26 **Abstract**

27 Terrestrial carbon (C) sequestration is limited by nitrogen (N), an empirically established
28 constraint that could intensify under CO₂ fertilisation and future global change. The terrestrial C
29 sink is estimated to currently sequester approximately a third of annual anthropogenic CO₂
30 emissions based on an ensemble of terrestrial biosphere models, which have been evaluated in
31 their ability to reproduce observations of the C, water, and energy cycles. However, their ability
32 to reproduce observations of N cycling and thus the regulation of terrestrial C sequestration by N
33 has been largely unexplored. Here, we evaluate an ensemble of terrestrial biosphere models with
34 coupled C-N cycling and their performance at simulating N cycling, outlining a framework for
35 evaluating N cycling that can be applied across terrestrial biosphere models. We find that models

36 exhibit significant variability across N pools and fluxes, simulating different magnitudes and
37 trends over the historical period, despite their ability to generally reproduce the historical
38 terrestrial C sink. Furthermore, there are no significant correlations between model performance
39 in simulating N cycling and model performance in simulating C cycling, nor are there significant
40 differences in model performance between models with different representations of fundamental
41 N cycling processes. This suggests that the underlying N processes that regulate terrestrial C
42 sequestration operate differently across models and appear to be disconnected from C cycling.
43 Models tend to overestimate tropical biological N fixation, vegetation C:N ratio, and soil C:N
44 ratio but underestimate temperate biological N fixation relative to observations. However, there
45 is significant uncertainty associated with measurements of N cycling processes given their
46 scarcity (especially relative to those of C cycling processes) and their high spatiotemporal
47 variability. Overall, our results suggest that terrestrial biosphere models that represent coupled C-
48 N cycling could be overestimating C storage per unit N, which could lead to biases in projections
49 of the future terrestrial C sink under CO₂ fertilisation and future global change (let alone those
50 without a representation of N cycling). More extensive observations of N cycling processes and
51 comparisons against experimental manipulations are crucial to evaluate N cycling and its impact
52 on C cycling as well as guide its development in terrestrial biosphere models.

53

54 **Plain Language Summary**

55 Nitrogen (N) is an essential limiting nutrient to terrestrial carbon (C) sequestration. We
56 evaluate N cycling in an ensemble of terrestrial biosphere models. We find that variability in N
57 processes across models is large. Models tended to overestimate C storage per unit N in
58 vegetation and soil, which could have consequences for projecting the future terrestrial C sink.
59 However, N cycling measurements are highly uncertain, and more are necessary to guide the
60 development of N cycling in models.

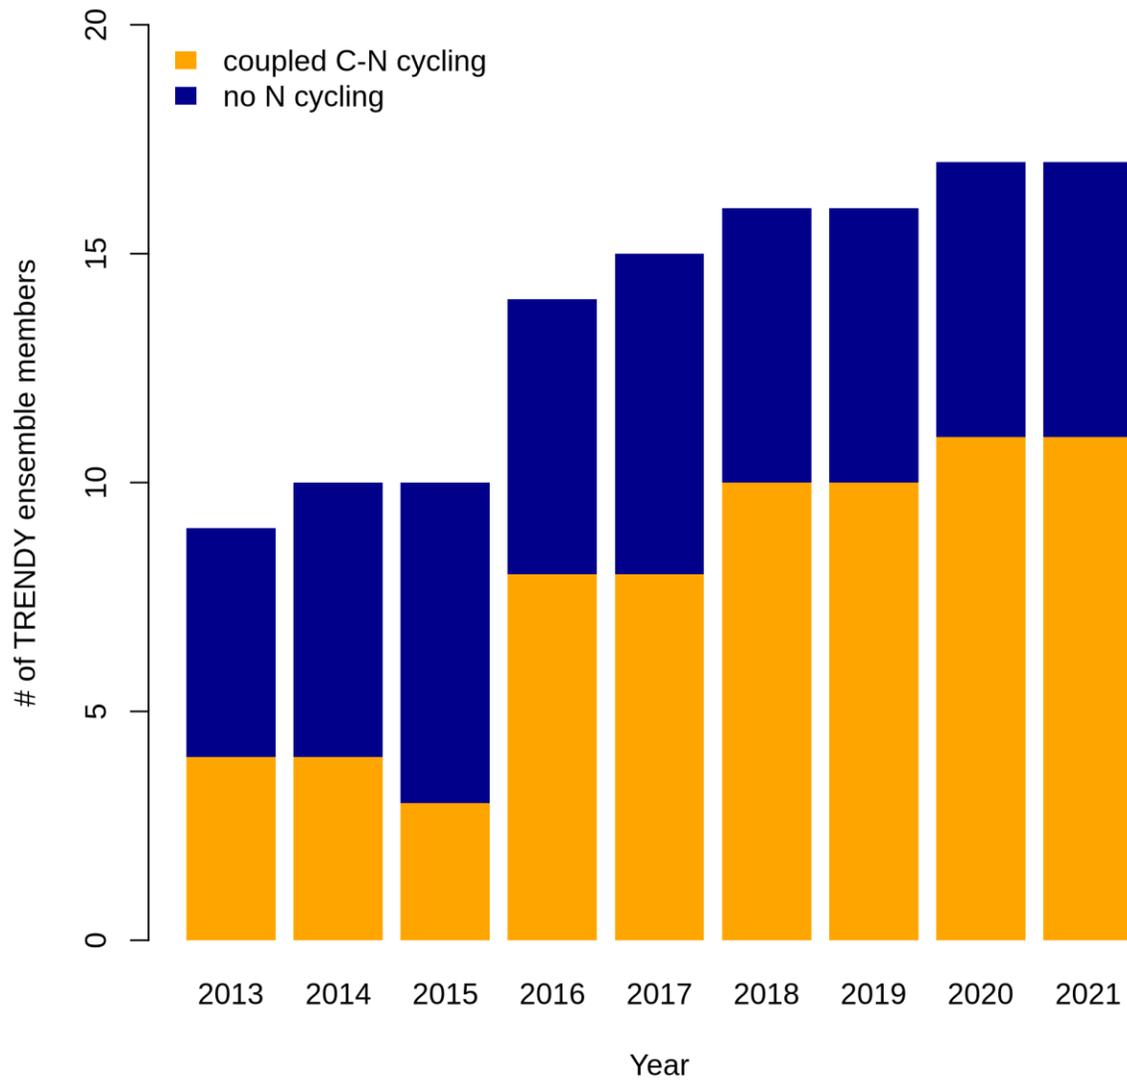

61

62 **1 Introduction**

63 The terrestrial biosphere is estimated to currently sequester approximately a third of
64 anthropogenic CO₂ emissions by the Global Carbon Project (GCP) (Friedlingstein et al., 2022).
65 The GCP annually reports an estimate of the global carbon (C) budget which includes an
66 estimate of the atmosphere-land CO₂ flux based on simulations of an ensemble of terrestrial
67 biosphere models – the trends in the land carbon cycle project (TRENDY) ensemble. In recent
68 years, the majority of the models within the TRENDY ensemble have incorporated a
69 representation of coupled C and nitrogen (N) cycling given the empirically established
70 importance of N limitation of vegetation growth (Elser et al., 2007; LeBauer and Treseder, 2008;
71 Wright et al., 2018): whereas only 4 out of 9 models represented coupled C-N cycling in the
72 2013 GCP, 11 out of 16 models represented coupled C-N cycling in the 2022 GCP (Figure 1).
73 Capturing N constraints on C cycling is critical for realistically simulating the terrestrial C sink,
74 which arises from the combined effects of concurrently acting global change drivers that are each
75 modulated by N: CO₂ fertilisation is limited by N (Terrer et al., 2019; Wang et al., 2020a),
76 intensifying N deposition increases N supply (O’Sullivan et al., 2019; Wang et al., 2017), rising

77 temperature and varying precipitation modulate decomposition and soil N availability (Liu et al.,
78 2017), and land use change and associated N fertilisation regimes determine N supply to crops.

79 Figure 1: Number of terrestrial biosphere models contributing to the Global Carbon Project (the
80 TRENDY ensemble) with and without coupled C-N cycling.

81

82 The TRENDY ensemble has been extensively evaluated against observations of the C,
83 water, and energy cycles (Collier et al., 2018; Friedlingstein et al., 2022; Seiler et al., 2022).
84 Within the GCP itself, the primary simulated C pools, C fluxes, and water fluxes are evaluated
85 using a skill score system developed by the International Land Model Benchmarking Project
86 (ILAMB) that quantifies model performance by comparing model simulations to observations
87 (Collier et al., 2018; Friedlingstein et al., 2022). ILAMB scores encompass the mean and
88 variability of a given variable (pool or flux) over monthly to decadal temporal scales and over
89 grid cell to global spatial scales. However, N cycling has not been explicitly evaluated despite its
90 importance in regulating C cycling. This is in part due to the relatively recent incorporation of N
91 cycling in terrestrial biosphere models (Figure 1) (Fisher and Koven, 2020; Hungate et al., 2003)
92 but also due to the paucity of global observation-based datasets of N cycling: N exists in many
93 forms and is lost from terrestrial ecosystems via numerous pathways (emissions of NH₃, N₂O,
94 NO_x and N₂ as well as NO₃⁻ and NH₄⁺ leaching), N processes are generally not measured in situ
95 in networks such as FLUXNET, and remote sensing methodologies for measuring N processes
96 are still in their infancy. Additionally, N processes exhibit extremely high spatial and temporal
97 variabilities and are thus challenging to measure. As such, N cycling has commonly been
98 evaluated by comparing simulated N pools and fluxes to global totals based on a small number of
99 observations that have been scaled up or averaged to yield a value with wide confidence intervals
100 (Davies-Barnard et al., 2020).

