11  
12 **Abstract**

13 Water storage plays a profound role in the lives of people across the Middle East and North Africa  
14 (MENA) as it is the most water stressed region worldwide. The lands around the Caspian and  
15 Mediterranean Seas are simulated to be very sensitive to future climate warming. Available water  
16 capacity depends on hydroclimate variables such as temperature and precipitation that will depend  
17 on socioeconomic pathways and changes in climate. This work explores changes in both the mean  
18 and extreme terrestrial water storage (TWS) under an unmitigated greenhouse gas (GHG) scenario  
19 (SSP5-8.5) and stratospheric aerosol intervention (SAI) designed to offset GHG-induced warming  
20 above 1.5 °C and compares both with historical period simulations. Both mean and extreme TWS are  
21 projected to significantly decrease under SSP5-8.5 over the domain, except for the Arabian Peninsula,  
22 particularly in the wetter lands around the Caspian and Mediterranean Seas. Relative to global  
23 warming, SAI partially ameliorates the decreased mean TWS in the wet regions while it has no  
24 significant effect on the increased TWS in drier lands. In the entire domain studied, the mean TWS is  
25 larger under SAI than pure greenhouse gas forcing, mainly due to the significant cooling, and in turn,  
26 a substantial decrease of evapotranspiration under SAI relative to SSP5-8.5. Changes in extreme  
27 water storage excursions under global warming are reduced by SAI. Extreme TWS under both future  
28 climate scenarios are larger than throughout the historical period across Iran, Iraq, and the Arabian  
29 Peninsula, but the response of the more continental eastern North Africa (NA) hyper-arid climate is  
30 different from the neighboring dry lands. In the latter case, we note a reduction in the mean TWS  
31 trend under both GHG and SAI scenarios, with extreme TWS values also showing a decline compared  
32 to historical conditions.

33 **Keywords:** Mean and extreme water storage; SSP5-8.5; Stratospheric Aerosol Intervention; Global  
34 warming; MENA region, Caspian and Mediterranean Seas

35

### 36 **500-character non-technical text**

37 Water storage (WS) plays a profound role in the lives of people in the Middle East and North Africa  
38 and Mediterranean climate “hot spots”. Simulated is WS changed by greenhouse gas (GHG) warming  
39 with and without stratospheric aerosol intervention (SAI). WS significantly increases in the Arabian  
40 Peninsula and decreases around Mediterranean under GHG. While SAI partially ameliorates the GHG  
41 impacts, projected WS increases in dry regions and decreases in wet areas relative to the present  
42 climate.

43

### 44 **1. Introduction**

45 The Middle East and North Africa (MENA), with 6% of the world’s population, are currently among  
46 the most water-stressed regions worldwide (Fragaszy et al., 2020). The dry climate, intensifying  
47 droughts, increasing population, and water over-extraction particularly across the Middle East  
48 (World Bank, 2017), make it home to 12 of the 17 most water-stressed countries on the planet  
49 (Hofste et al., 2019). Water availability is crucial for sanitation (Reiter et al., 2004), economic activity  
50 (UNESCO, 2003), ecosystems (Shiklomanov and Rodda, 2003), and hydrological systems (Mooney et  
51 al., 2005).

52

53 The MENA region has the largest expected economic losses from climate-related water scarcity,  
54 robustly estimated at 6–14 % of Gross Domestic Product (GDP) by 2050 (World Bank, 2017). MENA’s  
55 terrestrial water storage (TWS) is being intensively extracted and may act as a flashpoint for conflict  
56 (Famiglietti, 2014). TWS incorporates all water on the land surface (snow, ice, water stored in the  
57 vegetation, river, and lake water) and in the subsurface (soil moisture and groundwater). Beyond  
58 anthropogenic activities, natural climate variability such as drought frequency affects water storage  
59 and agriculture, which then impacts food security (Fragaszy et al., 2020). The Middle East is  
60 especially prone to severe and sustained droughts due to its location in the descending limb of the  
61 Hadley circulation and associated dry and semiarid climate (Barlow et al., 2016). The 1998-2012 14-  
62 year period was the worst drought in the past 900 years (Cook et al., 2016). Because the saturated  
63 vapor pressure of air is largely controlled by temperature, any change in temperature, as well as  
64 precipitation, substantially affects (Konapala et al., 2020; Ajjur and Al-Ghamdi, 2021; Hobeichi et al.,  
65 2022) the water storage capacity available to supply the increasing water demand in the region (Lian,

66 2021). The MENA region, having both low precipitation and high evaporation, is very vulnerable to  
67 climate change (Giorgi, 2006; Lelieveld et al., 2012; Tabari and Willems, 2018; Zittis et al., 2019).  
68 MENA water storage is therefore particularly sensitive to any perturbation of the water cycle  
69 imposed by global warming.

70

71 GHG warming has already adversely affected water resources in the MENA region (Wang et al., 2018)  
72 and is simulated to intensify water competition between states (Arnell, 1999) in the future. Although  
73 global warming is expected to increase precipitation and soil moisture across MENA (Cook et al.,  
74 2020), it will decrease runoff and groundwater recharge by larger amounts (Milly et al., 2005;  
75 Shaban, 2008; Suppan et al., 2008). Using the GHG emission scenario A1B simulated by nine CMIP3-  
76 class climate models, Droogers et al. (2012) projected that 22% of the future annual water shortage,  
77 199 km<sup>3</sup> in 2050 in MENA, will be due to global warming. 17 global climate models from Coupled  
78 Model Intercomparison Project Phase 6 (CMIP6) under SSP5-8.5 simulate a significant increase in  
79 precipitation (+0.05 to 0.3  $\mp$  0.1 mm day<sup>-1</sup>) over South-Eastern Saharan Desert in NA by the end of  
80 the century (Arjdal et al., 2023). They also projected that the total soil moisture would increase over  
81 Southern Saharan Desert under the SSP5-8.5 (6 to 20%) and SSP2-4.5 (4 to 14%). Based on TWS data  
82 from eight global climate models participating in CMIP6, a broad part of the dry MENA region tends  
83 to be wetter under SSP5-8.5 over 2071-2100 (Xiong et al., 2022). GHG-driven groundwater storage  
84 depletion in the Middle East during the 21<sup>st</sup> century will far exceed that during the 20<sup>th</sup> century due  
85 to the increased evapotranspiration (ET) and reduced volume of snowmelt (Wu et al., 2020).

86

87 Although MENA's adjacent densely populated region, the Mediterranean, has a better water storage  
88 state, it is projected to substantially suffer from reduced water availability under future GHG climate  
89 scenarios (Lionello et al., 2006). This is due to both projected significant decreases in rainfall  
90 (Azzopardi et al., 2020) and large increases in demand for irrigation water by the end of the 21<sup>st</sup>  
91 century (Fader et al., 2016). The precipitation and water availability in the Mediterranean region, to  
92 the northwest of the MENA, is also projected to be highly sensitive to global warming, particularly  
93 regarding water availability (Lionello et al., 2006), having the largest differences in the water  
94 availability between 1.5 and 2°C warming scenarios globally (Schleussner et al., 2016). Global  
95 warming decreases Mediterranean groundwater recharge according to simulations under the IPCC  
96 A2 and B2 scenarios simulated using ECHAM4 and HadCM3 models (Döll and Flörke, 2005). Runoff  
97 is decreased by 10-30% according to 12 models such as CCSM3, and ECHAM5/MPI-OM (Milly et al.,  
98 2005), and soil moisture z-scores (obtained by taking the difference from the average and then

99 dividing it by the standard deviation of the time series from the baseline period) by -1 to -4 in warm  
100 seasons according to simulations under SSP1-2.6, SSP2-4.5, SSP3-7.0, and SSP5-8.5 (Cook et al.,  
101 2020). Water availability in turn is lowered by 8-28% for a warming of 2 °C as simulated by 11  
102 CMIP5-class models by Schleussner et al. (2016). Likewise, Döll et al. (2018) found a strong drying in  
103 the Mediterranean region under global warming since the largest precipitation decreases worldwide  
104 were simulated in this region under SSP1-2.6, SSP2-4.5, SSP3-7.0, and SSP5-8.5 scenarios (Cook et  
105 al., 2020). CMIP5 model results also confirm that the global warming (RCP2.6 and RCP6.0)  
106 substantially decreases the TWS in the Mediterranean by the mid- (2030-2059) and late- (2070-  
107 2099) twenty-first century (Pokhrel et al., 2021).

108

109 If global mean surface temperature rises to exceed 1.5 °C above the preindustrial mean temperature,  
110 severe global consequences, and societal problems can be expected (Masson-Delmotte, 2022). Solar  
111 radiation modification (SRM), a form of intervention to cool the climate by reflecting sunlight, has  
112 been proposed as a potential method of limiting global temperature rises and the associated impacts  
113 of increased GHG emissions. SRM may be the only way to keep or reduce surface temperatures to 1.5  
114 °C given the reality of the GHG mitigation measures that have been agreed upon to date (MacMartin  
115 et al., 2022). Simulations have shown a 2% decrease in total solar irradiance roughly offsets global  
116 warming due to a doubling of CO<sub>2</sub> concentrations, and continuous injections of 10-18 Tg SO<sub>2</sub> per year  
117 would lead to a cooling of about 1 °C after several years (WMO, 2022). This is consistent with  
118 observed surface cooling after large volcanic eruptions, such as the 1991 Mt Pinatubo eruption which  
119 produced cooling of about 0.3 °C over a 2-3 year period (e.g., IPCC, 2021).

