10 **Abstract.** The filtered radiances measured by the Clouds and the Earth's Radiant Energy System (CERES) instruments are converted to shortwave (SW), longwave (LW), and window unfiltered radiances based on regressions developed from theoretical radiative transfer simulations to relate filtered and unfiltered radiances. This paper describes an update to the existing Edition 4 CERES unfiltering algorithm (Loeb et al., 2001), incorporating the most recent developments in radiative transfer modeling, ancillary input datasets, and increased computational and storage capabilities during the past 20 years. Simulations are performed with the updated MODTRAN 5.4 version. Over land and snow, the surface Bidirectional Reflectance Distribution Function (BRDF) is characterized by a kernel-based representation in the simulations, instead of the Lambertian surface used in the Edition 4 unfiltering process. Radiance unfiltering is explicitly separated into 4 seasonally dependent land surface groups based on the spectral radiation similarities of different surface types (defined by International Geosphere-Biosphere Programme); over snow, it is separated into fresh snow, permanent snow, and sea ice. This differs from the Edition 4 unfiltering process where only one set of regressions was used for land and snow, respectively.

20 The instantaneous unfiltering errors are estimated with independent test cases generated from radiative transfer simulations in which the 'true' unfiltered radiances from radiative transfer simulations are compared with the unfiltered radiances calculated from the regressions. Overall, the relative errors are mostly within  $\pm 0.5\%$  for SW, within  $\pm 0.2\%$  for daytime LW, and within  $\pm 0.1\%$  for nighttime LW for both CERES Terra Flight Model 1 (FM1) and Aqua FM3 instruments. The unfiltered radiances are converted to fluxes and compared to CERES Edition 4 fluxes. The global mean instantaneous fluxes for Aqua FM3 are reduced by 0.34 to 0.45  $\text{Wm}^{-2}$  for SW and increased by 0.25 to 0.46  $\text{Wm}^{-2}$  for daytime LW; for Terra FM1, they are reduced by 0.24 to 0.34  $\text{Wm}^{-2}$  for SW and increased by 0.08 to 0.28  $\text{Wm}^{-2}$  for daytime LW. Nighttime LW flux differences are negligible for both instruments.

## 1 Introduction

30 The Clouds and the Earth's Radiant Energy System (CERES) instruments have been continuously monitoring the earth's radiation budget at the surface, within the atmosphere, and at the top-of-atmosphere since 2000 (Wielicki et al. 1996). Currently, there are six CERES instruments onboard four satellites observing the Earth: Flight Model 1 (FM1) and FM2 on the EOS Terra satellite since 1999, FM3 and FM4 on the Aqua satellite since 2002, FM5 on the Suomi National Polar-orbiting Partnership (NPP) satellite since 2011, and most recently, FM6 on the NOAA-20 satellite since 2017. CERES instruments measure radiances in shortwave (SW, 0.3 – 5  $\mu\text{m}$ ), window (WN, 8 – 12 $\mu\text{m}$ ) and total (TOT, 0.3 – 200  $\mu\text{m}$ ) channels for FM1-5 and SW, longwave (LW, 5 – 40  $\mu\text{m}$ ) and total channels for FM6. The reflected and emitted radiances from earth scenes enter the instrument aperture, pass through the optical systems and are recorded by the instrument detectors and electronics [Loeb et al. 2001]. However, the measured filtered radiances must be converted to unfiltered radiances which are equivalent to the radiances arriving at the instrument prior to entering its optical system. The unfiltered radiances can be further converted to fluxes with angular distribution models (ADMs, Su et al. 2015) for scientific research [e.g. Sherwood et al. 2018, Loeb et al. 2021].

40 The radiance unfiltering process in the CERES Edition 4 product uses theoretical radiative transfer simulations to construct regression relationships between filtered and unfiltered radiances [Loeb et al. 2001]. If the CERES spectral response functions were spectrally invariant or earth scenes are spectrally invariant from each other, one set of regression coefficients would be sufficient to convert filtered radiances to unfiltered radiances. However, the spectral response functions are not spectrally flat (Fig. 1) and the spectral distribution of reflected and emitted energy varies with earth targets (Fig. 2). The radiance unfiltering process must therefore be scene-type dependent. In the CERES Edition 4 radiance unfiltering process, regression coefficients were constructed for land, ocean, and snow/sea ice, and further separated into clear and cloudy cases.