101 N cycling is implicitly evaluated by comparing terrestrial biosphere models without N
102 cycling to those with coupled C-N cycling in reproducing observations of the C, water, and
103 energy cycles in the absence of N cycle observations. Results suggest that there are only minor
104 differences between the performance of models with and without N cycling. There is no
105 significant difference between the terrestrial C sink simulated by the TRENDY models with and
106 without N cycling (Friedlingstein et al., 2022) nor between the terrestrial C sink simulated by the
107 models participating in the Multi-scale synthesis and Terrestrial Model Intercomparison Project
108 (MsTMIP) with and without N cycling (Huntzinger et al., 2017). Comparing the mean score
109 across all C, water, and energy cycle variables between TRENDY models with and without N
110 cycling yielded no significant difference (Seiler et al., 2022). However, TRENDY models
111 without N cycling had significantly higher scores for net biome productivity than TRENDY
112 models with N cycling (although all other variables were not significantly different between
113 TRENDY models with and without N cycling, including vegetation C, soil C, net biome
114 productivity, leaf area index, latent heat flux, and runoff, among others) (Seiler et al., 2022).
115 Despite this seeming absence of a difference between models with and without coupled C-N
116 cycling in simulating the current terrestrial C sink, it is imperative that N constraints on C
117 cycling are properly represented by terrestrial biosphere models in order to realistically simulate
118 the terrestrial C sink under future global change, which modifies the C-N balance through N
119 limitation of CO₂ fertilisation and intensifying N deposition among other effects of global
120 change. As such, explicitly evaluating N cycling processes themselves is necessary to assess the
121 ability of terrestrial biosphere models to capture the underlying mechanisms that determine
122 terrestrial C sequestration and thus to realistically project the future terrestrial C sink under
123 global change.

124 Here, we synthesise the N pools and fluxes simulated by 11 terrestrial biosphere models
125 in the TRENDY ensemble that participated in the 2022 GCP. We evaluate their performance in
126 reproducing observations of three key variables of the N cycle: biological N fixation, vegetation
127 C:N ratio, and soil C:N ratio. These three variables are critical to C cycling because (1)
128 biological N fixation is the dominant natural N supply to terrestrial ecosystems, influencing the
129 degree of N limitation of plant growth and thus terrestrial C sequestration, and (2) vegetation and
130 soil C:N ratios reflect assimilated C per unit N and thus terrestrial C storage.

131

132 **2 Methods**

133 **2.1 Simulation Protocol**

134 For the 2022 GCP (version 11), the TRENDY ensemble consisted of 16 terrestrial
135 biosphere models, 11 of which represent N cycling (CABLE-POP, CLM5.0, DLEM, ISAM,
136 JSBACH, JULES-ES, LPJ-GUESS, LPX-Bern, OCNv2, ORCHIDEEv3, and SDGVM).
137 Although SDGVM includes a representation of N cycling, its representation is simplistic and was
138 therefore not included. Additionally, CLASSIC contributed to the 2022 GCP without coupled C-
139 N cycling; the S3 simulation from the TRENDY protocol was repeated by CLASSIC with
140 coupled C-N cycling following the 2022 GCP protocol and was used here. Overall, we analysed
141 eleven models with coupled C-N cycling (Table 1).

142 Table 1: Terrestrial biosphere models in the TRENDY-N ensemble and descriptions of their
 143 representations of N limitation of vegetation growth, biological N fixation, vegetation response
 144 to N limitation (i.e., strategies in which vegetation invests C to increase N supply in N-limited
 145 conditions), and N limitation of decomposition.

	Reference	N limitation of vegetation growth	Biological N fixation	Vegetation response to N limitation	N limitation of decomposition
CABLE-POP	(Haverd et al., 2018)	$V_{cmax} = f(N)$ flexible C:N stoichiometry	Time-invariant	Static	N-invariant
CLASSIC	(Melton et al., 2020)	$V_{cmax} = f(N)$ flexible C:N stoichiometry	f(N limitation of vegetation growth)	Dynamic (biological N fixation)	N-invariant
CLM5.0	(Lawrence et al., 2019)	$V_{cmax} = f(N)$ flexible C:N stoichiometry	f(N limitation of vegetation growth)	Dynamic (biological N fixation, mycorrhizae, retranslocation)	f(soil N)
DLEM	(Tian et al., 2015)	$GPP = f(N)$	f(soil T, soil H ₂ O, soil C, soil N)	Dynamic (root allocation)	f(soil N)

146

147 We analysed the S3 simulation from the TRENDY protocol which includes historical
148 changes in atmospheric CO₂, climate, N deposition, N fertilisation, and land use from 1851 to
149 2021 (see Friedlingstein et al. (2022) for a full description of the simulation protocol). Briefly,
150 models were forced with atmospheric CO₂ from Dlugokencky and Tans (2022), the merged
151 monthly Climate Research Unit (CRU) and 6-hourly Japanese 55-year Reanalysis (JRA-55)
152 dataset or the monthly CRU dataset from Harris et al. (2020), N deposition from Hegglin et al.
153 (2016) / Tian et al. (2022), N fertilisation from the global N₂O Model Intercomparison Project
154 (NMIP) (Tian et al., 2018), and land use from the LUH2-GCB2022 (Land-Use Harmonization 2)
155 dataset (Chini et al., 2021; Hurtt et al., 2020; Klein Goldewijk et al., 2017a, b). We interpolated
156 outputs from all models to a common resolution of 1° x 1° using bilinear interpolation.

157 **2.2 Terrestrial biosphere model descriptions**

158 The terrestrial biosphere models in the TRENDY ensemble employ a wide variety of
159 assumptions and formulations of N cycling processes, reflecting knowledge gaps and divergent
160 theories (Table 1). Here we describe four fundamental aspects of N cycling for each terrestrial
161 biosphere model: N limitation of vegetation growth, biological N fixation, the response of
162 vegetation to N limitation (i.e., strategies in which vegetation invests C to increase N supply in
163 N-limited conditions), and N limitation of decomposition. These have been identified as
164 important challenges for representing N cycling in terrestrial biosphere models (Meyerholt et al.,
165 2020; Peng et al., 2020; Stocker et al., 2016; Wieder et al., 2015a; Zaehle et al., 2015; Zaehle and
166 Dalmonech, 2011).

167 Terrestrial biosphere models differ in how N limitation of vegetation growth is
168 represented (Thomas et al., 2015). Some TRENDY models represent flexible C:N stoichiometry
169 and modelled maximum carboxylation rate of photosynthesis (V_{cmax}) decreases with decreasing
170 leaf N (CABLE-POP, CLASSIC, CLM5.0, LPJ-GUESS, OCNv2, ORCHIDEEv3) following
171 empirical evidence (Walker et al., 2014). Other TRENDY models represent time-invariant C:N
172 stoichiometry and modelled GPP or NPP decreases with N limitation (DLEM, ISAM, JSBACH,
173 JULES-ES, and LPX-Bern). Importantly, flexible vs. time-invariant C:N stoichiometry
174 determines terrestrial C storage per unit N.

175 Biological N fixation is the dominant natural N supply to terrestrial ecosystems (Vitousek
176 et al., 2013). In terrestrial biosphere models, biological N fixation has generally been represented
177 phenomenologically as a function of either net primary productivity (NPP) or evapotranspiration
178 (ET) (Cleveland et al., 1999). More recently, representations of biological N fixation have been
179 updated such that it is up-regulated in N-limited conditions following empirical evidence (Menge
180 et al., 2015; Vitousek et al., 2013; Zheng et al., 2019). The majority of TRENDY models
181 represent biological N fixation phenomenologically (ISAM, JSBACH, JULES-ES, and LPJ-
182 GUESS). Three TRENDY models (CLASSIC, CLM5.0, and OCNv2) represent biological N
183 fixation mechanistically such that it increases with N limitation of vegetation and has an
184 associated C cost per unit N fixed (Kou-Giesbrecht and Arora, 2022; Lawrence et al., 2019;
185 Meyerholt et al., 2016; Shi et al., 2016; Fisher et al., 2010). These representations separate free-
186 living biological N fixation (via soil microbes, epiphytic microbes, lichens, bryophytes, etc.
187 (Reed et al., 2011)) from symbiotic biological N fixation, which is regulated by N limitation of

188 vegetation. DLEM derives biological N fixation as a function of soil temperature, soil moisture,
189 soil C, and soil N. LPX-Bern derives biological N fixation post hoc to simulate a closed N cycle,
190 implicitly including rock N sources (Joos et al., 2020). Finally, CABLE-POP and ORCHIDEEv3
191 represent biological N fixation as a specified time-invariant input over the historical period.
192 Importantly, representing the regulation of biological N fixation by N limitation does not only
193 determine biological N fixation itself but also modulates terrestrial C sequestration: it enables
194 vegetation to increase N uptake in N-limited conditions, reduce N limitation, and thus sustain
195 terrestrial C sequestration. Some TRENDY models (DLEM, LPJ-GUESS, and OCNv2) also
196 represent increasing C allocation to roots with increasing N limitation (Smith et al., 2014; Zaehle
197 and Friend, 2010) following empirical evidence (Poorter et al., 2012). This enables vegetation to
198 increase root N uptake in N-limited conditions, reduce N limitation, and thus sustain terrestrial C
199 sequestration. The response of vegetation to N limitation, which could also include increased C
200 allocation to mycorrhizae (Phillips et al., 2013) (represented in CLM5.0) or increased
201 retranslocation of N during tissue turnover (Du et al., 2020; Han et al., 2013; Kobe et al., 2005)
202 (represented in CLM5.0) is important for determining terrestrial C sequestration.

203 Decomposition rate is controlled by soil temperature, soil moisture, and N content in
204 litter, where increasing litter C:N ratio decreases decomposition rate (Cotrufo et al., 2013). Some
205 TRENDY models represent this reduction in decomposition rate with increasing litter C:N ratio
206 (CLM5.0, DLEM, ISAM, JSBACH, JULES-ES, and OCNv2) following empirical evidence.

207 **2.3 Observation-based datasets**

208 We interpolated observation-based datasets to a common resolution of $1^\circ \times 1^\circ$ using
209 bilinear interpolation for comparison against model outputs. To compare model outputs against
210 observation-based datasets we averaged model outputs over 1980–2021, which spans the period
211 in which most measurements were made.

212 **2.3.1 Biological N fixation**

213 A biological N fixation observation-based dataset was derived from Davies-Barnard and
214 Friedlingstein (2020), a global meta-analysis of field measurements of natural biological N
215 fixation (free-living and symbiotic) that scales biome-specific means onto the Collection 5
216 MODIS Global Land Cover Type International Geosphere-Biosphere Programme (IGBP)
217 product (Friedl et al., 2010). This dataset includes agricultural biological N fixation and assumes
218 that crop biological N fixation rates are equivalent to those of grasses.

219 The score of LPX-Bern in simulating biological N fixation is not analysed because it
220 implicitly includes rock N sources and is thus not directly comparable to the observation-based
221 dataset.