120

121 Many global climate models have simulated SRM in the form of stratospheric aerosol intervention  
122 (SAI). Model studies include the Stratospheric Aerosol Geoengineering Large Ensemble Project  
123 GLENS (e.g., Cheng et al., 2019; Simpson et al., 2019; Abiodun et al., 2021), the Geoengineering Model  
124 Intercomparison Project (Kravitz et al., 2013; Tilmes et al., 2013), as well as others (e.g., Bala et al.,  
125 2008; Jones et al., 2018; Muthyala et al., 2018). Compared with global warming, SAI decreases mean  
126 global precipitation (Govindasamy and Caldeira, 2000; Bala et al., 2008; Robock et al., 2008; Cheng  
127 et al., 2019; Simpson et al., 2019) as well as both the intensity and frequency of precipitation extremes  
128 caused by GHG-induced climate change (Tilmes et al., 2013; Muthyala et al., 2018). Dagon and Schrag  
129 (2016) is a rare article that focuses on the spatial variability of runoff and soil moisture responses to  
130 SRM. Although solar geoengineering weakens the global hydrologic cycle (e.g., Bala et al., 2008;  
131 Tilmes et al., 2013; Ricke et al., 2023), its regional impacts are method- and strategy-dependent

132 (Ricke et al., 2023) with potentially substantial changes in the regional precipitation patterns (Ricke  
133 et al., 2010; Tilmes et al., 2013; Crook et al., 2015; Dagon and Schrag, 2016, Tilmes et al., 2020). While  
134 differences in temperature fields vary relatively smoothly with radiative forcing, precipitation  
135 patterns are far more variable being dependent on atmosphere/ocean/land surface coupling on a  
136 wide range of spatial and temporal scales. Furthermore, SAI simulations rely on many model-specific  
137 details and parameterizations that tend to produce larger across-model differences than simulations  
138 using simpler forms of SRM (Visioni et al., 2021). While SAI may counteract the annual-mean water  
139 availability changes over land forced by GHG, it is not easy to offset the regional consequences,  
140 especially in the hydrological cycle, such as the Amazonian drying trend and its reduced precipitation,  
141 evaporation, and precipitation minus evaporation (Jones et al., 2018).

142

143 Although the MENA region and the adjacent Mediterranean region are known to be a “hot spot” for  
144 climatic change (Giorgi and Lionello, 2008; Bucchignani et al 2018), little has been done on potential  
145 changes in TWS across MENA especially under SRM climates. This study fills that knowledge gap and  
146 explores the changes that may occur in TWS under i) a high GHG emissions scenario, ii) the same GHG  
147 scenario combined with SAI designed to globally neutralize the GHG radiative forcing, and iii)  
148 compares both future climates with the historical conditions (1985-2014) across the Mediterranean,  
149 Middle East, and northern Africa.

150

## 151 **2. Data and Methods**

### 152 **2.1. Study Area**

153 The study area is composed of MENA and southern Europe to its north including the Caspian  
154 and Mediterranean Seas. MENA covers the large region from Morocco in the west to Iran in the east,  
155 containing all the Maghreb and the Middle Eastern countries from the 15<sup>0</sup>N to 45<sup>0</sup>N latitude and from  
156 20<sup>0</sup>W to 63<sup>0</sup>E longitude (Fig. 1). As well as a water-stressed region, MENA, is a worldwide hot spot  
157 for exacerbated extreme temperatures, aridity conditions, and drought (Giorgi and Lionello, 2008;  
158 Bucchignani et al., 2018). According to the Koppen Climate Classification System (Peel et al., 2007),  
159 MENA broadly has a hot and arid climate except for the coastal regions and highlands. Most of  
160 northern Africa (NA) has a desert climate and 90% is covered by the Saharan Desert. The 2 m air  
161 temperature rises to 50°C in summertime while the annual mean precipitation is less than 25 mm  
162 (Faour et al., 2016). The Arid Steppe climate predominates in Morocco, Algeria and Tunisia with cold  
163 winters (Faour et al., 2016) except for the Atlas Mountains which are cooler and wetter (annual mean  
164 precipitation of ~500mm).

Across the Middle East, the largest amount of precipitation falls in four main regions: the coastal eastern Mediterranean Sea, the south coast of the Caspian Sea, the western sides of the Zagros Mountains across Iran and Iraq, and the southern tip of the Arabian Peninsula. The Middle East also contains several major deserts having little to no precipitation: the Lut and Kavir deserts in the south-east and north-central regions in Iran, the Arabian Desert, the Syrian Desert, and the Negev in south-eastern corner of the Mediterranean Sea. Middle East precipitation often originates from moisture coming from the west over the Mediterranean Sea (Evans and Smith, 2006). The Red Sea and the Persian Gulf are also source regions for the heaviest precipitations across the area.

The Mediterranean area has mild wet winters and warm to hot, dry summers as well as a complicated morphology, owing to the many steep orogenic structures, distinct basins and gulfs, along with islands and peninsulas of various sizes (Lionello et al., 2006).

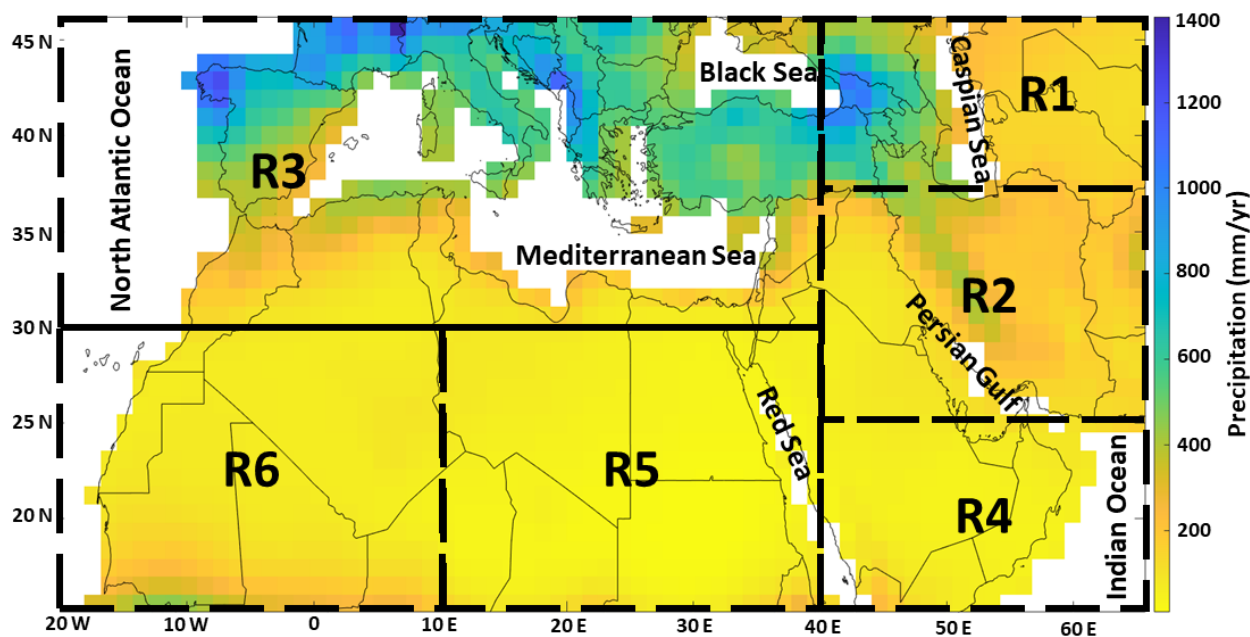

Based on its full range of climate types, we divided the study area into six sub-regions (R1 to R6) to explore the changes in hydroclimate variables under both global warming and SAI scenarios (Fig. 1). The regions R1 to R6 respectively refer to the lands around the Caspian Sea, eastern Middle East (largely containing Iran and Iraq), Mediterranean area, Arabian Peninsula, eastern NA, and western NA. The simulated present-day climatology (1985-2014) of each region for different hydrological quantities is summarized in Table 1.. Potential evapotranspiration (ET) is the amount of evaporation that would occur if a sufficient water source were available. The Thornthwaite method was used to calculate the potential ET based on the monthly mean temperature and latitude data for each grid. Evaporation from both soil and canopy and transpiration are summed up to obtain the real ET, which is the quantity of water actually removed from a surface by evaporation and transpiration. The lands around the Caspian and Mediterranean Seas with a cooler climate, have the highest precipitation and real ET while more continental eastern NA with hyper-arid climate (with annual precipitation less than 100 mm) has the lowest precipitation, real ET, soil moisture, and TWS. The lands around the Caspian Sea have the highest soil moisture and TWS. More continental refers to an area with characteristics that are typical of continental climates and is less influenced by the moderating effects of nearby oceans.

197 **Table 1.** The medians of precipitation, temperature, real evapotranspiration (ET), soil moisture,  
 198 terrestrial water storage (TWS), and potential ET over each region (R1 to R6, see Fig. 1) during the  
 199 historical period according to the model outputs. The results for global warming and SAI are further  
 200 shown in Table S1.

Region	R1	R2	R3	R4	R5	R6
Precipitation (mm/yr)	321	182	479	78	48	112
Temperature ( $^{\circ}$ C)	14.2	20.5	17.2	27.0	23.7	25.3
Real ET (mm/yr)	419	187	388	72	50	112
Soil moisture (Kg/m $^2$ )	1846	1771	1572	1353	1155	1287
TWS (Kg/m $^2$ )	2091	1776	1623	1348	1167	1313
Potential ET (mm/yr)	74	123	74	210	143	185

204 **Figure 1.** The MENA's annual precipitation map during the historical period. Regions R1 to R6  
 205 largely refer to the lands around the Caspian Sea, the eastern Middle East (largely containing Iran  
 206 and Iraq), the Mediterranean area, Arabian Peninsula, eastern North Africa (NA), and western NA,  
 207 respectively.  
 208

## 209 2.2. Model simulations and scenarios

210 We examined the data from the NCAR Community Earth System Model version 2- Whole Atmosphere  
 211 Community Climate Model Version 6 (CESM2(WACCM6)) that simulated the CMIP6 (Eyring et al.,  
 212 2016) scenarios. CESM2 ranks among the top nine models known for their accuracy in simulating

213 global precipitation patterns, based on the Hellinger distance metric, which compares the bivariate  
214 empirical densities of CESM2 with those of 34 CMIP6 models, against historical precipitation data  
215 sourced from the Global Precipitation Climatology Centre (GPCC) (Abdelmoaty et al., 2021). CESM2  
216 has precipitation biases about 20% lower than CESM1 (Danabasoglu et al., 2020). CESM2(WACCM6)  
217 has an interactive stratospheric aerosol treatment (Danabasoglu et al., 2020) that is consistent with  
218 observations (Mills et al., 2016). For global terrestrial ET, the CESM2(WACCM6) ranked as the  
219 second-best model among 19 CMIP6 models (Wang et al., 2021). Furthermore, CESM2(WACCM6),  
220 reproduced the observed global land carbon trends remarkably well (Danabasoglu et al., 2020), and  
221 includes a full ocean model (Parallel Ocean Program version 2, POP2) to simulate the response of  
222 stratospheric aerosol change in the climate.

