distributions) due to co-condensation in the three different modelling scenarios (0.1 , 0.3 and 1.0 m s^{-1} updrafts). The median (Q_{50}) ΔCDNC yielded using the CJ distribution is shown with a black cross. The colorful markers represent CDNC (without accounting for co-condensation) in form of a swarmplot. (b) The median initial dry size distributions calculated from the simulations exceeding the 75th percentile in ΔCDNC ($\leftrightarrow Q_{75}$; thick lines) and remaining below the 25th percentile ($\leftrightarrow Q_{25}$; thin lines), respectively. The median is calculated by taking a median of the log-normal parameters from both sets of simulations (in black) and from the measurement data (in grey). The data are shown for the simulation performed with a 0.3 m s^{-1} updraft. The black lines are drawn from the ICPM input modal parameters and the grey lines from the measured size distribution data. (c) The relationship between the modeled ΔCDNC and the initial organic vapor concentration within the $\log_{10}C^g$ range from -4 to 4 ($C_{g,-4:4}^{\text{INIT}}$). The marker color-coding represents the initial dry size distribution surface area (A). The plot background is colored with the modeled maximum supersaturations (s_{max}). These are calculated from s_{max} binned ΔCDNC vs $C_{g,-4:4}^{\text{INIT}}$ linear fit 90% confidence intervals (CI; area between CI is colored). The figure shows that A anticorrelates with s_{max} (see Eq. 3). The data are shown for the simulations performed with a 0.3 m s^{-1} updraft only.

949
 950 **Figure 6 (a)** The seasonal cycle of the dry aerosol size distribution surface area (S) calculated from the long-term aerosol size
 951 distribution observations (2012–2017; left y-axis), where the markers represent the median values, the darkest shading the
 952 interquartile range and the lighter shading the area between the 5th and 95th percentiles. The panel also contains the median
 953 seasonal cycles of organic mass fraction and the κ hygroscopicity parameter compiled from the same long-term period (right
 954 y-axis). The green horizontal line refers to the dry surface area threshold of $100 \mu\text{m}^2 \text{cm}^{-3}$ from Fig. 5, under which the greatest
 955 ΔCDNC are modeled using the BAECC data. **(b)** A density plot showing the observations of S under different ambient
 956 temperatures during the 2012–2017 long-term period. The A threshold of $100 \mu\text{m}^2 \text{cm}^{-3}$ is again shown with the horizontal
 957 green line. The vertical dashed green line is a rough estimate for the start of the thermal growing season, which also refers to
 958 the starting point of the majority of the BVOC emissions. The markers show the ICPM simulation data color-coded with the
 959 associated ΔCDNC (simulations yielding the ΔCDNC below the 25th percentile are shown in blue, simulations yielding
 960 ΔCDNC above the 75th percentile in red and the simulations between those limits are shown in white).

Figure 7 (a) Percentage of times the criteria ($D_2/D_1 < 6$ and $N_1 > 1000 \text{ cm}^{-3}$) are met at SMEAR II between the 2012–2017 measurement period. D_2 , D_1 and N_1 are attained from bimodal fits calculated for the measured PNSD using the Hussein et al. (2005) algorithm. (b) The percentage of times the criteria are met in a 2009–2013 UKESM1 simulation. D_2 , D_1 and N_1 are the modal parameters representing the soluble accumulation mode and soluble Aitken mode parameters. The gray markers refer to boreal grid cells, where the median updraft velocity at cloud base is between 0.2 and 0.5 m s⁻¹. (c–d) Monthly median size distributions from the long-term PNSD measurements at SMEAR II and UKESM1 simulation, respectively. The UKESM1 size distributions are calculated from the log-normal PNSD parameters for nucleation, soluble Aitken and soluble accumulation modes assuming geometric standard deviations of $\sigma = 1.59$ for nucleation and soluble Aitken modes and $\sigma = 1.4$ for the soluble accumulation mode. The soluble coarse mode is not included in the analysis.