222 **2.3.2 Vegetation C:N ratio**

223 A vegetation C:N ratio observation-based dataset was derived by scaling biome-specific
224 means for vegetation C:N ratios from the TRY plant trait database (Kattge et al., 2020) onto the
225 Collection 5 MODIS Global Land Cover Type IGBP product (Friedl et al., 2010) and combining
226 it with the remote sensing leaf N content product from Moreno-Martínez et al. (2018). First, we

227 obtained N content per dry mass for leaves, root, and stem, as well as C content per dry mass for
228 leaves, root, and stem from the TRY plant trait database. We selected entries that reported
229 species. Second, we obtained plant functional type (PFT) for each species from the TRY plant
230 trait database. We categorised each PFT into the IGBP land cover types (Table A1) and then
231 used this to categorise each entry into the IGBP land cover types using species. We averaged
232 across entries in each IGBP land cover type. Third, we divided mean tissue C content per tissue
233 dry mass by mean tissue N content per tissue dry mass for each tissue and for each IGBP land
234 cover type. Fourth, we weighed each tissue by its PFT-specific fraction of total biomass from
235 Poorter et al. (2012) to obtain total vegetation C:N ratio for each IGBP land cover type. Fifth, we
236 scaled total vegetation C:N ratio and leaf N content per dry mass for each IGBP land cover type
237 to the Collection 5 MODIS Global Land Cover Type IGBP product. Sixth, we multiplied derived
238 total vegetation C:N ratio relative to leaf N content per dry mass by the remote sensing leaf N
239 content per dry mass product (Moreno-Martínez et al., 2018) to obtain a vegetation C:N ratio
240 observation-based dataset.

241 **2.3.3 Soil C:N ratio**

242 A soil C:N ratio observation-based dataset was derived from soil C and soil N products
243 from SoilGrids (Poggio et al., 2021), which provides globally gridded datasets of soil organic C
244 and total soil N at a 250m x 250m resolution for six layers up to a depth of 200 cm. These
245 estimates are derived using machine learning methods and soil observations from 240 000
246 locations across the globe and over 400 environmental covariates. We summed soil C over all
247 layers and soil N over all layers (using the bulk density and depth of each layer) then obtained
248 the soil C:N ratio.

249 **2.3.4 C cycling variables**

250 In addition to evaluating N cycling variables, we also evaluated the primary C cycling
251 variables: gross primary productivity (GPP), net biome productivity (NBP), vegetation C
252 (CVEG), soil C (CSOIL), and leaf area index (LAI). These variables have been previously
253 evaluated in detail for the terrestrial biosphere models in the TRENDY ensemble (GCP 2021) in
254 Seiler et al. (2022). Seiler et al. (2022) gives further details on the observation-based datasets
255 used to evaluate the primary C cycling variables. Briefly, we evaluated GPP against MODIS
256 (Zhang et al., 2017), GOSIF (Li and Xiao, 2019), and FLUXCOM (Jung et al., 2020) products.
257 We evaluated NBP against the CAMS (Agustí-Panareda et al., 2019), CarboScope (Rödenbeck
258 et al., 2018), and CT2019 (Jacobson et al., 2020) products. We evaluated CVEG against the
259 GEOCARBON (Avitabile et al., 2016; Santoro et al., 2015), Zhang and Liang (2020), and Huang
260 et al. (2021) products. We evaluated LAI against AVHRR (Claverie et al., 2016), Copernicus
261 (Verger et al., 2014), and MODIS (Myneni et al., 2002) products. We evaluated CSOIL against
262 HWSD (Todd-Brown et al., 2013; Wieder, 2014) and SoilGrids (Hengl et al., 2017) products.
263 These observation-based products are globally gridded.

264 **2.4 Model evaluation with the Automated Model Benchmarking R Package (AMBER)**

265 The Automated Model Benchmarking R (AMBER) package developed by Seiler et al.
266 (2021) quantifies model performance in reproducing observation-based datasets using a skill

267 score system that is based on ILAMB (Collier et al., 2018). Five scores assess the simulated
268 time-mean bias (S_{bias}), monthly centralised root-mean-square-error (S_{rmse}), seasonality (S_{phase}),
269 inter-annual variability (S_{iav}), and spatial distribution (S_{dist}) in comparison to the observation-
270 based dataset. Scores are dimensionless and range from 0 to 1, where higher values indicate
271 better model performance. The overall score for each variable ($S_{overall}$) is

$$272 \quad S_{overall} = \text{mean}(S_{bias}, S_{rmse}, S_{phase}, S_{iav}, S_{dist})$$

273 We calculated the overall score for each C and N cycling variable. Because biological N fixation,
274 vegetation C:N ratio, and soil C:N ratio datasets are representative of the present-day (as a single
275 time point), S_{rmse} , S_{phase} , and S_{iav} are not defined and thus do not contribute to $S_{overall}$. This also
276 holds for vegetation C and soil C. The calculation of each score is described in detail in Seiler et
277 al. (2022).

278 **2.5 Statistics**

279 We used a Mann-Kendall trend test to assess the existence of a statistically significant
280 trend in the time series over the historical period for simulated C and N cycling variables (Hipel
281 and McLeod, 1994). We conducted two analyses to compare model performance in simulating C
282 cycling vs. N cycling. First, we calculated Spearman's rank correlation coefficient to assess the
283 existence of statistically significant correlations between overall scores, present-day global
284 values, and Kendall's tau. Second, we used a t-test or ANOVA (p-value < 0.05) to assess the
285 existence of statistically significant differences between overall scores, present-day global
286 values, and Kendall's tau for models with different representations of N limitation of vegetation
287 growth, biological N fixation, vegetation response to N limitation, and N limitation of
288 decomposition (Table 1).

289

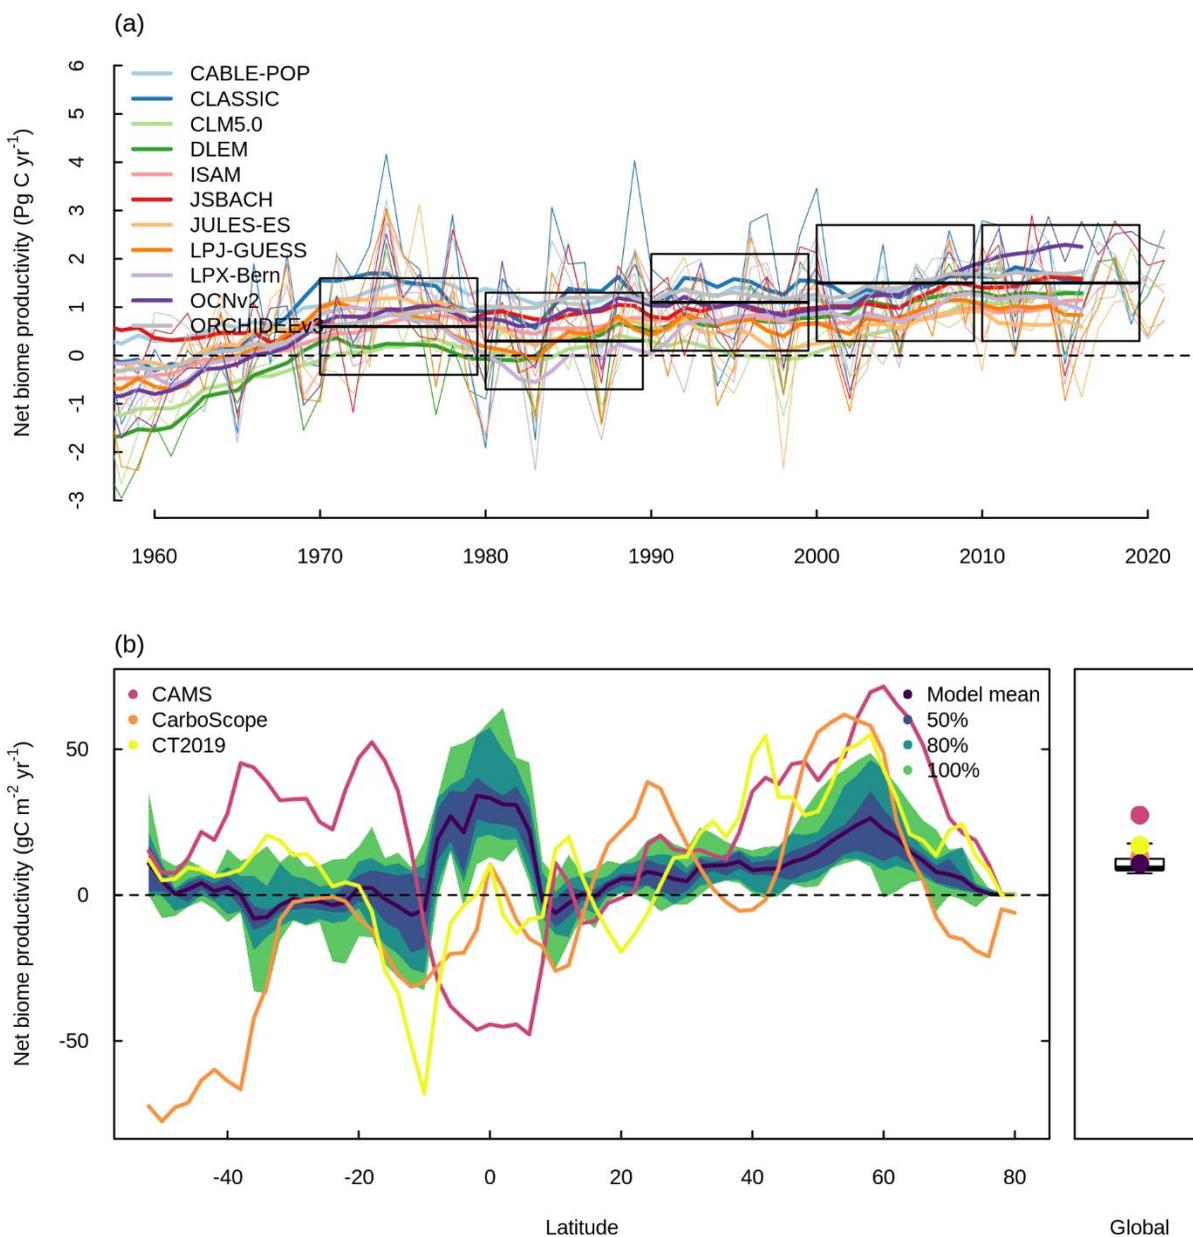

290 **3 Results**

291 **3.1 Net biome productivity**

292 Figure 2 shows NBP simulated by the TRENDY ensemble models with coupled C-N
293 cycling (hereafter referred to as the TRENDY-N ensemble). NBP is the difference between the
294 net natural atmosphere-land flux of CO₂ and land use change CO₂ emissions. Positive values of
295 NBP indicate a terrestrial C sink whereas negative values of NBP indicate a terrestrial C source.
296 All TRENDY-N ensemble models suggest a terrestrial C sink for the present-day, agreeing with
297 the global C budget constraint from the 2022 Global C Budget with most models within two
298 standard deviations of the mean (1.5 ± 0.6 Pg C for 2012–2021) (Figure 2a). The TRENDY-N
299 ensemble agrees reasonably well with observations globally, agreeing somewhat better with
300 CarboScope and CT2019 than with CAMS (Figure 2b). However, the latitudinal distributions of
301 the observation-based datasets display weak agreement among themselves with opposing signs
302 in multiple regions due to differences in the inversion models and atmospheric CO₂
303 measurements used in each dataset (Figure 2b). The largest differences occur at southern
304 latitudes and at high northern latitudes and is in part due to the smaller land area at these

305 latitudes. The region showing the strongest agreement is mid to high northern latitudes, in which
306 both the TRENDY-N ensemble and observations suggest a terrestrial C sink (Figure 2b).