223

224 CESM2 also demonstrates satisfactory performance in simulating historical climate conditions  
225 within the study area. In the evaluation by Babaousmail et al. (2021), which assessed 15 CMIP6  
226 models in replicating monthly rainfall patterns spanning from 1951 to 2014 in NA, CESM2(WACCM6)  
227 emerged as one of the top-performing models. It accurately captured rainfall peaks across the region,  
228 albeit with a slight overestimation (ranging from 5 to 10 mm/month) in the southern areas and a  
229 slight underestimation (ranging from 0 to 20 mm/month) in the northern regions. Despite these  
230 minor deviations, CESM2(WACCM6) was recognized as one of the models for well simulating  
231 precipitation patterns across NA, achieving a Taylor skill score of 0.62. Evaluation of  
232 CESM2(WACCM6) across the Mediterranean coasts placed it at the 9<sup>th</sup> and 17<sup>th</sup> positions out of 31  
233 CMIP6 models for its performance in simulating temperature and precipitation (Bağçaci et al., 2021).  
234 Furthermore, when it comes to simulating precipitation relative to observational data for  
235 northeastern Iran during the period of 1987-2005, CESM2 stood out as the top-performing model  
236 among six CMIP6 models (Zamani et al., 2020). Assessing the representation of spatial and temporal  
237 variations in historical precipitation from 1980 to 2014 across Africa and the Arabian Peninsula, the  
238 CMIP6 multi-mean ensemble (inclusive of CESM2(WACCM6)) demonstrated reasonable  
239 performance, as highlighted in Nooni et al. (2023).

240

241 The SAI simulation we use (SSP5-8.5-SAI) is designed to employ SAI together with the high GHG  
242 emissions scenario, SSP5-8.5 with the target of limiting the mean global temperatures to 1.5°C above  
243 the pre-industrial (1850–1900) conditions (Tilmes et al., 2020). Under SSP5-8.5 forcing, Tilmes et al.  
244 (2020) projected this threshold is exceeded around the year 2020 in CESM2(WACCM6). The  
245 atmospheric component of CESM2(WACCM6) has a resolution of 1.25° in longitude and 0.9° in

246 latitude. The experiment injects SO<sub>2</sub> at 180° longitude at four predefined latitudes (30°N, 30°S, 15°N,  
247 and 15°S) at around 25 km in 15°N/S and around 22 km at 30°N/S as suggested by Tilmes et al.  
248 (2018), using a feedback control algorithm to maintain not just the global mean temperature, but the  
249 interhemispheric and equator-to-pole temperature gradients (Tilmes et al., 2020). For SSP5-8.5-SAI,  
250 most of the sulfur mass was injected at 15°S, some at 15°N and 30°S, and very little at 30°N. We used  
251 the monthly TWS (the sum of snow water equivalent and soil moisture (Wu et al., 2021)),  
252 precipitation, temperature, water evaporation from soil and canopy, transpiration, soil moisture, and  
253 leaf area index (LAI) data from all five ensemble members (r1 to r5) of the SSP5-8.5 scenario and the  
254 three available ensemble members (1-3) of SSP5-8.5-SAI. The results for variables other than TWS  
255 are shown in the Supplementary Information. For the historical period, we used all three available  
256 realizations (r1 to r3) from CESM2(WACCM6). For the anomaly analysis relative to historical  
257 conditions and the multiple linear regression models, we used the first three ensembles of SSP5-8.5,  
258 consistent with the three available historical members. We compare the GHG and SAI scenarios over  
259 2071-2100 with the 1985-2014 historical period.

260

261 We focused on the historical period from 1985 to 2014 rather than the entire historical dataset  
262 spanning from 1850 to 2100 for several reasons. Firstly, recent historical climate data may exhibit  
263 less uncertainty, given that additional meteorological stations with improved data quality are  
264 available to be used for model calibrations (Zhang et al., 2020). Secondly, this selected historical  
265 period offers valuable insights into the observable impacts of climate change, which are highly  
266 pertinent to present-day societal and environmental challenges. These insights are of utmost  
267 importance to policymakers and communities alike. Thirdly, the chosen historical 30-year time  
268 period aligns with the 30-year periods considered for the GHG emissions and SAI scenarios, ensuring  
269 consistency in our statistical analysis. We focus on the 2071-2100 future period because the  
270 anticipated changes in TWS driven by GHG emissions are expected to be more pronounced during  
271 this time frame (Pokhrel et al., 2021). Furthermore, the SAI forcing is strongest in the later period of  
272 the simulation and is expected to produce a more significant result.

273

### 274 **2.3. Return periods**

275 We are interested in climate extremes, not only changes in means. Therefore, we examine how the  
276 frequency of events of some particular levels are likely to change under different scenarios. We use  
277 the generalized extreme value (GEV) distribution function to estimate the probability distribution  
278 function of the TWS extremes. A return period is an estimated average time between events such as

279 floods or river discharge flows. It is calculated by generating the 95% normal-approximate  
 280 confidence intervals in accordance with the mean and variance of the variable (here TWS).

281 The GEV probability density and cumulative distribution functions are defined as (Gilleland, 2020):

$$282 \quad g(z) = \frac{1}{\sigma} t(z)^{1+\xi} e^{-t(z)}; \quad G(z) = e^{-t(z)}; \quad t(z) = \begin{cases} \left\{ 1 + \xi \left( \frac{z-\mu}{\sigma} \right) \right\}^{-1/\xi}, & \xi \neq 0 \\ e^{-\left( \frac{z-\mu}{\sigma} \right)}, & \xi = 0 \end{cases} \quad (1)$$

283 For  $\xi \neq 0$ , we have  $t(z)^{1+\xi} = \left\{ 1 + \xi \left( \frac{z-\mu}{\sigma} \right) \right\}^{-(1+1/\xi)}$  and for  $\xi = 0$ , the  $x$  domain restricted to

284  $\xi \left( \frac{z-\mu}{\sigma} \right) > -1$ . The GEV distribution is parameterized using  $\xi$ ,  $\mu$ , and  $\sigma$  which are the shape,

285 location, and scale parameters, respectively and analogous to the skewness, mean and standard  
 286 deviation. We assume that the GEV is the valid distribution function for variables  $z_1, \dots, z_n$   
 287 representing the annual maximum return TWS levels, where the quantiles of the distribution  
 288 function give the return levels,  $z_p$ . The return levels are the solutions to  $G(z_p) = 1 - p$ , which yields  
 289 (Gilleland, 2020):

$$290 \quad z_p = \begin{cases} \mu - \frac{\sigma}{\xi} [1 - \{-\ln(1-p)\}]^{-\xi} & \text{for } \xi \neq 0 \\ \mu - \sigma \ln\{-\ln(1-p)\} & \text{for } \xi = 0 \end{cases} \quad (2)$$

291  $p$  is probability corresponding to  $z_p$ . The return period is obtained as:

$$292 \quad \text{return period}(i) = 1 / (1 - \text{cdf}(i)) \quad (3)$$

293 where  $\text{cdf}$  is the cumulative distribution function. We also calculated the 95% asymptotic lower and  
 294 upper confidence intervals based on the Kolmogorov-Smirnov statistic (Doksum and Sievers, 1976).  
 295 We used the concatenated TWS anomaly data for the historical period, high GHG emissions, and SAI  
 296 scenarios to analyze the return periods. As an example, the relationship between empirical quantiles  
 297 and model quantiles as well as the probability density versus quantiles for the regions R2 and R5 are  
 298 shown in Figs. S1 and S2.

299

#### 300 **2.4. Multiple linear regression (MLR) model**

301 We want to analyze how the primary driving climate fields (surface air temperature, precipitation,  
 302 ET, and LAI (i.e., vegetation coverage)) for TWS vary spatially and among the different scenarios

303 (Zhang et al., 2022). We use a simple multiple linear regression (MLR) model with TWS as the  
304 dependent variable (Y) for each ensemble member in each region. The following procedures were  
305 conducted:

306 i) We employed the variable clustering (VARCLUS) procedure to thoroughly assess collinearity  
307 among the variables. VARCLUS is a method that effectively segregates a set of numeric variables into  
308 disjoint or hierarchical clusters, each characterized by a linear combination of the variables within  
309 the cluster (Sarle, 1990). The criterion is that when the proportion of the variance explained by a  
310 cluster is larger than 0.8, it is advisable to select one variable from that cluster. Based on the results  
311 obtained from VARCLUS (Figs. S3 and S4), we made specific decisions to enhance the robustness of  
312 our analysis. For instance, we identified strong correlations exceeding 0.9 between potential ET and  
313 temperature (Tables S2-S13 in the Supplementary Information), as well as between soil moisture  
314 and TWS in all cases (except for the eastern NA (R5) in Tables S2-S13). Consequently, we chose to  
315 exclude potential ET and soil moisture from our analysis due to their high levels of correlation with  
316 temperature and TWS, respectively.