50 A reliable relationship between filtered and unfiltered radiances preferably requires accurate spectral simulations covering a wide  
 55 unfiltering process. For radiative transfer modeling, MODTRAN 3.7 is replaced by MODTRAN 5.4 with HITRAN database  
 updates for atmospheric gas absorptions and incorporation of discrete-ordinate-method radiative transfer (DISORT, Stammes et al.,  
 1997) to calculate multiple scattering faster and with higher fidelity. Over land, the simulations in the Edition 4 radiance unfiltering  
 process used Lambertian surfaces for a limited number of surface types, which might not be a sufficient representation of the  
 various land surface types. Furthermore, one set of regression coefficients were developed and applied regardless of the spectral  
 differences among land surfaces. With the advancement of land surface albedo/BRDF observations from the Moderate Resolution  
 Imaging Spectroradiometer (MODIS), we can characterize the surface Bidirectional Reflectance Distribution Functions (BRDFs)  
 much better than the Lambertian representation in the model simulations. This allows us to identify spectral radiation characteristics  
 among various land surface types, both globally and temporally, upon which the unfiltering coefficients can be developed and  
 applied to more specific land surface types.

60 To further reduce unfiltered radiance uncertainties, we also use simulations that better match observations to develop the regression  
 coefficients. Over ocean, a better implementation of the Cox-Munk BRDF model [Cox and Munk 1954] is used. Over land, we  
 modify the BRDF kernel parameters from MODIS BRDF/albedo products to better capture the hot spot feature for vegetation  
 [Maignan et al., 2004]. Over snow/seaice, simulations that best match observations are used to develop the regression coefficients  
 for Greenland and Antarctica for permanent snow, seaice, and fresh snow, respectively. For overcast simulations, we replace the  
 65 built-in cloud properties in MODTRAN 5.4 with realistic ones.

In addition to the above improvements, we increase the number of solar zenith angle (SZA) and viewing zenith angle (VZA) bins,  
 at which to calculate the regression coefficients, to reduce the unfiltered radiance uncertainties. The number of SZA and VZA bins  
 are increased from 5 to 13 and 5 to 7, respectively; while the number of relative azimuth angle (RAZ) bins remains unchanged at  
 5 bins.

70 This paper is organized as follows. Section 2.1 describes the unfiltering algorithm, which is the same as that in Loeb et al. (2001).  
 Detailed radiative transfer simulations are described in section 2.2. Section 3 presents error analysis of the unfiltering process.  
 Section 4 presents applications of the updated radiance unfiltering process to CERES observed filtered radiances to obtain  
 unfiltered radiances, with which the fluxes are converted for the four seasonal months in 2010.

## 2 Methodology

### 75 2.1 Unfiltering algorithm

The reflected solar and emitted thermal radiances from Earth's surface and atmosphere pass through the optics of CERES  
 instruments. The filtered measurements must be converted to reflect the true reflected and emitted radiances prior to entering  
 CERES instruments. The algorithms were described in detail in Loeb et al. (2001); a brief description is given below.

80 The unfiltered reflected shortwave, emitted longwave and window radiances are defined as follows:

$$m_u^{SW} = \int_0^\infty I_\lambda^r d\lambda \quad (1a)$$

$$m_u^{LW} = \int_0^\infty I_\lambda^e d\lambda \quad (1b)$$

$$m_u^{WN} = \int_{\lambda_1}^{\lambda_2} I_\lambda^e d\lambda \quad (1c)$$

85 where  $\lambda$  is the wavelength,  $I_\lambda^r$  and  $I_\lambda^e$  ( $\text{Wm}^{-2}\text{sr}^{-1}\mu\text{m}^{-1}$ ) are the reflected solar and emitted thermal radiances,  $\lambda_1=8.1 \mu\text{m}$  and  $\lambda_2 =$   
 $11.8 \mu\text{m}$  define a wavelength interval within the thermal window range in CERES FM1-FM5. Given instrument spectral response  
 functions, CERES measured filtered radiances can be modeled as

$$m_f^j = \int_0^\infty S_\lambda^j I_\lambda d\lambda \quad (2)$$

90 where  $S_\lambda^j$  is the spectral response function,  $I_\lambda$  is the radiance incident on the instrument,  $j$  denotes the SW, TOT, or WN channel.