307 Figure 2: Net biome productivity (NBP) simulated by the TRENDY-N ensemble. a. Global NBP
 308 from 1960 to 2021. The boxes indicate the global C budget constraint (difference between fossil
 309 fuel CO₂ emissions and the growth rate of atmospheric CO₂ and the uptake of CO₂ by oceans;
 310 mean \pm 2 standard deviation) from the 2022 Global C Budget (Friedlingstein et al., 2022). Thick
 311 lines indicate the moving average over 10 years and thin lines indicate the annual time series. b.
 312 Latitudinal distribution and global mean of NBP (averaged over 1980–2021) in comparison to
 313 three datasets (CAMS (Agustí-Panareda et al., 2019), CarboScope (Rödenbeck et al., 2018), and
 314 CT2019 (Jacobson et al., 2020)). The boxplot shows the median, interquartile range (box), and
 315 80% percentiles (whiskers) of the global mean of NBP.

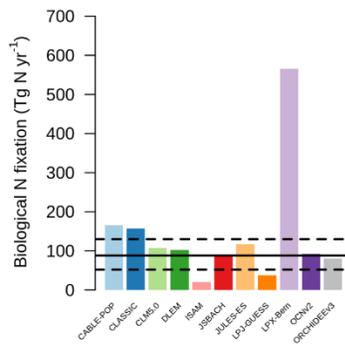

316

317 **3.2 Overview of N cycling**

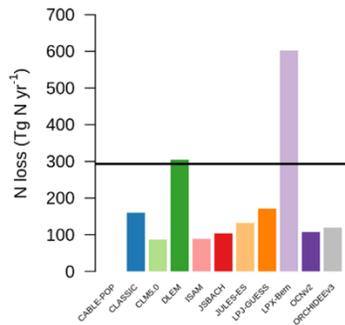

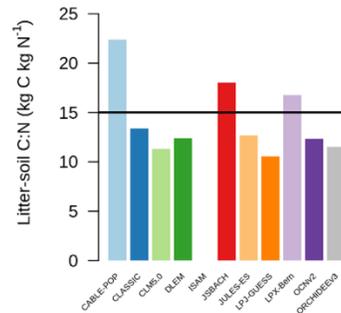

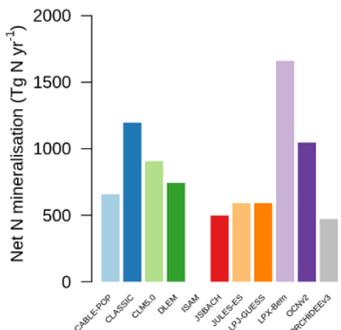

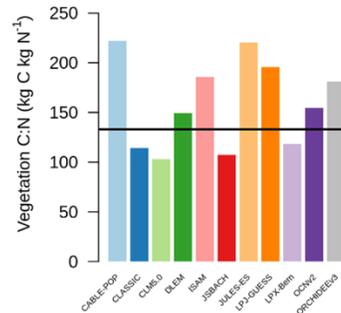

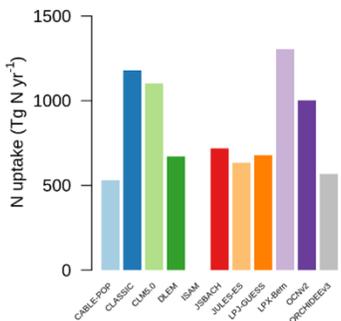

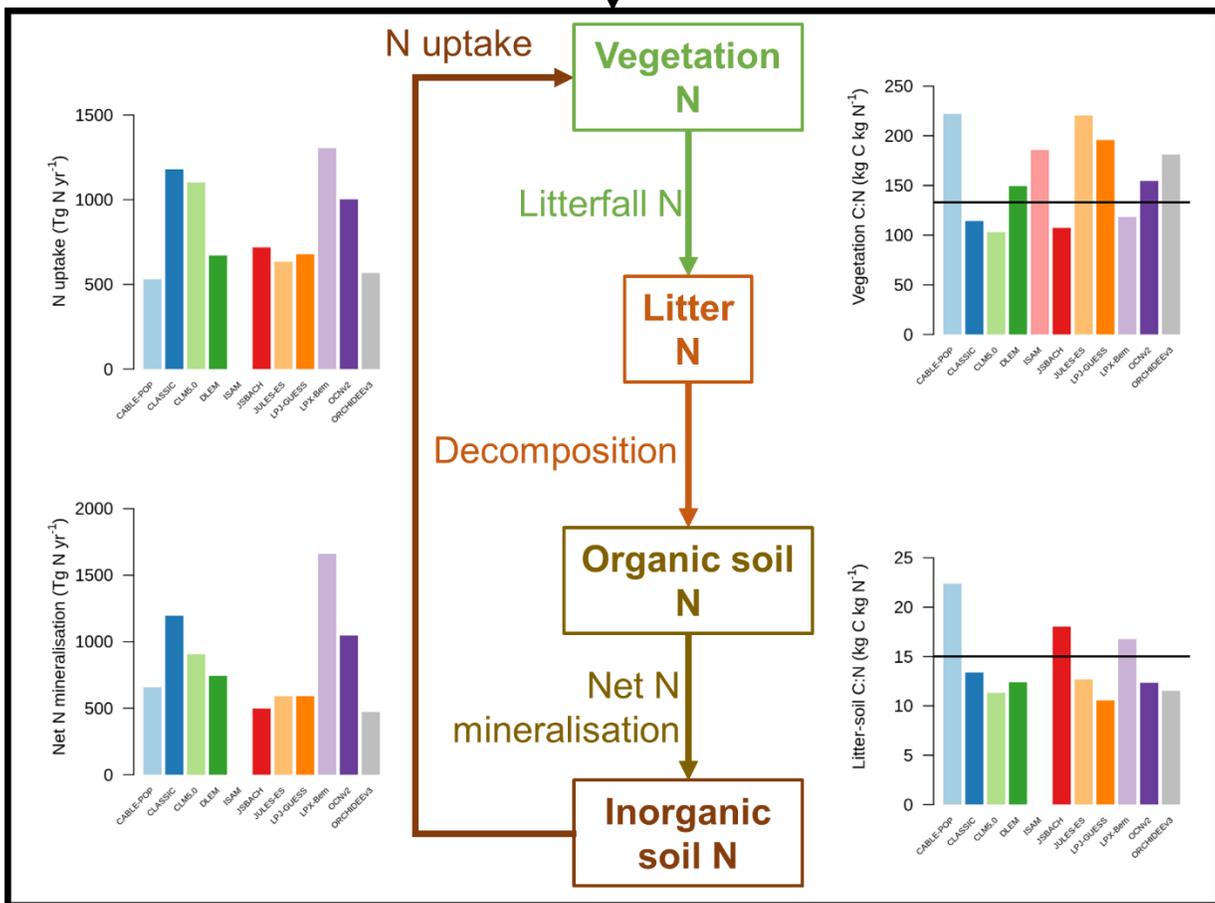

318 Figure 3 shows a schematic of the N cycle alongside the primary N fluxes and C:N ratios
319 of the primary pools simulated by the TRENDY-N ensemble for the present-day (averaged over
320 1980–2021) as well as observation-based estimates for these variables that have previously been
321 used for model evaluation (Davies-Barnard et al., 2020). Simulated biological N fixation ranged
322 between 20 and 566 Tg N yr⁻¹ (Table 2) in comparison to the observation-based estimate of 88
323 Tg N yr⁻¹ (52 – 130 Tg N yr⁻¹). Simulated N₂O emissions ranged between 0.9 and 11.0 Tg N yr⁻¹
324 (Table 2) in comparison to the observation-based estimate of 10.8 Tg N yr⁻¹ (7.1 – 16.0 Tg N yr⁻¹)
325 (Tian et al., 2020). Simulated N losses (which include emissions of NH₃, N₂O, NO_x and N₂ as
326 well as NO₃⁻ and NH₄⁺ leaching) ranged between 87 and 603 Tg N yr⁻¹ (Table 2) in comparison
327 to the observation-based estimate of 293 Tg N yr⁻¹ (Fowler et al., 2013). The simulated
328 vegetation C:N ratio ranged between 103 and 222 (Table 2) in comparison to the observation-
329 based estimate of 133 (Zechmeister-Boltenstern et al., 2015). The simulated combined litter-soil
330 C:N ratio ranged between 10 and 64 (Table 2) in comparison to the observation-based estimate
331 of 15 (Zechmeister-Boltenstern et al., 2015). Biological N fixation has the largest inter-model
332 spread with a coefficient of variation of 1.06 (Table 2). Figure 4 shows the geographical
333 distribution of the primary N pools and fluxes simulated by the TRENDY-N ensemble for the
334 present-day (averaged over 1980–2021) and variation across models is shown in Figure A1.

335 Figure 3: The N cycle and the primary N pools and fluxes simulated by the TRENDY-N
336 ensemble (averaged over 1980–2021). Horizontal black lines indicate observation-based
337 estimates that have previously been used for model evaluation (biological N fixation from
338 Davies-Barnard and Friedlingstein (2020), vegetation and combined litter-soil C:N ratios from
339 Zechmeister-Boltenstern et al. (2015), N₂O emissions from Tian et al. (2020), and N losses from
340 Fowler et al. (2013)). The black box indicates the terrestrial biosphere. N enters the terrestrial
341 biosphere via biological N fixation, N deposition, and N fertilisation (entering the organic soil N
342 pool, the inorganic soil N pool (ammonium (NH₄⁺) or nitrate (NO₃⁻)), or the vegetation N pool).
343 N is transferred from the inorganic soil N pool to the vegetation N pool via N uptake. N is
344 transferred from the vegetation N pool to the litter N pool via N litterfall. N is transferred from
345 the litter N pool to the organic soil N pool via decomposition. N is transferred from the organic
346 soil N pool to the inorganic soil N pool via net N mineralisation. N exits the terrestrial biosphere
347 via N loss (which includes N leaching from soils and N₂O, NO_x, NH₃, and N₂ emissions from
348 both soils and land use change). Not all models provide output for each N pool or flux. Note that
349 biological N fixation simulated by LPX-Bern implicitly includes rock N sources.