317 ii) We considered a linear regression model with potential independent variables (X): temperature,  
318 precipitation, real ET, and LAI. We conducted a temporal autocorrelation analysis on all the variables,  
319 including temperature, precipitation, real ET, and LAI data for each model. This analysis was carried  
320 out using the Autocorrelation function at a 95% confidence level. In all regions (except R4), the  
321 autocorrelation results indicated that the lags at the first and second months were statistically  
322 significant, while the third month lag was almost non-significant. Therefore, we modified the LMS  
323 model to include information from the two preceding months in these regions. However, in region  
324 R4, we observed different patterns. In this region, both real ET and temperature significantly  
325 depended on their respective conditions from the two previous months, while precipitation did not  
326 show this effect. Moreover, LAI in R4 exhibited dependencies on the first three and four preceding  
327 months under the SSP5-8.5 and SSP5-8.5-SAI scenarios, respectively. Consequently, we incorporated  
328 specific lagged months for each variable in R4.

329 iii) Identifying the outliers using the Bonferroni  $p$ -values (i.e., Bonferroni correlation) and then  
330 removing them. Bonferroni correlation is a modification for  $p$ -values when several dependent or  
331 independent statistical tests are being accomplished concurrently on a single data set. A Bonferroni  
332 correction divides the critical  $p$ -value by the number of comparisons being made (Bland and Altman,  
333 1995). The number of outlier data points excluded varies from zero to 5 (over the 700 point) in the  
334 36 models.

335 iv) Fitting the final model after removing the outliers. In all regions and scenarios, the MLR models  
 336 are statistically significant at the 95% level. The variance explained ( $R^2$ ) varies from around 0.3 in  
 337 the dry southern MENA to 0.89 and 0.96 in the wetter lands around the Caspian and Mediterranean  
 338 Seas.

339 v) Assessing the relative “importance” of the variables for TWS in the final model using the Lindeman,  
 340 Merenda, and Gold (LMG) method (Lindeman et al., 1980), where the fractional variance accounted  
 341 for is determined as the independent variable-order average over average contributions in models  
 342 of different sizes. The LMG method considers the average contributions of each variable across  
 343 different model sizes and then averages these averages to provide a more robust measure of variable  
 344 importance. The LMG can be defined as (Grömping, 2007):

$$345 \quad LMG(x_k) = \frac{1}{p!} \sum_{\text{Permutation}} seqR^2(\{x_k\} | r) \quad (4)$$

346 where  $seqR^2(\{x_k\} | S_k(r)) = R^2(\{x_k\} \cup S_k(r)) - R^2(S_k(r))$  and

$$347 \quad R^2(S) = \frac{\text{Model SS}(\text{model with regressors in set } S)}{\text{Total SS}}$$

348 Orders have the same  $S_k(r) = S$  summarize into a single summand, we therefore can re-write  
 349 Eq. (4):

$$350 \quad LMG(x_k) = \frac{1}{p!} \sum_{S \subseteq \{x_1, \dots, x_p\} \setminus \{x_k\}} n(S)!(p - n(S) - 1)! seqR^2(\{x_k\} | S) \quad (5)$$

351 LMG has been recommended by Johnson and LeBreton (2004) and Grömping (2007) since it uses  
 352 both direct effects and impacts adjusted for other regressors in the model. As the considered  
 353 variables may be correlated with each other, when a new predictor is added to a model that already  
 354 contains other predictors, its impact can be influenced by the presence of those other variables. The  
 355 LMG method takes into account these interactions and adjusts the variable's contribution to reflect  
 356 its unique impact while considering the effects of other regressors. Importance is a unitless variable  
 357 and the sum of all independent variable importance's in each model equals the model's explained  
 358 variance. Here we use all three ensemble members separately to estimate the robustness of the  
 359 importance estimates.

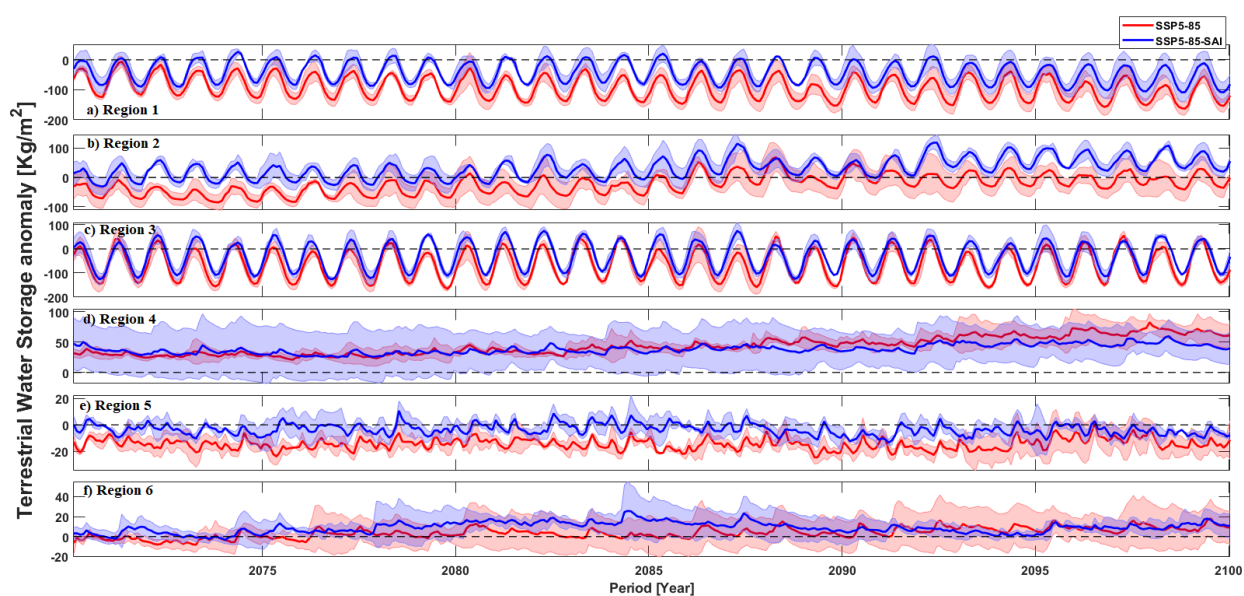

360

### 361 **3. Results:**

#### 362 **3.1. Mean terrestrial water storage (TWS) changes due to GHG and SAI**

363 In this section, we present the projected changes in TWS across MENA and the lands around the  
 364 Caspian and Mediterranean Seas. We discuss trends in the TWS anomalies relative to TWS averaged  
 365 over the historical period (1985-2014) in response to both GHG (SSP5-8.5) forcing and to GHG+SAI.

366 Figure 2 illustrates the original TWS anomalies, while Fig. S5 exclusively presents the long-term  
 367 component, providing a clearer understanding of the changes under climate scenarios. The positive  
 368 and negative anomalies in these figures refer to increasing and decreasing TWS, respectively. The  
 369 trend decreases in the northern parts (R1 and R3) and eastern NA (R5) with a hyper-arid climate but  
 370 rises in the Arabian Peninsula (R4) and western NA (R6) under both GHG and SAI scenarios,  
 371 particularly over the latter part of the 21<sup>st</sup> century. In all regions, the SAI climate TWS is higher than  
 372 SSP5-8.5 or at least lies in the across-range of SSP5-8.5 towards the end of the century, especially in  
 373 R2 and R5 (Figs. 2 and S5). The TWS difference between SAI and global warming in the region R2,  
 374 particularly over the latter part of the 21<sup>st</sup> century, is greater relative to the rest of the domain. The  
 375 TWS change is smaller in the hyper-arid eastern NA (R5) than the other regions under both climate  
 376 scenarios.

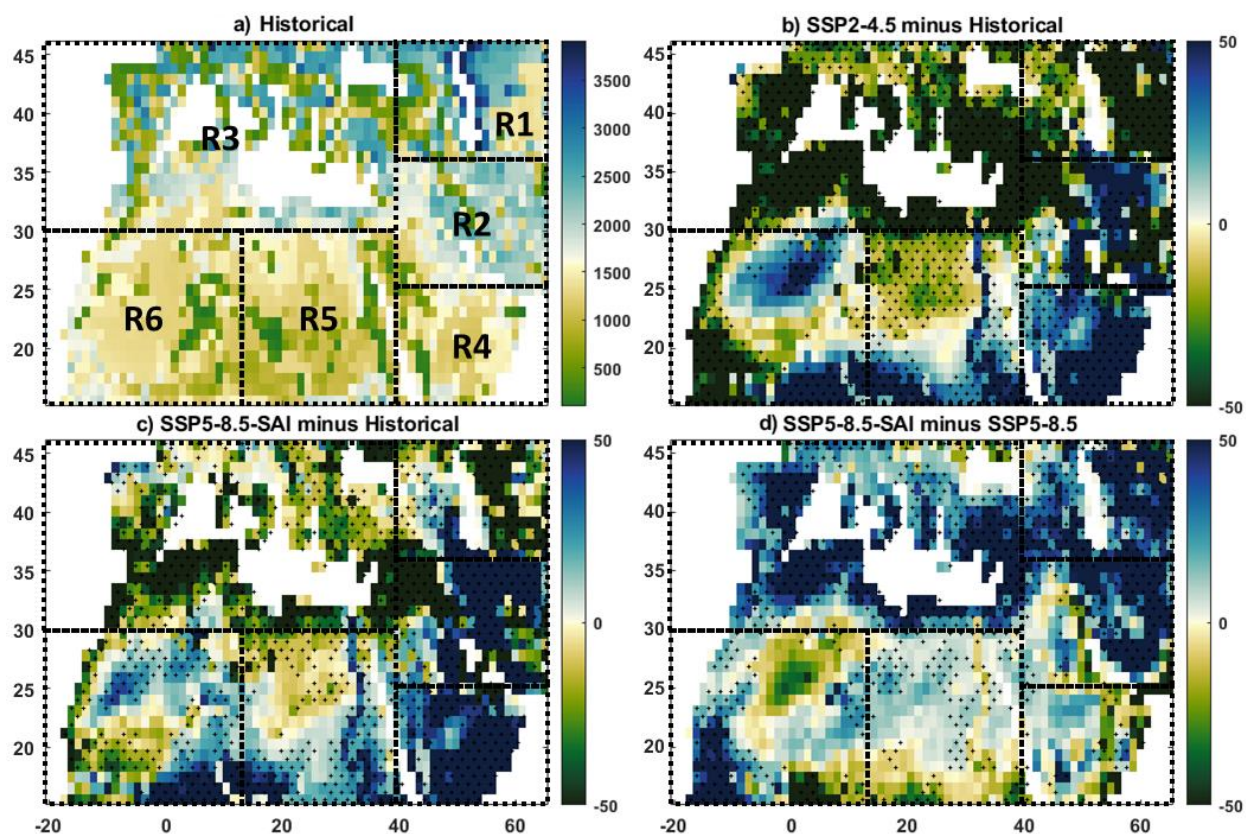

377  
 378 **Figure 2.** The TWS anomaly relative to the TWS averaged over the historical period across MENA  
 379 and the lands around the Caspian and Mediterranean Seas under global warming without (SSP5-  
 380 8.5) and with SAI (SSP5-8.5-SAI). Figures a-f respectively are for regions R1 to R6. Shading in each  
 381 curve shows the across-ensemble range. The dashed line crossing the  $y$ -axis at zero in each subplot  
 382 is the ensemble mean of TWS over the historical period (1985-2014).