For CERES FM1-FM5, the relationships between filtered radiance and unfiltered radiance are constructed through regression as  
 follows:

$$m_u^{SW} = a_0 + a_1 m_f^{SWr} + a_2 (m_f^{SWr})^2 \quad (3a)$$

$$95 \quad m_u^{WN} = b_0 + b_1 m_f^{WN} + b_2 (m_f^{WN})^2 \quad (3b)$$

$$m_u^{LW}(DAY) = c_0 + c_1 m_f^{SWr} + c_2 m_f^{TOT} + c_3 m_f^{WN} \quad (3c)$$

$$m_u^{LW}(NIGHT) = d_0 + d_1 m_f^{TOT} + d_2 m_f^{WN} \quad (3d)$$

100 For FM6, the window channel is replaced by a LW channel, and the unfiltered LW radiances can be determined by  $m_f^{SWr}$  and  $m_f^{TOT}$  during daytime, and  $m_f^{TOT}$  at night:

$$m_u^{LW_{SW_{TOT}}}(DAY) = e_0 + e_1 m_f^{SWr} + e_2 m_f^{TOT} \quad (3e)$$

$$m_u^{LW_{SW_{TOT}}}(NIGHT) = f_0 + f_1 m_f^{TOT} \quad (3f)$$

The unfiltered LW radiances can also be determined directly from  $m_f^{LW}$ :

$$105 \quad m_u^{LW_{LW}} = g_0 + g_1 m_f^{LW} + g_2 (m_f^{LW})^2 \quad (3g)$$

In Equations (3a)-(3g),  $a_0, a_1, a_2, b_0, b_1, b_2, c_0, c_1, c_2, c_3, d_0, d_1, d_2, e_0, e_1, e_2, e_3, f_0, f_1, f_2, g_0, g_1,$  and  $g_2$  are theoretically derived regression coefficients.  $m_f^{SWr}$  is the reflected portion of the filtered SW radiance and it is determined by removing the emitted thermal portion  $m_f^{SWe}$  from  $m_f^{SW}$ :

$$110 \quad m_f^{SWr} = m_f^{SW} - m_f^{SWe} \quad (4)$$

For FM1-FM5,  $m_f^{SWe}$  is determined by a relationship between measured  $m_f^{SW}$  and  $m_f^{WN}$  at night:

$$m_f^{SWe} = h_0 + h_1 m_f^{WN} + h_2 (m_f^{WN})^2 \quad (5a)$$

115 For FM6,  $m_f^{SWe}$  is determined by a relationship between measured  $m_f^{SW}$  and  $m_f^{LW}$  at night:

$$m_f^{SWe} = k_0 + k_1 m_f^{LW} + k_2 (m_f^{LW})^2 \quad (5b)$$

It is useful to emphasize the definitions of the unfiltered SW and LW radiances; in the remainder of the paper, the unfiltered SW radiances are the reflected radiances and the unfiltered LW radiances are the thermal emitted radiances.

## 120 2.2 Spectral radiance simulations

### 2.2.1 Radiative transfer model

The regression coefficients used to convert CERES observed filtered radiances to unfiltered radiances are developed from radiative transfer simulations over typical earth scenes. We use MODTRAN 5.4 [Berk et al., 2016] for the radiative transfer simulations, replacing MODTRAN 3.7 in the Edition 4 unfiltering process. A few major improvements in MODTRAN 5.4 as compared to  
125 MODTRAN 3.7 include, but are not limited to [Berk 2004, Berk 2016]:

- (1) MODTRAN 5.4 is based on HITRAN 2012 [Rothman, et al., 2013], while MODTRAN 3.7 is based on HITRAN 1992 [Rothman, et al., 1992],
- (2) MODTRAN 5.4 uses correlated-k algorithm, which significantly improves the accuracy of multiple scattering calculations [Berk et al., 1998],
- 130 (3) MODTRAN 5.4 allows finer spectral resolution simulations,
- (4) MODTRAN 5.4 fully treats the auxiliary molecular species, and
- (5) MODTRAN 5.4 calculates multiple scattering faster and with higher fidelity with an improved incorporation of discrete-ordinate-method radiative transfer (DISORT, Stamnes et al., 1997) into MODTRAN 5.4.

135 The simulations are performed for clear and overcast conditions, and radiances for broken clouds are linearly weighted with clear-sky and overcast radiances for cloud fractions of 0.25, 0.50 and 0.75. Simulations are performed from 0 to 40000 wavenumbers per cm (0.25  $\mu\text{m}$  to 1000  $\mu\text{m}$ ) with a spectral resolution of 2 wavenumbers per cm.