352 fixation, e. N uptake, f. net N mineralisation, g. N₂O emissions, and h. N loss simulated by the
353 TRENDY-N ensemble (averaged across models over 1980–2021). Variation across models is
354 shown in Figure A1.

355

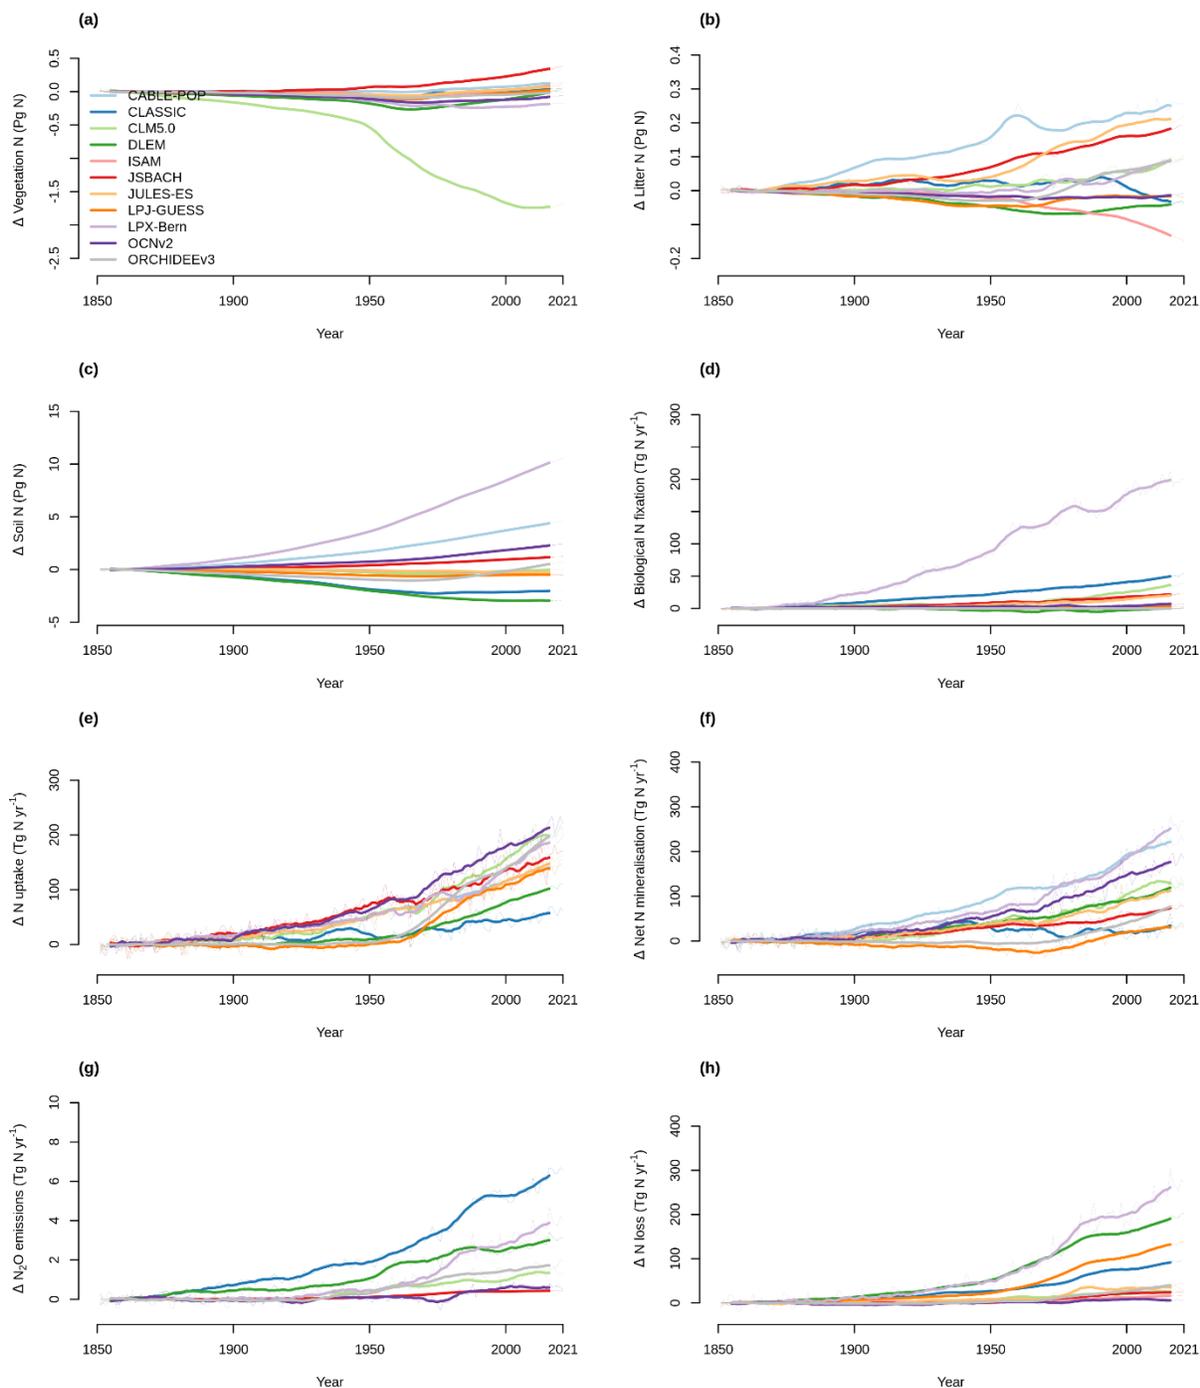

356 Table 2: Global N pools, N fluxes, and C:N ratios simulated by the TRENDY-N ensemble (mean
 357 and coefficient of variation across models over 1980–2021).

	Coefficient of variation	Global mean	Global median	Global minimum	Global maximum
Vegetation N (Tg N)	0.41	2.94	2.94	1.50	5.58
Litter N (Tg N)	0.81	1.94	1.08	0.73	5.61
Soil N (Tg N)	0.67	101.43	81.21	32.10	277.41
Biological N fixation (Tg N yr ⁻¹)	1.06	139.63	101.83	19.92	565.53
N uptake (Tg N yr ⁻¹)	0.33	838.78	698.11	529.53	1304.87
Net N mineralisation (Tg N yr ⁻¹)	0.45	836.00	700.28	471.39	1661.53
N ₂ O emissions (Tg N yr ⁻¹)	0.53	7.06	9.04	0.86	11.01
N loss (Tg N yr ⁻¹)	0.85	187.62	125.96	87.02	602.77
Vegetation C:N ratio	0.28	159.28	154.50	102.84	222.22
Soil C:N ratio	0.90	17.32	11.13	10.00	63.57