383  
 384 Fig. 3 depicts the TWS differences between the historical (1985-2014) and the future climate  
 385 scenarios over the 2071-2100 period. Consistent with the above findings, Figs. 3b and S6a-c show  
 386 that the TWS response to GHG forcing in the wet regions around the Caspian (R1) and Mediterranean  
 387 (R3) Seas is simulated as declining, while across the (semi)arid MENA region, particularly in central  
 388 Iran (R2), the Arabian Peninsula (R4), and the southern portions of NA (R5 and R6), there is a positive  
 389 trend. Under global warming, the largest decrease in TWS occurs around the Caspian (particularly in

390 the east) and the Mediterranean (except for its north) while its most robust increase happens in the  
 391 southern margins of NA and the eastern parts of the Arabian Peninsula. SAI (Figs. 3c and S6d, e, and  
 392 f) partially counteracts the changes imposed by the increased GHG emission, particularly in the  
 393 wetter lands around the Caspian and Mediterranean Seas which are simulated as experiencing TWS  
 394 decrease under global warming. Temporal-ensemble mean TWS due to GHG forcing (Fig. 3b) is only  
 395 partially reversed by SAI (Fig. 3d), and the water storage shortfall is not fully canceled out by the  
 396 intervention (Fig., 3c and d). However, simulated TWS in Iran and the southern half of MENA has  
 397 greater water storage under SAI relative to the historical period (Fig. 3c).

398

399

400 **Figure 3.** Ensemble mean maps of TWS across the studied domain in the historical climate (a) over  
 401 1985-2014 and their projected future changes in the 2071-2100 period under the SSP5-85 GHG  
 402 scenario (SSP5-8.5 minus historical (b) and GHG+SAI minus historical (c)). The extent to which the  
 403 SAI impacts the TWS changes imposed by global warming is further shown (SAI minus SSP5-8.5  
 404 (d)). Hatched areas show where all ensemble members agree on the sign of the changes.

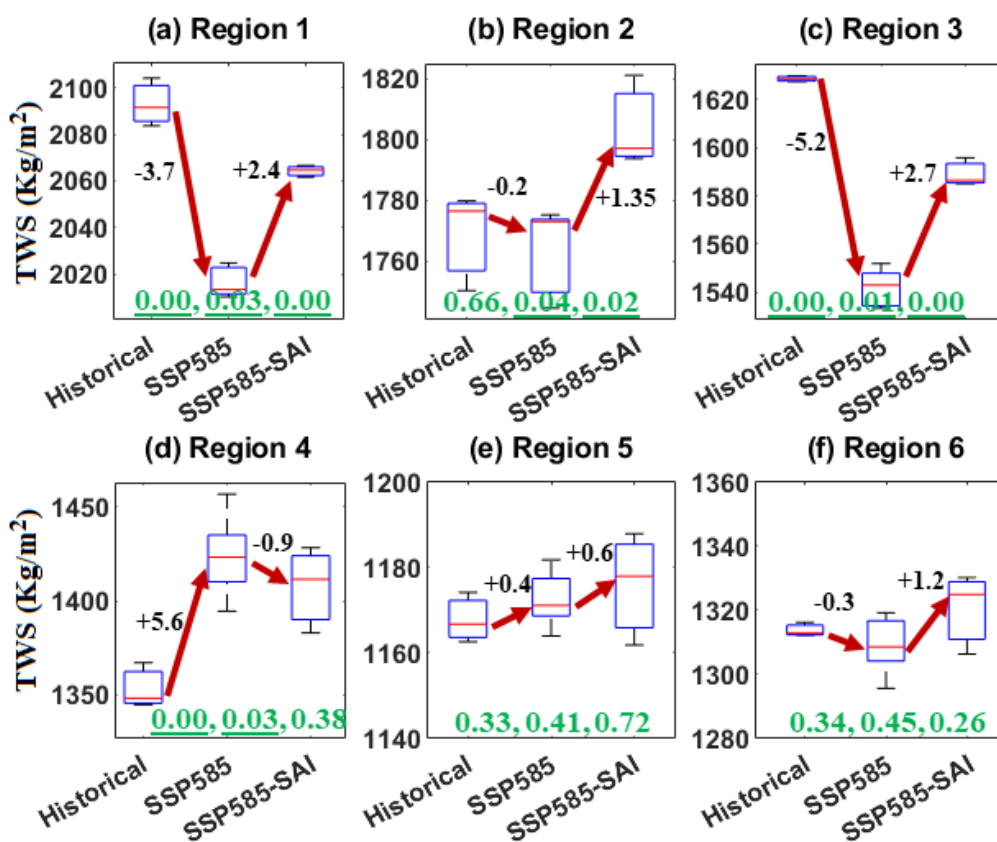

405

406 In Fig. 4, we compare how simulated TWS statistical distributions vary between scenarios for each  
 407 region. Mean TWS significantly ( $p < 0.05$ ) decreases in the wetter lands around the Caspian (R1) and  
 408 Mediterranean (R3) Seas to the north (3.7-5.2% on area average) while it significantly increases in

409 the dry region of Arabian Peninsula (5.6%) in response to GHG warming. SAI, on the whole, partially  
 410 reverses the projected changes in TWS from increasing GHG concentrations toward its historical  
 411 values. Interestingly, SAI overcompensates the TWS changes imposed by the high GHG forcing in Iran  
 412 and Iraq (R2) where this region shows no significant change under GHG emissions (Figs. 4b). SAI also  
 413 has an amplifying effect in R5 and a slight overcompensation in R6, but its impact is statistically  
 414 insignificant.

415

416

417  
 418 **Figure 4.** Box and whiskers plot of the changes in the Terrestrial Water Storage (TWS) in regions 1  
 419 to 6 over 2071-2100 under SSP5-8.5 and SSP5-8.5-SAI relative to historical conditions (1985-  
 420 2014). The titles of each subplot refer to the regions. The median for each experiment is denoted by  
 421 the red line, the upper (75<sup>th</sup>) and lower (25<sup>th</sup>) quartiles by the top and bottom of the box, and  
 422 ensemble limits by the whisker extents. The positive/negative values in black are the change  
 423 percent under SSP5-8.5 and SSP5-8.5-SAI relative to the median of the historical period data. The  
 424 three values in green refer to *p*-values between historical and global warming, historical and SAI,  
 425 and global warming and SAI, respectively, obtained from *t*-test analysis in which the underlined *p*-  
 426 values are statistically significant.

427

428 We also compared the changes in TWS with changes in precipitation, temperature, real ET, soil  
 429 moisture, and potential ET over each region under both global warming and SAI scenarios (Figs. S7

430 to S10 in the Supplementary Information). The TWS decreasing patterns under both SSP5-8.5 and  
431 SSP5-8.5-SAI scenarios across the entire study area are similar to soil moisture change patterns (Fig.  
432 S7 and S9 in Supplementary Information), but are more widespread than precipitation under global  
433 warming (Fig. S9). Notably, in the Mediterranean and the dry MENA region, the soil moisture  
434 variability accounts for the dominant component of TWS variability (Pokhrel et al., 2021). However,  
435 the decreased TWS is seen beyond the regions of reduced precipitation (Fig. S9), from beyond the  
436 Mediterranean and Atlantic coasts to include Syria, Iraq, and the lands around the Caspian Sea as well  
437 as to a wide portion of NA (Fig. 4). These include places where precipitation is either increasing or  
438 shows no significant change, consistent with results reported by Cook et al. (2020).

439

440 In Summary, our findings show that the SSP5-8.5-SAI scenario has a potential to partially offset the  
441 significant changes in mean TWS imposed by SSP5-8.5 over the entire MENA. While SAI (Fig. 3d)  
442 succeeded in reversing mean TWS deficits in the wetter lands around the Caspian and Mediterranean  
443 Seas driven by the GHG SSP5-8.5 scenario (Fig. 3b), it did not fully cancel out the TWS deficits (Figs.  
444 3c, 4a, and 4c). However, in the dry MENA regions (Fig. 3d), particularly Iran (containing the Lut  
445 desert in the south-east region and the Kavir desert in the north-central), Iraq, and the Arabian  
446 Peninsula (housing the Arabian Desert), SAI resulted in higher mean water storage relative to the  
447 historical period (Figs. 3c and 4).