### 2.2.2 Resolution in the number of angular bins

140 In the Edition 4 unfiltering process, regression coefficients are evaluated at 5 SZA bins, 5 VZA bins and 5 RAZ bins. The number of SZA bins is increased from 5 to 13, the number of VZA bins is increased from 5 to 7 to minimize the radiance unfiltering uncertainties, and the number of RAZ bins remains the same at 5 bins as in the Edition 4 unfiltering process. The detailed analysis will be shown in section 3. Table 1 shows the SZAs, VZAs, and RAZs at which the radiance unfiltering coefficients are determined

for SW, daytime LW and WN radiances. For nighttime LW and WN radiances, the unfiltering regression coefficients are evaluated at VZA bins only.

### 145 2.2.3 Clear-sky simulations over ocean

Over ocean, the surface is characterized by the Cox-Munk model [Cox and Munk, 1954] in the radiative transfer model simulations. The implementation of Takashima (1985) in MODTRAN 3.7 simulations for the Edition 4 CERES radiance unfiltering is replaced by the Second Simulations of the Satellite Signal in the Solar Spectrum (6S) radiative transfer code [Vermeote et al., 1997], which includes the radiance contributions from ocean whitecaps and underwater in addition to the specular reflections from the ocean surface. Figure 3 shows that the simulation by the 6S radiative transfer code characterizes the ocean surface radiances better than that of Takashima, particularly for VZAs greater than 50°.

The radiative transfer simulations over clear-sky ocean use the same atmospheric and surface temperature conditions as that in the Edition 4 (Table 2). For each solar-viewing angular bin, 7 simulations are used to calculate coefficients over clear-sky ocean.

### 2.2.4 Clear-sky simulations over land

155 The radiance unfiltering process is highly scene-dependent, and therefore, it is critical to identify and classify the scene types. In the CERES Edition 4 radiance unfiltering process, regression coefficients were constructed for land, ocean, and snow/sea ice, and further separated into clear and cloudy cases. Particularly, over land, Edition 4 used simulations for 6 land surface types, namely desert, dry sand, vegetation, coniferous forest, forest conifer species, and dry meadows grass (Table 4 in Loeb et al, 2001), from which one set of coefficients was developed for each sun-viewing angular bin regardless of land surface types.

160 During the last 20 years, we have gained better observations of land surfaces. One of the observations is MODIS derived land surface albedo/BRDF products. It is based on the semiempirical reciprocal RossThick-LiSparse model [Li and Strahler, 1992; Lucht et al., 2000]. The BRDF at the surface can be modeled as a linear combination of three terms:

$$\rho(\theta_0, \theta, \phi) = f_{iso} + f_{vol}K_{vol}(\theta_0, \theta, \phi) + f_{geo}K_{geo}(\theta_0, \theta, \phi) \quad (6)$$

165 where the first term on the right-hand side of the equation is the isotropic scattering contribution,  $K_{vol}$  in the second term is the RossThick kernel to characterize volumetric scattering from horizontally homogeneous leaf canopies, and  $K_{geo}$  in the third term is the LiSparse kernel to characterize geometrical-optical surface scattering from three-dimensional objects. The kernel fitting parameters  $f_{iso}$ ,  $f_{vol}$ , and  $f_{geo}$  were derived from atmospherically corrected, multi-angular land surface BRDFs. The derived kernel parameters are available at the 7 MODIS spectral bands (0.47  $\mu\text{m}$ , 0.55  $\mu\text{m}$ , 0.65  $\mu\text{m}$ , 0.86  $\mu\text{m}$ , 1.2  $\mu\text{m}$ , 1.6  $\mu\text{m}$ , and 2.1  $\mu\text{m}$ ) over a 16-day cycle over land. Validation efforts have shown that the MODIS albedo/BRDF retrievals are in good agreement with field measurements, typically within 10% [Liang et al., 2002, Jin et al., 2003a, 2003b; Wang et al., 2004].

175 With the MODIS derived kernel fitting parameters  $f_{iso}$ ,  $f_{vol}$ , and  $f_{geo}$  from albedo/BRDF products for the 7 MODIS bands, we are able to estimate the spectral fitting parameters, which are used to calculate the spectral radiation. The determination of the fitting parameters at other wavelengths across the SW and LW range is described as follows:

(1) at wavelengths between 0.47  $\mu\text{m}$  and 2.1  $\mu\text{m}$ , calculate the fitting parameters with all 7 band parameters by the spline interpolation.