358

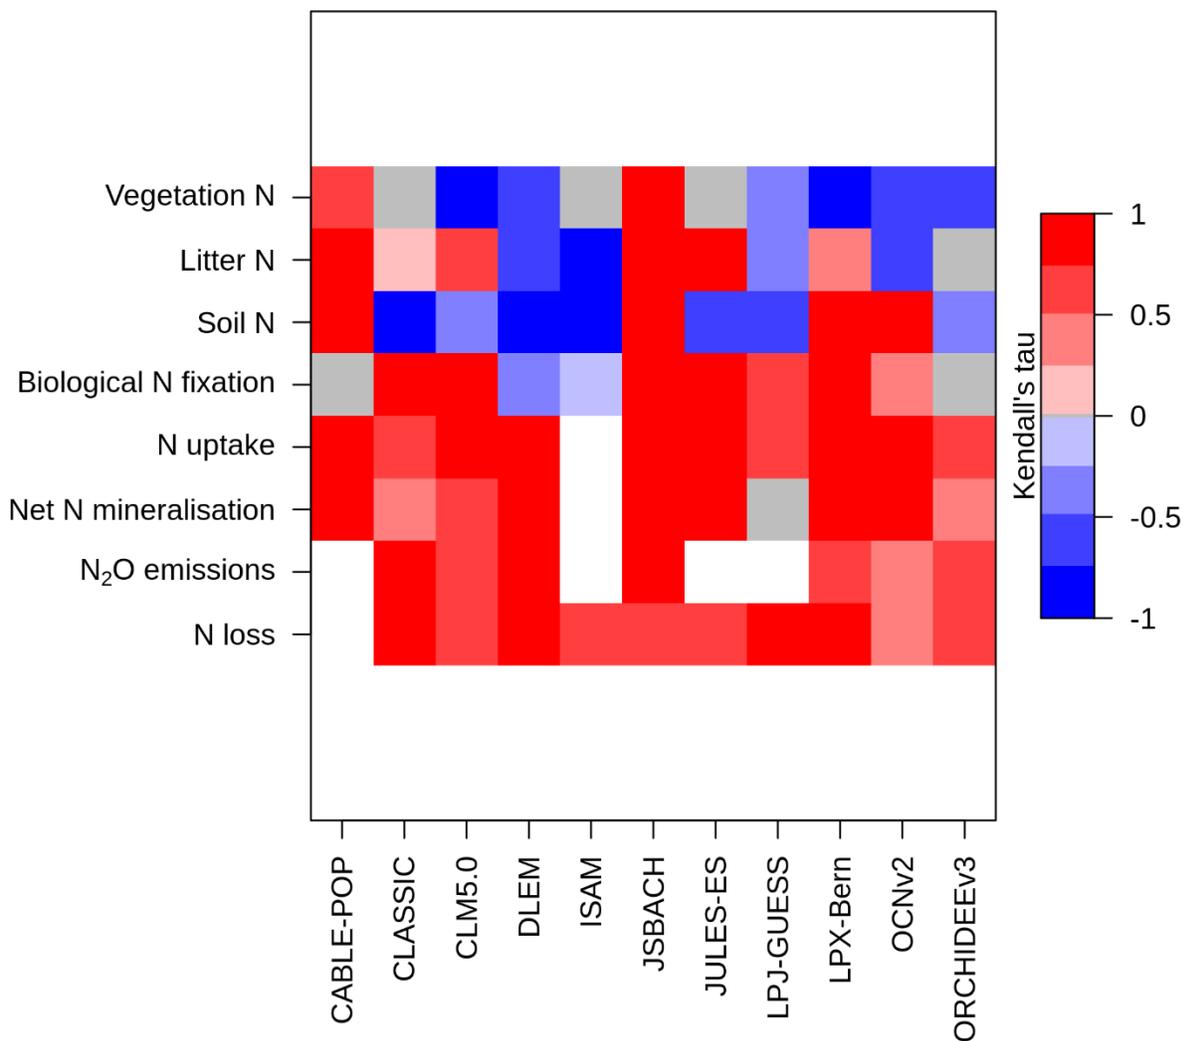

359 Figure 5 shows the time series of the change from pre-industrial levels of the primary N
360 pools and fluxes from 1850 to 2021 simulated by the TRENDY-N ensemble. Figure 6 shows the
361 corresponding Kendall's tau which identifies the existence of a statistically significant trend
362 (Table A2). Over the historical period, some models suggest decreasing vegetation N (6/11
363 models), whereas other models suggest increasing vegetation N (2/11 models) or no trend in
364 vegetation N (3/11 models). Some models suggest decreasing soil N (7/11 models), whereas
365 other models suggest increasing soil N (4/11 models). Some models suggest increasing
366 biological N fixation (7/11 models), whereas other models suggest decreasing biological N
367 fixation (2/11 models) or no trend in biological N fixation (2/11 models). All models suggest
368 increasing N uptake (10/10 models). Most models suggest increasing net N mineralisation rate
369 (9/10 models) or no trend in N mineralisation rate (1/10 models). All models suggest increasing
370 N₂O emissions (7/7 models) and increasing N loss (10/10 models).

371 Figure 5: Time series of the change from the pre-industrial level (averaged over 1850–1870) of a.
 372 vegetation N, b. litter N, c. soil N, d. biological N fixation, e. N uptake, f. net N mineralisation,
 373 g. N₂O emissions, and h. N loss simulated by the TRENDY-N ensemble from 1850 to 2021.
 374 Figure A5 shows the time series for each N pool and N flux simulated by the TRENDY-N
 375 ensemble from 1850 to 2021.

376

377 Figure 6: Kendall's tau from the Mann-Kendall test (p -value < 0.05) for each N pool and N flux
 378 time series simulated by the TRENDY-N ensemble from 1850 to 2021 (Table A2). A positive
 379 value (red) indicates an increasing trend and a negative value (blue) indicates a decreasing trend
 380 Gray indicates a statistically insignificant value and white indicates a missing value.

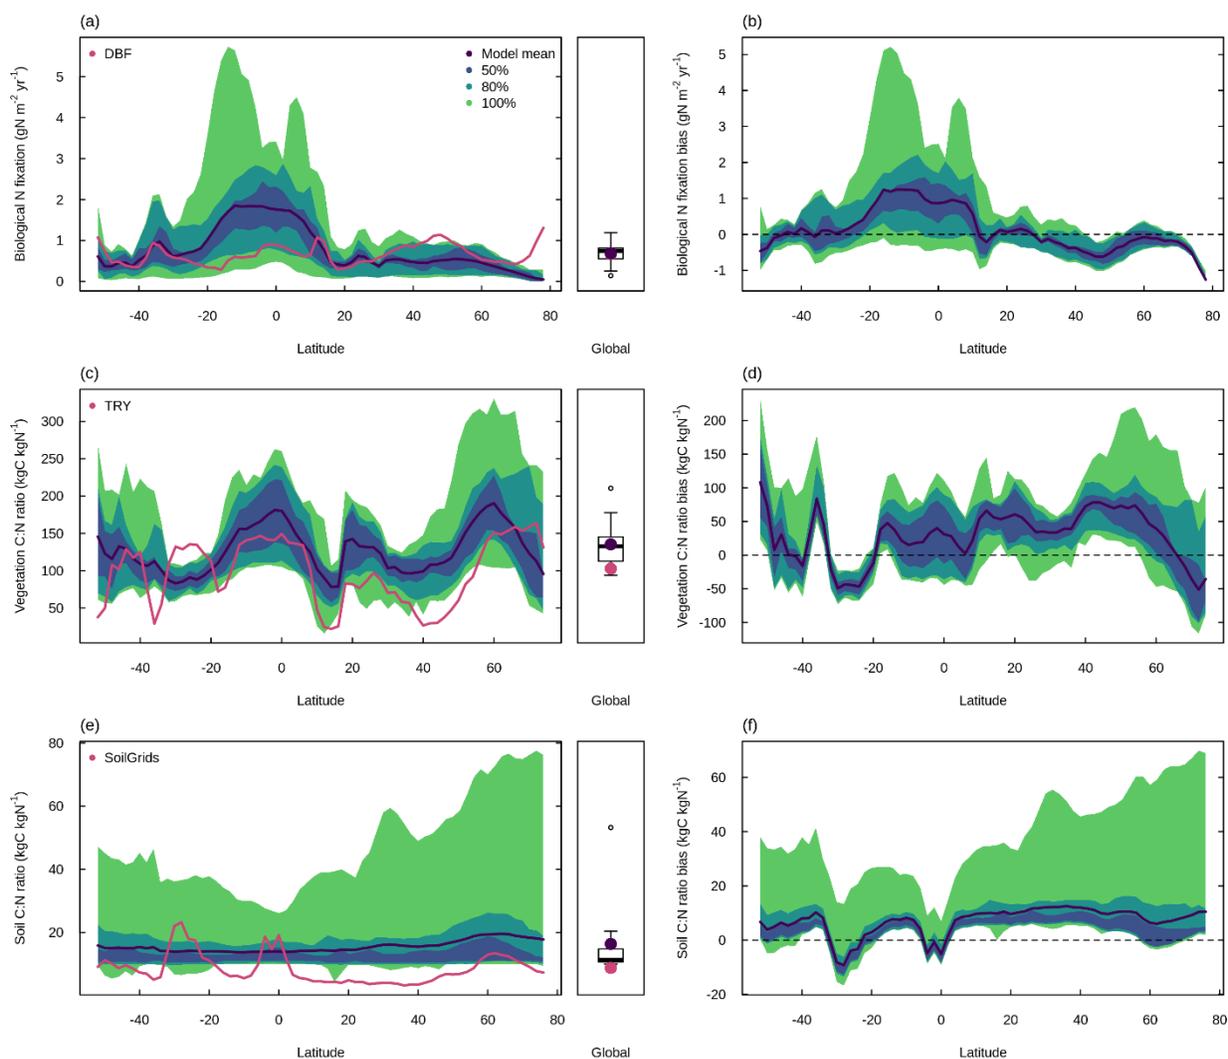

381

382 **3.3 Evaluation of biological N fixation, vegetation C:N ratio, and soil C:N ratio**

383 In comparison to the observation-based dataset from Davies-Barnard and Friedlingstein
384 (2020), the TRENDY-N ensemble reproduced global biological N fixation (101.8 Tg N yr⁻¹ vs.
385 88 Tg N yr⁻¹; Figure 7a and Table 2) but overestimated low-latitude biological N fixation and
386 underestimated high-latitude biological N fixation in the Northern hemisphere (Figure 7b). In
387 comparison to the observation-based dataset from the TRY plant trait database, the TRENDY-N
388 ensemble overestimated the global vegetation C:N ratio (154.5 vs. 102.8; Figure 7c and Table 2)
389 and overestimated the vegetation C:N ratio across latitudes while capturing its latitudinal pattern
390 (Figure 7d). In comparison to the observation-based dataset from SoilGrids, the TRENDY-N
391 ensemble overestimated the global soil C:N ratio, simulating a relatively constant soil C:N ratio
392 across latitudes (11.1 vs. 8.8; Figure 7e and Table 2). The TRENDY-N ensemble was thus
393 unable to capture the latitudinal pattern of the soil C:N ratio (Figure 7f).