448

### 449 **3.2 Changes in extreme TWS**

450 We compared changes in the expected return frequency of comparatively rare events to those during  
451 the historical period. Changes in mean conditions discussed so far are clear, but the changes in  
452 extremes display even larger separations between those expected under pure GHG forcing and the  
453 GHG+SAI scenarios. An increase in the return level or decrease in the return period of TWS means  
454 that the rare levels of high water availability increase, while a decrease in return level for a given  
455 period means that rich water availability events become rarer. We applied a GEV distribution to the  
456 complete dataset of monthly TWS values without explicitly setting maximum values in Fig. 5. For  
457 comparison, we also extracted the annual maximum TWS values and provided the corresponding  
458 fitted GEV distribution. Overall, the probability densities for both datasets exhibit a high degree of  
459 similarity across various regions and scenarios (e.g., Figs. S11 and S12). Additionally, the graphs  
460 depicting return levels versus return periods based on annual maximums (Fig. S13) closely resemble  
461 the results obtained from the entire dataset (Fig. 5). In all cases, the trends are highly similar  
462 (compare Figs. 5 and S13), although it's worth noting that the annual maximums scenario exhibits

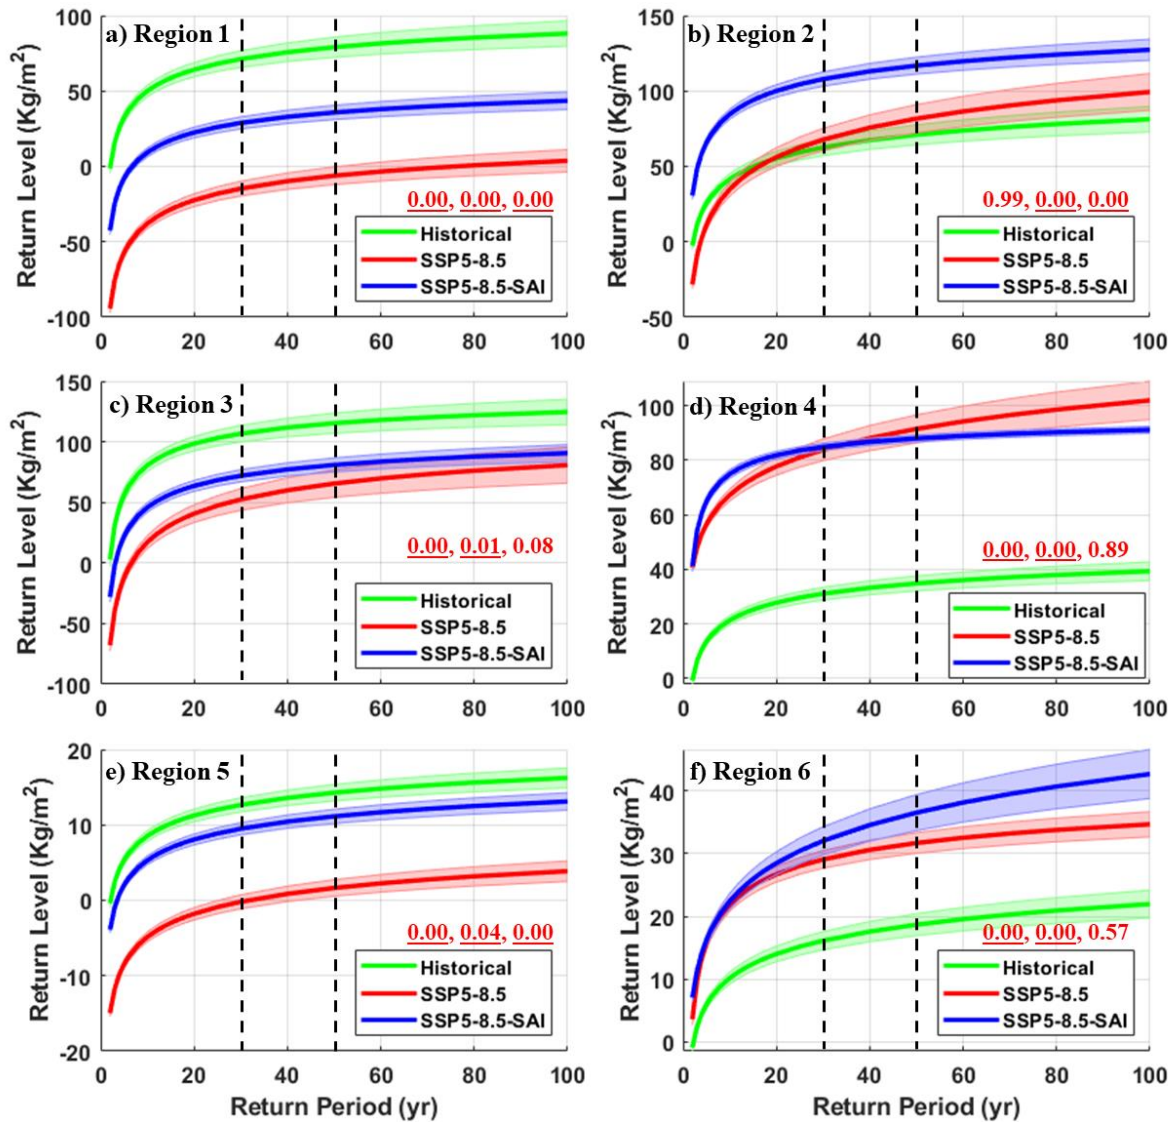

463 slightly wider upper and lower bounds compared to the entire dataset scenario. We therefore focus  
464 on the results obtained from the entire dataset. Fig. 5 shows the return levels versus return period  
465 curves with the 95% lower and upper bands. To determine which curves (including its upper and  
466 lower bounds) are significantly different from each other ( $p$ -values less than 0.05), we first conducted  
467 the repeated measures analysis of variance which compares means across one or more variables that  
468 are based on repeated observations, and then performed post hoc Tukey-Kramer comparisons. The  
469 expected return levels versus return period curves (Fig. 5) decrease in response to both GHG  
470 warming and GHG+SAI in the Caspian and Mediterranean Seas area (R1 and R3) as well as in the  
471 eastern NA (R5) as a more continental dry land but increase in the Arabian Peninsula (R4) and  
472 western NA (R6). In Iran and Iraq (R2), SAI leads to a significant increase in expected TWS return  
473 levels relative to both historical conditions and the high GHG emission scenarios (Fig. 5b) while SAI  
474 tends to partially counteract the GHG-driven TWS changes in R1, R3, R4, and R5. Larger TWS levels  
475 are expected for the entire MENA compared with the GHG climate alone, particularly in Iran, Iraq,  
476 and the western NA. Nonetheless, compared to the historical period, the Arabian Peninsula (Fig. 5d)  
477 is the region with the most robust increase in the extreme TWS under both the global warming and  
478 SAI scenarios. Extreme TWS in its neighbor dry land of eastern NA with a hyper-arid climate is still  
479 smaller than the historical conditions.

480

481 Table 2 quantitatively compares the differences between TWS (and its corresponding 95% lower and  
482 upper bounds in Fig. 5) changes at 30-, 50-, and 100-yr return periods under historical, global  
483 warming, and SAI scenarios. Global warming, on the whole, decreases the TWS extremes (i.e., fewer  
484 wetter conditions) at 30- to 100-year return periods over all the study areas except for the Arabian  
485 Peninsula (R4) and western NA (R6). The most robust decreases in the extreme TWS imposed by  
486 global warming relative to historical conditions occur in the lands around the Caspian R1 (-108% on  
487 average over return periods from 30- to 100-year) and Mediterranean R3 (-43% on average) and the  
488 eastern NA R5 (-89% on average) are partially suppressed by SAI. A small increase in the extreme  
489 TWS in Iran and Iraq (R2) simulated under GHG (+15%) is overcompensated by SAI (+57%).  
490 Although SAI decreases the TWS in the Arabian Peninsula (-11%) relative to global warming, it still  
491 tends to experience the most robust extreme water storage increases in the future (+153%)  
492 compared with historical conditions. In western NA, the SAI simulation slightly intensifies the  
493 increased extreme TWS imposed by high GHG emissions by +27%. Although SAI partially  
494 compensates for the changes over most of the study area (positive SSP5-8.5-SAI minus SSP5-8.5  
495 values in Table 2), on the whole, extreme TWS tend to increase in the dry regions of Iran and Iraq,

496 the Arabian Peninsula, and western NA while substantially decreasing in the wetter lands around the  
 497 Caspian and Mediterranean Seas, and to lower degrees, in the eastern NA as a more continental dry  
 498 land compared with historical conditions.  
 499

500  
 501 **Figure 5.** The TWS anomaly return level versus return period using the first three realizations for  
 502 the historical, SSP5-8.5, and SSP5-8.5-SAI in regions 1 to 6 (a to f). The two parallel dashed black  
 503 lines refer to 30- (left) and 50-year (right) return periods. Shading in each curve is the 95% upper  
 504 and lower confidence bands. The three values in red refer to *p*-values between historical and  
 505 global warming, historical and SAI, and global warming and SAI, respectively, obtained from the  
 506 repeated measures analysis of variance and the post hoc Tukey-Kramer comparisons in which the  
 507 underlined *p*-values are statistically significant.  
 508

509

510 **Table 2.** The percent differences (%) between the medians of the TWS return level at 30-, 50-, and  
511 100-year return periods using the first three realizations for the historical, SSP5-8.5, and SSP5-8.5-  
512 SAI. Consistently, the value inside the parenthesis is the percent difference-range values between  
513 lowers and uppers 95% confidence intervals from different scenarios.