(2) at wavelengths below 0.47  $\mu\text{m}$ , the fitting parameter  $f_\lambda$  is calculated based on the fitting parameters at 0.47  $\mu\text{m}$  ( $f_{0.47}$ ) and 0.55  $\mu\text{m}$  ( $f_{0.55}$ ), respectively, along with the spectral reflectances in JPL surface spectral reflectances. Equation 7 shows that one fitting parameter at  $\lambda$  is estimated from  $f_{0.47}$  by scaling it with  $R_\lambda$  and  $R_{0.47}$ , which are the JPL surface spectral reflectances at  $\lambda$  and 0.47  $\mu\text{m}$ , respectively. Equation 8 shows that another one is estimated from  $f_{0.55}$  scaled with  $R_\lambda$  and  $R_{0.55}$ :

$$f_{0.47}^{est} = f_{0.47} \frac{R_\lambda}{R_{0.47}} \quad \text{and} \quad (7)$$

$$f_{0.55}^{est} = f_{0.55} \frac{R_\lambda}{R_{0.55}} \quad (8)$$

185 The fitting parameter at  $\lambda$  is then calculated as:

$$f_\lambda = f_{0.47}^{est} \frac{(\lambda - 0.55 \mu\text{m})^2}{(\lambda - 0.47 \mu\text{m})^2 + (\lambda - 0.55 \mu\text{m})^2} + f_{0.55}^{est} \frac{(\lambda - 0.47 \mu\text{m})^2}{(\lambda - 0.47 \mu\text{m})^2 + (\lambda - 0.55 \mu\text{m})^2}, \quad (9)$$

that is, we put more weights on  $f_{0.47}^{est}$  than  $f_{0.55}^{est}$ .

- (3) the same approach is used to calculate the fitting parameters at wavelengths above 2.11  $\mu\text{m}$  based on the fitting parameters at the 1.6  $\mu\text{m}$  and 2.1  $\mu\text{m}$  channels.

190

Figure 4 shows an example comparing SW reflected radiance simulations to CERES observed SW radiances for evergreen needleleaf forest. It clearly shows that the simulations with MODIS derived surface BRDF angularly match observations far better than the simulations with a Lambertian surface. However, the simulations based on MODIS derived surface BRDF still underestimate BRFs around the hot spot angles for vegetated surfaces, where the VZA is equal to the SZA in the backward direction.

195

Based on the RossThick-LiSparse model, Maignan et al. (2004) modified  $K_{geo}$ , the geometrical scattering kernel, to highlight the hot spot feature for vegetated surfaces. In the simulations for this version of the radiance unfiltering process, we replaced  $K_{geo}$  for RossThick-LiSparse model with that defined in Maignan et al. (2004). The calculation of new fitting parameters  $f_{iso}$ ,  $f_{vol}$ , and  $f_{geo}$  is described as follows:

200

(1) calculate BRFs at various sun-viewing angles with the MODIS retrieved fitting parameters for the 7 MODIS spectral bands. The calculations are performed with a bin width of  $10^\circ$  for SZA, VZA, and RAZ.

(2) with the calculated BRFs in (1), calculate the fitting parameters based on the model described in Maignan et al. (2004) to highlight the hot spot feature of vegetations. The same model is also implemented in MODTRAN 5.4 to simulate the land surface reflectance.

205

Figure 4 shows that the simulations with the modified  $K_{geo}$  capture the sharp increases of BRFs around the hot spot angles better than the simulations based on the original RossThick-LiSparse model.

210

More importantly, based on the spectral simulations with the MODIS derived kernel fitting parameters, we can identify the radiation spectral characteristics across various land surface types. Figure 5 shows simulations for the 16 land surface types defined by International Geosphere-Biosphere Programme (IGBP, Table 3) in January. It suggests that the differences in the spectral radiances among different surface types should be considered in the radiance unfiltering process. With a K-means clustering approach, the 16 simulations can be classified into 4 groups in January based on their radiance spectral similarities. We also found that the grouping is different for other seasons (April, July, and October) as compared to January (Table 4). Furthermore, although Fig. 6a indicates that the spectral shapes of evergreen broadleaf forest (IGBP 02) are similar in all four seasons, the spectral shapes of deciduous needleleaf forest (IGBP 03, Fig. 6b) are not, suggesting that we also might need to consider the seasonal variations. To verify the seasonal sensitivity, Figure 7 shows that the clear-sky SW and daytime LW fluxes over land are substantially different when radiances are unfiltered by using unfiltering coefficients developed for January versus those developed for July.