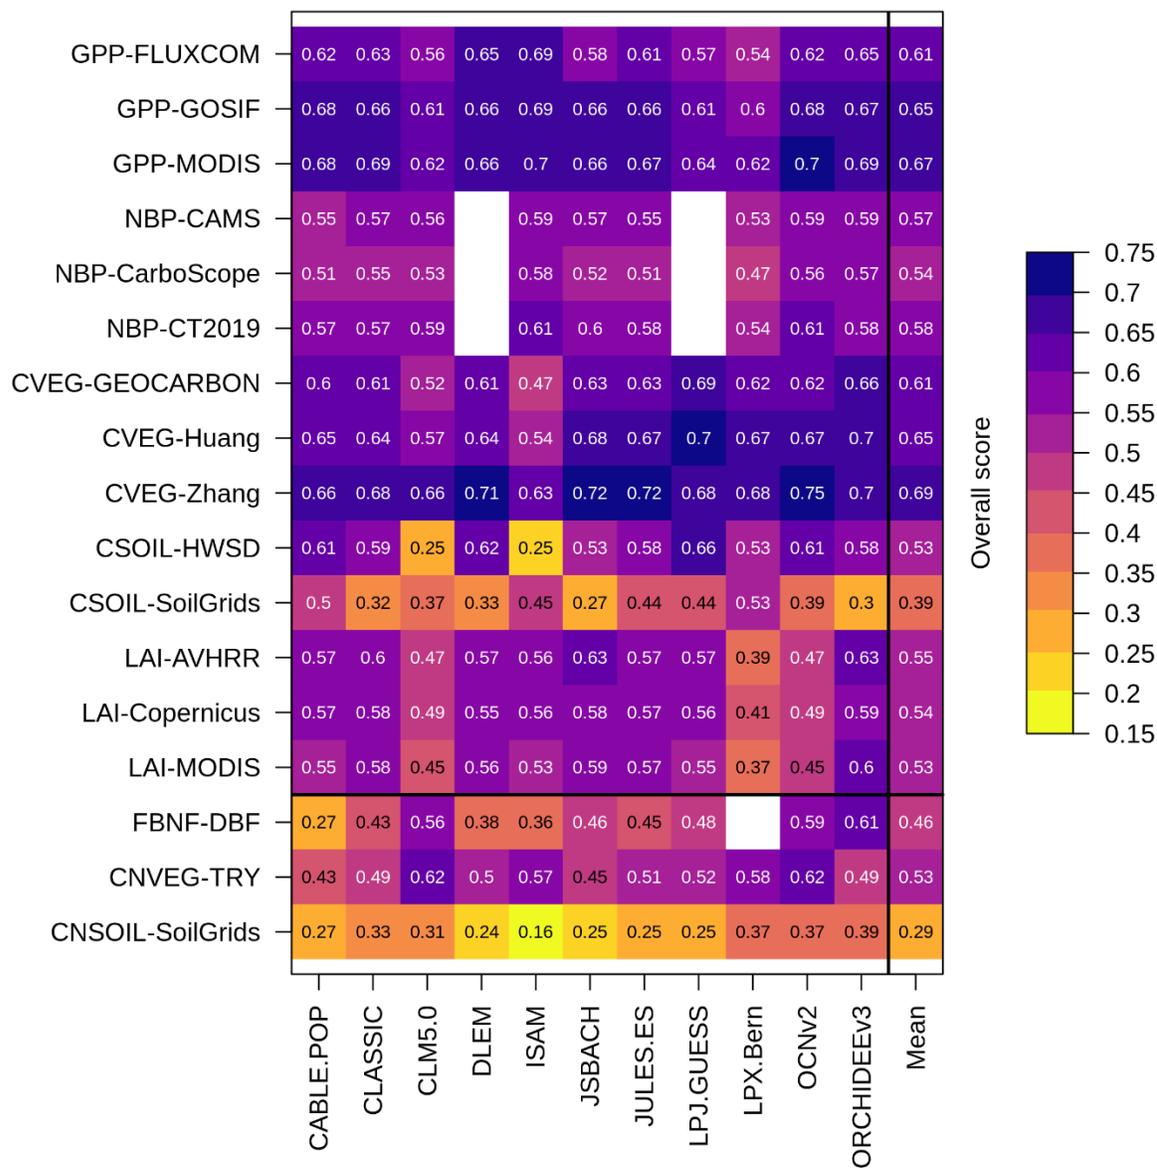

394 Figure 7: Latitudinal distributions and global means of biological N fixation, vegetation C:N
 395 ratio, and soil C:N ratio simulated by the TRENDY-N ensemble (averaged across models over
 396 1980–2021) in comparison to observations. ace. show the latitudinal distribution of the mean and
 397 boxplots show the global mean. bdf. show the latitudinal distribution of the bias. Latitudinal
 398 distributions show the mean (black line) and the 50%, 80%, and 100% percentiles across models.
 399 Boxplots show the median, interquartile range (box), and 80% percentiles (whiskers) across
 400 models. Observation-based datasets are from Davies-Barnard and Friedlingstein (2020) for
 401 biological N fixation, the TRY plant trait database for vegetation C:N ratio, and SoilGrids for
 402 soil C:N ratio. LPX-Bern simulations are not shown in ab. Latitudinal distributions and global
 403 means of individual models in the TRENDY-N ensemble are shown in Figure A6.

404

405 The overall score is a metric of model performance in reproducing an observation-based
406 dataset. Overall scores for biological N fixation, vegetation C:N ratio, and soil C:N ratio (0.46,
407 0.53, and 0.29 averaged across models, respectively) were lower than those for C cycling
408 variables (0.58 averaged across all C cycling variables and across models) (Figure 8). The mean
409 overall score for vegetation C:N ratio across models (0.53) was lower than the mean overall
410 scores for vegetation C across models (which ranged from 0.61 to 0.69 depending on the
411 observation-based dataset used to derive the score). Similarly, the mean overall score for soil
412 C:N ratio across models (0.29) was lower than the mean overall scores for soil C across models
413 (which ranged from 0.39 to 0.53 depending on the observation-based dataset used to derive the
414 score).

415 Figure 8: Overall scores of the TRENDY-N ensemble in simulating C and N cycling variables:
 416 gross primary productivity (GPP), net biome productivity (NBP), vegetation C (CVEG), soil C
 417 (CSOIL), leaf area index (LAI), biological N fixation (FBNF), vegetation C:N ratio (CNVEG),
 418 and soil C:N ratio (CNSOIL). Abbreviations of the observation-based datasets are described in
 419 the Methods and in Seiler et al. (2022).

420

421 For N cycling variables, the overall score is composed of the time-mean bias score
422 (which assesses the difference between the time-mean of model simulations and the time-mean
423 of the observation-based dataset) and the spatial distribution score (which assesses the ability of
424 the model to reproduce the spatial pattern of the observation-based dataset) (Collier et al., 2018;
425 Seiler et al., 2022). For biological N fixation, the time-mean bias score averaged across models
426 was 0.50 and the mean spatial distribution score across models was 0.41 (Table A3). For the
427 vegetation C:N ratio, the time-mean bias averaged score across models was 0.46 and the mean
428 spatial distribution score across models was 0.59 (Table A3). For the soil C:N ratio, the time-
429 mean bias score averaged across models was 0.39 and the mean spatial distribution score across
430 models was 0.19 (Table A3).

431 Note that, for C fluxes, the overall score is composed of not only the time-mean bias
432 score and the spatial distribution score, but also the monthly centralised root-mean-square-error
433 score (which assesses the ability of the model to reproduce the time series of the observation-
434 based dataset), the seasonality score (which assess the ability of the model to reproduce the
435 seasonality of the observation-based dataset), and the inter-annual variability score (which
436 assesses the ability of the model to reproduce the inter-annual variability of the observation-
437 based dataset) because observation-based datasets of C fluxes are available over time (whereas
438 observation-based datasets of C pools and all N cycling variables are representative of the
439 present-day (as a single time point)).

440 **3.4 Model performance for C cycling vs. N cycling**

441 There were no statistically significant correlations between the overall score of NBP (as
442 well as other primary C variables) and the overall scores of the primary N variables across the
443 TRENDY-N ensemble (Figure A2). Furthermore, there were no statistically significant
444 correlations between the present-day global value of NBP and the present-day global values of
445 the primary N variables across the TRENDY-N ensemble (Figure A3). Finally, there were no
446 statistically significant correlations between Kendall's tau of NBP and Kendall's tau of the
447 primary N variables across the TRENDY-N ensemble (Figure A4).

448 **3.5 Model performance for different representations of N cycling processes**

449 There were no statistically significant differences in overall scores between models with
450 different representations of N limitation of vegetation growth (decreasing V_{cmax} and flexible C:N
451 stoichiometry vs. decreasing NPP), different representations of biological N fixation (function of
452 N limitation of vegetation growth vs. function of NPP or ET vs. time-invariant), different
453 representations of the response of vegetation to N limitation (dynamic vs. static), or different
454 representations of N limitation of decomposition (function of soil N vs. N-invariant) (Table A4).
455 However, models that represented decomposition as a function of soil N had a significantly
456 higher NBP score (for CT2019) than models that represented decomposition as N-invariant.
457 Similarly, there were no statistically significant differences between present-day global values or
458 Kendall's tau of primary C and N pools and fluxes between models with different representations
459 of N limitation of vegetation growth, biological N fixation, vegetation response to N limitation,

460 and N limitation of decomposition (Table A5 and A6). This is likely in part due to the low
461 number of models and the confounding influence of other process representations.

462

463 **4 Discussion**

464 **4.1 Evaluation of N cycling in terrestrial biosphere models**

465 Despite the ability of all TRENDY-N models to simulate the historical terrestrial C sink
466 in line with observations (Figure 2), there is substantial variation in simulated N cycling
467 processes by the models. The magnitude of N pools and fluxes differ considerably between
468 models (Figures 3 and A1). Additionally, the historical trajectories of these N pools and fluxes
469 differ between models: some models simulate increasing vegetation N and soil N whereas others
470 simulate decreasing vegetation N and soil N between 1850 and 2021 (Figures 5 and 6). These
471 trajectories are the result of a host of interacting global change drivers (CO₂ fertilisation,
472 intensifying N deposition, rising temperature and varying precipitation, land use change and
473 associated N fertilisation regimes) whose effects are challenging to disentangle without
474 additional simulations. For example, while intensifying N deposition and N fertiliser use could
475 drive increasing soil N and N uptake, land use change could increase N losses from both
476 vegetation N and soil N. Most models suggest increasing biological N fixation between 1850 and
477 2021. This occurs either as a result of increasing vegetation biomass or the up-regulation of
478 biological N fixation due to N limitation imposed by CO₂ fertilisation or a combination thereof,
479 depending on the representation of biological N fixation in a given model (Table 1). This follows
480 observations that suggest that biological N fixation is stimulated by CO₂ fertilisation (Zheng et
481 al., 2020; Liang et al., 2016), although its mechanism (i.e., up-regulated biological N fixation in
482 N-limited conditions) may not be captured. Similarly, most models also suggest increasing N
483 uptake between 1850 and 2021. This also occurs as a result of increasing vegetation biomass,
484 increasing soil N from intensifying N deposition and N fertiliser use, or increasing biological N
485 fixation, mycorrhizae and root allocation due to N limitation imposed by CO₂ fertilisation, again
486 dependent on the representation of the vegetation response to N limitation in a given model
487 (Table 1). Most models suggest increasing net N mineralisation rate between 1850 and 2021
488 likely due to rising temperature following observations (Liu et al., 2017). Most models suggest
489 increasing N₂O emissions (and N losses) between 1850 and 2021 likely due to rising temperature
490 and intensifying N deposition and N fertiliser use following observations (Tian et al., 2020).

491 We focused on three key N cycling processes for evaluation: biological N fixation,
492 vegetation C:N ratio, and soil C:N ratio. These three key N cycling processes have important
493 implications for projecting the future terrestrial C sink. Biological N fixation is the dominant
494 natural N supply to terrestrial ecosystems and allows vegetation to increase N uptake in N-
495 limited conditions, reduce N limitation, and thus sustain terrestrial C sequestration, such as in
496 response to N limitation imposed by CO₂ fertilisation (Zheng et al., 2020; Liang et al., 2016).
497 Vegetation and soil C:N ratios reflect assimilated C per unit N and thus terrestrial C
498 sequestration. They can potentially vary, such as in response to high photosynthesis rates relative
499 to N uptake rates driven by CO₂ fertilisation (Elser et al., 2010). Overall scores of N cycling

500 variables, which quantify model performance in reproducing an observation-based dataset, are
501 lower than overall scores of corresponding C cycling variables, suggesting that models could be
502 less capable of capturing N cycling processes than C cycling processes (Figure 8). However, this
503 could also be due to the significant uncertainty associated with measurements of N cycling
504 processes as discussed below.