Region	(SSP5-8.5 - Historical)/Historical*100			(SSP5-8.5-SAI - Historical)/Historical*100			(SSP5-8.5-SAI - SSP5-8.5)/Historical*100		
	30-yr	50-yr	100-yr	30-yr	50-yr	100-yr	30-yr	50-yr	100-yr
R1	-121 (-130, -113)	-108 (-117, -100)	-96 (-105, -88)	-59 (-62, -57)	-55 (-57, -53)	-51 (-53, -49)	61 (56, 68)	53 (48, 60)	45 (40, 52)
R2	8 (6, 11)	15 (12, 17)	22 (20, 24)	73 (66, 81)	65 (58, 73)	57 (50, 65)	64 (55, 75)	50 (41, 60)	34 (25, 46)

R6	80 (73, 89)	70 (63, 77)	58 (52, 65)	99 (95, 103)	95 (93, 99)	94 (93, 96)	18 (14, 22)	26 (21, 30)	36 (31, 41)

514  
515

### 516 3.3 Drivers of TWS change

517 To assess which variables have the most impact on mean TWS under both global warming and SAI,  
518 we fitted an MLR model to each ensemble member separately in each of the six regions (Figs. 6 and  
519 7). The most important variable for the mean TWS under both global warming and SAI scenarios is  
520 region-specific. In the wet lands surrounding the Caspian (R1) and Mediterranean (R3) Seas,  
521 temperature and precipitation are the primary drivers of TWS changes. In contrast, in the Middle  
522 East, characterized by predominantly dry climates (R2 and R4), vegetation coverage (i.e., LAI) plays  
523 a dominant role. This observation aligns with the fact that temperature limits ET in the wet regions,  
524 while in arid and hot regions, the availability of water for ET is the predominant limiting factor (Bao  
525 et al., 2021). In NA, where TWS changes are irregular, temperature holds the greatest significance in  
526 the eastern regions (R5), while real ET is the primary driver in the west (R6). Warmer climate  
527 enhances the atmospheric water content over regions and seasons (Cook et al., 2020) since 1°C  
528 warming is accompanied by ~7% enhancement in the air water storage capacity (Trenberth, 2011),  
529 and, in turn, increases the evaporative demand (Arnell, 1999), and vice versa for cooler conditions.  
530 Real ET itself is mostly controlled by temperature and available water for evaporation (i.e.,  
531 precipitation, soil moisture, and vegetation coverage). With just temperature and precipitation as  
532 independent variables, we find that the temperature under both global warming and SAI is generally  
533 more important for TWS than precipitation over the wet lands around the Caspian and

534 Mediterranean Seas as well as the eastern NA. In contrast, precipitation plays a stronger role on TWS  
 535 in Iran, Iraq, and the western NA with lower precipitation under both future climate scenarios.

536

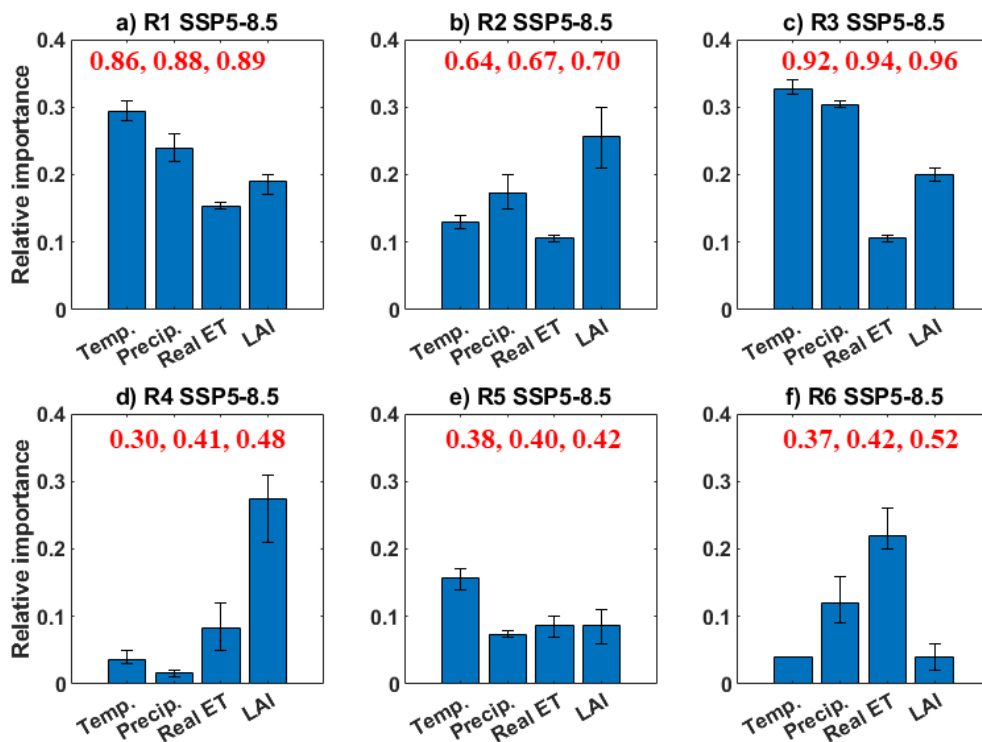

537 The regression models indicate that TWS is mostly driven by the combined impacts of changes in  
 538 vegetation coverage, real ET, temperature and precipitation, consistent with the fact that  
 539 precipitation is not the only controlling factor for water resources (Cook et al., 2014; Wu et al., 2020).

540 However, the temperature in the Mediterranean area with the highest precipitation over the entire  
 541 domain studied plays a more important role than precipitation, vegetation coverage, and real ET  
 542 under both warming and SAI scenarios.

543

544 Caution is required when interpreting the relative importance results for the arid regions of R4 to R6  
 545 as their variance explained ( $R^2=0.3$  to  $0.52$ ) from the MLR models is smaller than those (up to  $0.89$   
 546 and  $0.96$ ) for the wetter lands around the Caspian and Mediterranean Seas. This, most probably,  
 547 arises from the arid to hyper-arid climate of R4 to R6 with a small and irregular annual precipitation,  
 548 and, in turn, irregular TWS anomaly time series (Figs. 2d, e, and f).

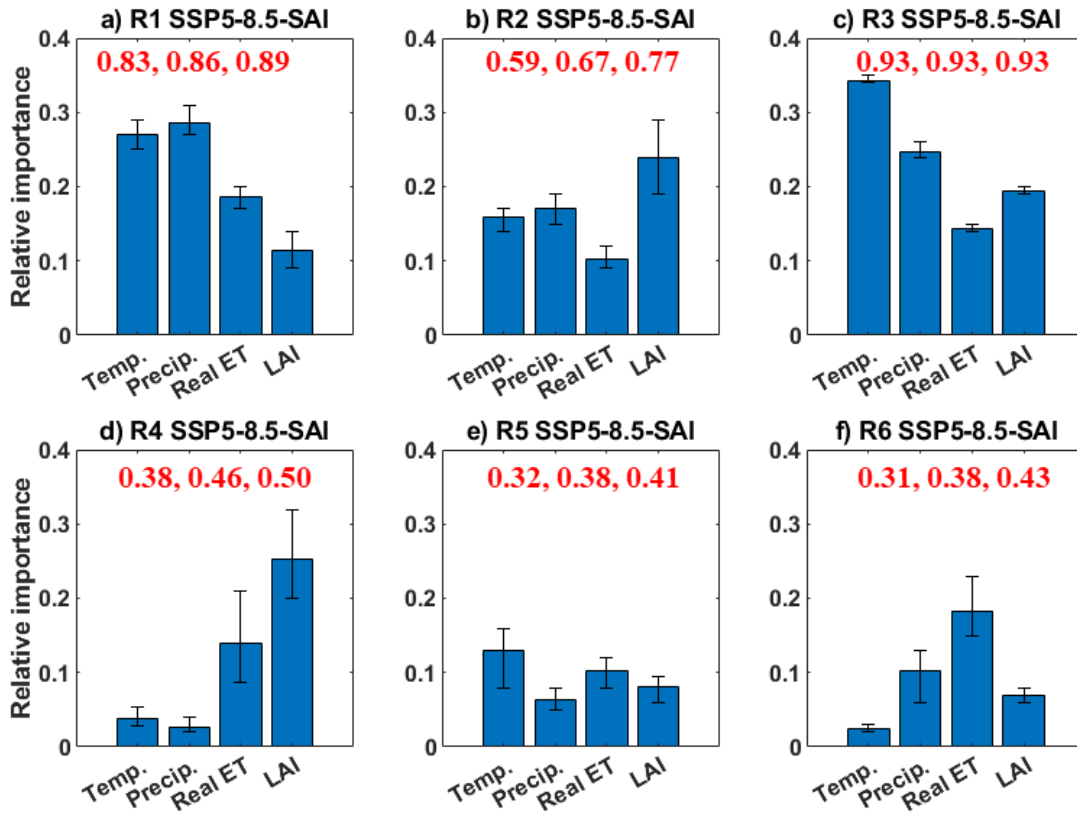

549

550

551 **Figure 6.** LMG importance plot (Lindeman et al., 1980) of the four independent variables in the  
 552 regression for TWS for the global warming SSP5-8.5 scenario in each region. The bar and range-bar  
 553 respectively show the ensemble mean importance and the range of importance from the three

554 ensemble members. The three values in red on each subplot shows the minimum, mean, and  
 555 maximum variances explained by models.  
 556

557  
 558 **Figure 7.** As in Fig. 6, but for the SSP5-8.5-SAI scenario.  
 559

560 **4. Discussion**

561 We have analyzed the potential impacts of the unmitigated global warming SSP5-8.5 scenario (GHG)  
 562 and the same GHG emissions trajectory with the addition of SAI (GHG+SAI) on both the mean and  
 563 extreme water storage across the lands around the Caspian and Mediterranean Seas, Middle East,  
 564 and NA. We have used the CESM2(WACCM) climate model simulations with three realizations of each  
 565 historic and SSP5-8.5-SAI scenario and five available realizations for SSP5-8.5. In response to high  
 566 GHG emission over the 2071-2100 period, the mean TWS decreases in the wetter regions (i.e., around  
 567 the Caspian and Mediterranean Seas with mild wet winters and warm to hot, dry summers), in  
 568 agreement with the previous studies based on SSP5-8.5 (e.g., Cook et al., 2020; Scanlon et al., 2023),  
 569 RCP2.6 and RCP4.5 (e.g., Döll et al., 2018) as well as with projections from 11 global hydrological  
 570 models (Schewe et al., 2014) with globally forced 2°C warming (Schleussner et al., 2016). Similarly,  
 571 a decrease in precipitation (Kim and Byun, 2009), surface runoff (Cook et al., 2020), and TWS

572 (Pokhrel et al., 2021) has been reported across Mediterranean coasts under GHG warming. In  
573 contrast, the mean TWS increases or shows no significant change in the MENA, housing several major  
574 deserts with minimal precipitation. The temporal-ensemble mean TWS increase in the southern  
575 MENA is consistent with other climate model simulations showing increased precipitation and soil  
576 moisture in CMIP6 simulations under SSP5-8.5 (Cook et al., 2020), and SSP2-4.5 (Ajjur et al., 2021;  
577 Scanlon et al., 2023). This further aligns with a projected northward shift of the inter-tropical  
578 convergence zone (ITCZ) in eastern Africa, mostly during a months of May to October (Mamalakis et  
579 al., 2021), leading to increased moisture transfer to the Southern Middle East and NA (Waha et al.,  
580 2017).

581

582 Given the prevailing water scarcity challenges in many regions of the Middle East where population  
583 growth is a continuing concern (Oroud, 2008), by mitigating the vulnerability to global warming, SAI  
584 may offer a potential strategy to augment the regional water resources across the area, particularly  
585 in the dry regions of Iran (containing the Lut desert in the south-east region and the Kavir desert in  
586 the north-central), Iraq, and the Arabian Peninsula (housing the Arabian Desert), as compared with  
587 the pure GHG forced scenario. Similarity, Jones et al. (2018) found that SAI could effectively  
588 counteract the changes in available water imposed by global warming on Earth's lands. Mousavi et  
589 al. (2023) also found increased soil moisture and enhanced vegetation coverage would lead to the  
590 reduction of dust concentration in the MEAN region under SAI.

591

592 The more robust and widespread deficit in mean TWS compared to precipitation in the area, which  
593 is in line with results reported by Cook et al. (2020), highlights the profound roles that other  
594 variables/processes have on the increased ET such as greater atmospheric moisture demand (Dai et  
595 al., 2013, 2018) and greater vegetation water use (Mankin et al., 2019) owing to warmer conditions  
596 under global warming, consistent with regression model results. According to MLR model results  
597 (Figs. 6 and 7), the projected changes in TWS were not solely attributable to precipitation; its  
598 interplay with other factors, such as vegetation coverage, temperature, and ET play a pivotal role.  
599 The vegetation coverage as the primary variable influencing changes in TWS in the MENA region  
600 substantially increases under global warming (Figs. S14 and S15). It has an important, but often  
601 complex and uncertain, role in surface water content (Lemordant et al., 2018; Trugman et al., 2018);  
602 the denser vegetation coverage, the higher evapotranspiration rates. Furthermore, although  
603 precipitation over a broad portion of MENA is lowered under SAI relative to global warming, the  
604 mean TWS, in general, increases across a broad portion of the MENA region in response to the

605 intervention. TWS significantly increases over Iran and Iraq under SAI compared to historical and  
606 global warming (Fig. 4b) as gains in available water from decreased temperature and, in turn, ET is  
607 largely sufficient to compensate for decreased precipitation (Figs. S8 and S10), signifying that in  
608 addition to precipitation, the water storage also strongly depends on local temperature (Ajjur et al.,  
609 2021). As an example, around the Caspian Sea (R1), although the changes in precipitation imposed  
610 by global warming are simulated to have been fully restored by SAI, the temperature has not; and in  
611 turn, the TWS is not fully restored by SAI. This is consistent with MLR model results (Fig. 7a) in which,  
612 beyond the precipitation, temperature also plays an important role in TWS across R1. Other studies  
613 also found that changes in precipitation does not necessarily correlate with changes in surface water,  
614 due to differences in precipitation and evaporation responses under SAI (Irvine et al., 2016).

615

616 Our findings, on the whole, suggest that the specific SAI scenario considered here could help water  
617 storage in the dry regions (R2, R4, R5, and R6), i.e., leads to higher soil moisture and TWS compared  
618 with both the historical conditions and pure GHG-induced global warming. Likewise, Dagon and  
619 Scharg (2017) documented a rise in mean water availability and soil moisture during a period of June  
620 to August in MENA using SolarGeo simulations, consistent with the significant reduction in daily  
621 maximum temperatures and ET across the Middle East. This works through the combined positive  
622 effects of (1) a substantial decrease in temperature and ET over the entire study area compared with  
623 SSP5-8.5 global warming, and (2) the increased precipitation in the southern MENA dry regions  
624 relative to historical conditions. The Middle East may therefore benefit from the water enrichment  
625 from climate change through the implementation of solar intervention (Burnell, 2021). However, the  
626 wet and colder regions, particularly around the Mediterranean coasts, may have less water storage  
627 compared with the historical period but more water relative to the GHG scenario due to a significant  
628 decrease in ET under SAI. Simpson et al. (2019) also reported a noteworthy decline of 18.5% in  
629 available water (precipitation minus evaporation) across the Mediterranean area under high GHG  
630 emissions while it has been partially reversed (only 5%) by a decrease in evaporation under SAI.

631

632 Although SAI partially compensates for the extreme TWS changes in most of the study area, aligning  
633 with findings by Jones et al. (2018), the overall extreme TWS trend indicates an increase in dry  
634 regions of Iran and Iraq, Arabian Peninsula, and western NA. Conversely, there is a substantial  
635 decrease in extreme TWS in the wetter lands around the Caspian and Mediterranean Seas, and to  
636 lower degrees, in the eastern NA compared to historical conditions. The implications of our findings  
637 under both future climate scenarios (SSP5-8.5 and SSP5-8.5-SAI) extend beyond hydrology and

638 water resources management. Changes in TWS have significant implications for climate adaptation,  
639 flood and drought risk management, and infrastructure planning. Some dry areas such as Iran, Iraq,  
640 and the Arabian Peninsula are projected to receive greater extreme TWS under both global warming  
641 and SAI or only SAI, and these regions have suffered historically from flooding (e.g., Abbaspour et al.,  
642 2009; Ghavidel and Jafari Hombari, 2020; Dezfuli et al., 2021). The significant increase in extreme  
643 TWS enhances their flood risks. Hence, governments in these regions should plan for adaptations to  
644 water megastructures such as the dams on the large rivers of Karkheh and Karun in western Iran and  
645 the Euphrates and Tigris in Iraq, since they have been mostly designed with historical hydrology in  
646 mind.

647

648 There are several caveats and caution needed for our results. First, our findings are based on a single  
649 model simulation (CESM2) and a single scenario climate scenario SSP5-8.5 with (three available  
650 realizations) and without (five available realizations) SAI. Future studies should consider alternative  
651 SAI scenarios to explore the sensitivity of our results to model and scenario choices. The SSP  
652 scenarios include some that clearly portray undesirable futures, especially the high emissions SSP5  
653 scenarios or the regional rivalry SSP3 that illustrate the danger of unchecked climate change  
654 (MacMartin et al., 2022). There are more caveats for the SAI experiment used here (1) it deploys in  
655 2020, therefore does not simulate any plausible future, and (2) takes into account solely the high-  
656 emissions scenario SSP5-8.5 that is suitable for capturing a high “signal” compared to internal  
657 variability. This is useful for understanding the science but inconsistent with present-day projections  
658 of mitigation attempts (Burgess et al., 2020). However, while the signal is stronger under high GHG  
659 emissions, it is plausible that the directions and patterns of response would be similar in a lower-  
660 emission experiment, with the magnitude of changes roughly depending on the degree of warming  
661 being suppressed by SAI (e.g., MacMartin et al., 2019).

662

## 663 **5. Conclusions**

664 The current study is the first attempt for understanding the influence of GHG emission and SAI  
665 scenarios on both mean and extreme water storage changes over the lands around the Caspian and  
666 Mediterranean Seas, Middle East, and northern Africa under global warming and SAI scenarios  
667 compared to the historical 1985-2014 conditions. The mean TWS is projected to decrease across the  
668 wetter lands around the Caspian and Mediterranean Seas to the north (3.7-5.2% on average) but  
669 increase over the most MENA region (up to 5.6% over the Arabian Peninsula) that has a drier climate  
670 under the high GHG forcing compared to the present-day conditions.

671

672 Although the SAI tends to reverse, to a degree, the significant changes in TWS revealed by SSP5-8.5  
673 over the entire area, it significantly overcompensates for the slightly reduced TWS under the high  
674 GHG scenario in Iran and Iraq. MLR model analysis of driving factors suggests that the impacts of  
675 temperature on water storage changes, like precipitation, are also important under both high GHG  
676 forcing and SAI scenarios. Although SAI mostly decreases precipitation over most of the domain, it is  
677 accompanied by higher mean TWS across the entire study area due to the cooler climate.

678

679 Although significant changes in the extreme TWS under high GHG emissions are reduced by SAI, the  
680 changes due to both future climate changes are still large relative to the historical period across a  
681 broad portion of the domain. With SAI, TWS significantly decreases in the eastern lands around the  
682 Caspian Sea while substantially increasing across the Middle East regions of Iran, Iraq, and the  
683 Arabian Peninsula. This may increase flood risks since water megastructures have been mostly  
684 designed with historical hydrology in mind. Finally, the SAI scenario appears to increase accessible  
685 water storage in the dry regions of the Middle East and northern Africa. The wetter and colder lands  
686 around the Caspian and Mediterranean Seas may have less available water compared with the  
687 historical conditions, although SAI partially ameliorates the changes imposed by global warming.

688

689

690 **Data availability:**

691 The data for CESM2 simulations are publicly available via its website: [https://esgf-](https://esgf-node.llnl.gov/search/cmip6/)  
692 [node.llnl.gov/search/cmip6/](https://esgf-node.llnl.gov/search/cmip6/). To access these specific data via ESGF website use the Source ID =  
693 CESM2-WACCM, Experiment ID=ssp585, and Frequency = mon. The SSP5-8.5-SAI data are freely  
694 available at <https://www.earthsystemgrid.org/dataset/ucar.cgd.cesm4.geomip.ssp5.html>  
695 (<https://doi.org/10.26024/t49k-1016>).