505 The TRENDY-N ensemble reproduced global observation-based biological N fixation
506 but tended to overestimate low-latitude biological N fixation and underestimate high-latitude
507 biological N fixation (Figure 7ab). This is likely because most models represented biological N
508 fixation phenomenologically as a function of a measure of vegetation activity (either NPP or
509 ET). Since there is higher vegetation activity at low latitudes than at high latitudes these models
510 thus represent higher biological N fixation at low latitudes than at high latitudes. However,
511 because biological N fixation is down-regulated in non-N-limited conditions, it is often down-
512 regulated at low latitudes, which are generally not (or at least less) N-limited (Barron et al.,
513 2011; Batterman et al., 2013; Sullivan et al., 2014). While CLASSIC, CLM5.0, and OCNv2 can
514 represent the down-regulation of biological N fixation in non-N-limited conditions, they still
515 simulate high low-latitude biological N fixation. This suggests that the strength of regulation of
516 biological N fixation could be insufficient and/or that there could be unaccounted N sources at
517 low latitudes. For example, rock N weathering could be a significant N source to terrestrial
518 ecosystems. Some estimates have suggested that rock N weathering could be as high as 11 – 18
519 Tg N yr⁻¹ globally (Houlton et al., 2018) but is not explicitly represented in the TRENDY-N
520 ensemble (with the exception of LPX-Bern which calculates all external N sources post hoc to
521 simulate a closed N cycle thereby implicitly including rock N sources). The discrepancy between
522 modelled and observed biological N fixation could also be due to uncertainty in the observation-
523 based dataset given the difficulties associated with measuring biological N fixation (Soper et al.,
524 2021). Ecological theory (Hedin et al., 2009) has suggested that natural biological N fixation
525 should be higher at low latitudes given large N losses, in contrast to the observation-based
526 dataset from Davies-Barnard and Friedlingstein (2020). Furthermore, the observation-based
527 dataset from Davies-Barnard and Friedlingstein (2020) did not explicitly account for agricultural
528 biological N fixation but rather assumed that crop biological N fixation rates are equivalent to
529 those of grasses although they are likely to be much greater (Peoples et al., 2021; Herridge et al.,
530 2022).

531 The TRENDY-N ensemble overestimated global observation-based vegetation C:N ratio
532 but reproduced its latitudinal pattern (as also indicated by its higher spatial distribution score)
533 (Figure 7cd). This is because most models represent different plant functional types (e.g.,
534 evergreen needleleaf trees, deciduous broadleaf trees, evergreen broadleaf trees, etc.) with
535 different tissue C:N ratios (which can either be flexible within a constrained range or time-
536 invariant). These plant functional types are geographically distributed according to similar land
537 cover products. The TRENDY-N ensemble overestimated global observation-based soil C:N
538 ratio and failed to reproduce its latitudinal pattern (as also indicated by its lower spatial
539 distribution score) (Figure 7ef). In particular, models failed to reproduce the peak at the equator
540 and the peak at approximately -30°S, corresponding to tropical forests and deserts respectively.
541 This is because most models represent a constant soil C:N ratio (both temporally and spatially)

542 and are thus unable to capture the spatial variability in the soil C:N ratio. Improving the
543 representation of soil N is an important future direction for terrestrial biosphere model
544 development given the essential feedbacks between soil N and soil C.

545 **4.2 Disconnect between C and N cycling in terrestrial biosphere models**

546 The importance of N limitation of terrestrial C sequestration is empirically established.
547 (Elser et al., 2007; LeBauer and Treseder, 2008; Wright et al., 2018). It has already influenced
548 the historical terrestrial C sink (Wang et al., 2020a) and it is expected to be especially important
549 under future CO₂ fertilisation and global change (Terrer et al., 2019). While all TRENDY-N
550 models simulate the historical terrestrial C sink in line with observations (and are no different
551 from TRENDY models without a representation N cycling (Seiler et al., 2022)), our results
552 suggest a disconnect between C and N cycling in these models. First, the models exhibit a wide
553 spread across simulated N pools and fluxes. Second, there are no significant correlations between
554 model performance in simulating N cycling and model performance in simulating C cycling.
555 Third, there are no statistically significant differences between models with different
556 representations of fundamental N cycling processes (N limitation of vegetation growth,
557 biological N fixation, the response of vegetation to N limitation, and N limitation of
558 decomposition).

559 Overall, our results suggest that the underlying N cycling processes that regulate
560 terrestrial C sequestration operate differently across models and may not be fully captured given
561 that models are calibrated to C cycling. The spread across models suggests that approaches to
562 represent N cycling processes vary among models and that there is no clear consensus yet on
563 what the best approaches are. Studies have explored the validity of different representations of N
564 cycling processes within a single model, suggesting that alternative representations of a
565 biological N fixation, ecosystem C:N stoichiometry, and ecosystem N losses lead to substantial
566 differences in simulated C cycling (Kou-Giesbrecht and Arora, 2022; Meyerholt et al., 2020;
567 Peng et al., 2020; Wieder et al., 2015a). This disconnect between C and N cycling will become
568 particularly consequential for projecting the terrestrial C sink under future global change, which
569 is likely to modify the C-N balance through N limitation of CO₂ fertilisation and intensifying N
570 deposition among other effects of global change.

571 **4.3 Future directions**

572 Evaluating N cycling in terrestrial biosphere models is severely restricted by the lack of
573 available observations of N cycling. N cycling processes are notoriously difficult to measure,
574 such as biological N fixation (Soper et al., 2021) and gaseous N losses (Barton et al., 2015). In
575 the past, N cycling has been commonly evaluated by comparison to estimates of global N pools
576 and fluxes derived from a small number of observations that have been scaled up or averaged to
577 yield a value with wide confidence intervals (Davies-Barnard et al., 2020). Not only are these
578 global totals highly uncertain, but they also do not allow for the analysis of spatial patterns. Here,
579 we present an improved framework to evaluate three key N cycling processes – biological N
580 fixation, vegetation C:N ratio, and soil C:N ratio – in terrestrial biosphere models. However,
581 these globally-gridded observation-based datasets are also uncertain, given uncertainty in the

582 estimates of tissue C:N ratios for different plant functional types and tissue fraction of total
583 biomass (especially those of roots and wood which had a lower number of measurements in
584 comparison to that of leaves), as well as in the measurements and models used to derive soil N
585 (Batjes et al., 2020). More observations of these N cycling processes are necessary to reduce
586 uncertainty. Temporally explicit measurements are important for assessing intra-annual and
587 inter-annual variability. Leveraging advances in remote sensing (Knyazikhin et al., 2013;
588 Townsend et al., 2013; Cawse-Nicholson et al., 2021) as well as incorporating N cycling process
589 measurements into research networks such as FLUXNET (Vicca et al., 2018) is essential.
590 Multiple observation-based datasets from different sources and derived via different
591 methodologies of a given N cycling process are necessary to evaluate observational uncertainty
592 (Seiler et al., 2021). Global observations of other important N cycling processes (such as N
593 mineralisation and N losses) are necessary to fully evaluate N cycling in terrestrial biosphere
594 models. Additionally, hindcast simulations of the transition from the Last Glacial Maximum to
595 the preindustrial period can be used in combination with proxy-based reconstructions of past
596 N₂O emissions (Fischer et al., 2019) as well as C stocks (Jeltsch-Thömmes et al., 2019) for
597 model evaluation and can serve as a constraint for terrestrial biosphere models (Joos et al., 2020).

598 Modelled experimental manipulations (such as CO₂ fertilisation or N fertilisation
599 experiments) are imperative to evaluate model formulations of the underlying mechanisms of C-
600 N cycling interactions (Medlyn et al., 2015; Wieder et al., 2019; Zaehle et al., 2014). Derived
601 nutrient limitation products (Fisher et al., 2012) can also be applied to evaluate present-day
602 nutrient cycling when phosphorus (P) is accounted for (Braghiere et al., 2022). Evaluating the
603 ability of models to simulate present-day N cycling processes, as we did here, is only one method
604 of assessing their ability to simulate N limitation of terrestrial C sequestration. A robust test of
605 the simulated response to CO₂ fertilisation and N fertilisation across models would be ideal for
606 evaluating the ability of models to represent the regulation of C cycling by N cycling under
607 global change and thus their ability to realistically simulate the future terrestrial C sink.

608 While some of the models in the TRENDY-N ensemble have the capability of
609 representing coupled C, N, and P cycling (Goll et al., 2012; Nakhavali et al., 2022; Sun et al.,
610 2021; Wang et al., 2010, 2020b; Yang et al., 2014), P cycling was not active in the model
611 simulations in the GCP 2022. P limitation could be important for limiting terrestrial C
612 sequestration, especially in low-latitude forests (Elser et al., 2007; Terrer et al., 2019; Wieder et
613 al., 2015b). As more models incorporate coupled C-N-P cycling (Reed et al., 2015; Braghiere et
614 al., 2022), observation-based datasets of P will also be necessary for model evaluation.

615

616 **5 Conclusions**

617 Because the TRENDY-N ensemble overestimated both vegetation and soil C:N ratios, it
618 is possible that models could overestimate assimilated C per unit N and thus future terrestrial C
619 sequestration under CO₂ fertilisation. Alongside discrepancies in biological N fixation, this could
620 lead to biases in projections of the future terrestrial C sink by the TRENDY-N ensemble. Not to
621 mention there are several other terrestrial biosphere models in the TRENDY ensemble that do

622 not represent coupled C-N cycling. While the models are capable of reproducing the current
623 terrestrial C sink, the spread across the models in simulating N cycling suggests that C-N
624 interactions operate differently across models and may not be fully captured given that models
625 are calibrated to C cycling. However, these C-N interactions are critical for projecting the
626 terrestrial C sink under global change in the future.

627 **Code availability**

628 AMBER is available at <https://gitlab.com/cseiler/AMBER>.

629

630 **Data availability**

631 Biological N fixation, vegetation C:N ratio, and soil C:N ratio are available at
632 <https://gitlab.com/sian.kougiesbrecht/trendy-nitrogen>.

633

634 **Author contribution**

635 SKG designed and conducted the study and prepared the initial manuscript. VA and CS provided
636 feedback on the initial manuscript and its subsequent revisions. The other co-authors conducted
637 TRENDY simulations and provided feedback on the manuscript.

638

639 **Competing interests**

640 The authors declare that they have no conflict of interest.

641

642 **Acknowledgements**

643 The authors would like to thank T Davies-Barnard for compiling the observations used to
644 evaluate biological N fixation. ORCHIDEEv3 simulations were granted access to the HPC
645 resources of GENCI-TGCC under the allocation A0130106328.

646 **Appendix A**