215

220

In a summary, the radiative transfer simulations over land are performed for each IGBP land surface type based on the 10-year averaged RossThick-LiSparse model fitting parameters from collection 6 MODIS derived albedo/BRDF products MCD43C1 [Strahler, 1999; Gao et al., 2005]. The unfiltering regression coefficients for land are constructed for 4 surface groups in each of the 4 seasons (winter, spring, summer and fall, respectively). The surface temperatures are prescribed using the median values of a 5-year surface temperature climatology for each IGBP type as calculated from the Goddard Earth Observing System reanalysis (Rienecker et al., 2008), version 5.4.1, included in the Edition 4 CERES Single Satellite Footprint TOA/Surface Fluxes and Clouds (SSF) product data. Depending on the location of a surface type, either a standard, midlatitude summer/winter, or subarctic summer/winter atmospheric profile is used. Dust aerosol is used over the bare soil and rocks (IGBP type 16) and open shrublands (IGBP type 7). Rural aerosol is used over other IGBP types. Depending on the surface types, the aerosol optical depths (AODs) use 5, 25, 50, 75 and 95 percentiles of a 5-year AOD climatology from AOD retrieved by MODIS (collection 5.1), also included in the CERES SSF product. Simulations are also separated for daytime and nighttime with different surface temperature to account for diurnal temperature variations. For each land surface type, there are 8 to 10 clear-sky cases for each sun-viewing geometry.

225

230

### 2.2.5 Simulations over snow

235

It is still a challenge to simulate radiation from snow/ice surfaces. In the Edition 4 CERES radiance unfiltering process, the simulations over snow surfaces were characterized by the Warren-Wiscombe model [Wiscombe and Warren, 1980]. Compared to CERES observations (Fig. 8), the simulations with the Warren-Wiscombe snow model overestimate BRF for smaller VZAs and underestimate for larger VZAs, whereas the simulations with the RossThick-LiSparse model are better although they are still unable to match observations at larger VZAs. The unfiltering regression coefficients are developed separately for permanent snow, fresh snow, and sea ice, which contrasts to that in the Edition 4 where one set of regression coefficients is used for snow and sea ice. We select the best simulations to match the observations in terms of BRF angular variations in the solar plane to develop regression coefficients to reduce the unfiltered radiance uncertainties as much as possible. The CERES clear-sky observations are compared to simulations based on 10-year of MODIS retrieved BRDF fitting parameters for Greenland and Antarctica using averages in April, July, October, and December, and all months. From these 10 simulation candidates, the SW regression coefficients are constructed from two simulations that best match and envelop observed radiances for each snow/sea ice surface. For example, the regression coefficients over Greenland are calculated by using simulations based on MODIS BRDF fitting

240

parameters averaged over all months for Greenland and Antarctica; the regression coefficients over fresh snow are calculated by using simulations based on MODIS BRDF fitting parameter averages over Greenland in October and over Antarctica in April. Median values of surface temperature from a 5-year climatology for each snow/sea ice surface are used in the simulations for SW radiance unfiltering. Also from these 10 simulation candidates, the LW and WN regression coefficients are constructed from a simulation that best matches observations along with 3 surface temperatures which are the 25<sup>th</sup>, 50<sup>th</sup>, and 75<sup>th</sup> percentile values of a 5-year climatology for each snow/sea ice surface. Tropospheric aerosols are used with a visibility of 300 km and the subarctic winter atmospheric profile is used.

## 2.2.6 Simulations for overcast conditions

In the Edition 4 radiance unfiltering process, simulations for overcast conditions were performed with built-in cloud optical single scattering properties in MODTRAN 5.4, such as asymmetry factors, scattering coefficients and single scattering albedos. We update them with more realistic cloud optical single scattering properties to better match the observed radiances. For water clouds, the single scattering properties, including phase functions, are based on the Mie scattering calculations; for ice clouds, a two-habit ice cloud model is used [Liu et al., 2016, Loeb et al., 2018]. The same models are used in other CERES products, such as cloud property retrievals. A detailed comparison of various ice models can be found in Loeb et al. (2018). For the number of streams for DISORT, an examination of simulated radiances showed that 8 streams for water clouds and 16 streams for ice clouds are sufficient. The overcast properties used in radiative transfer simulations over ocean, land and snow are shown in Table 5.

The simulations of deep convective clouds are also included to construct the LW regression coefficients over ocean and land. The conditions used in the deep convective cloud simulation are shown in Table 6.

## 2.2.7 Summary of constructed coefficients

To briefly summarize, the regression coefficients are calculated for 13 SZAs, 6 VZAs, and 5 RAZs for SW and daytime LW, and 6 VZAs for nighttime LW for each scene type. Scene type is determined by ocean, land (separated into 4 groups in each of the seasons: spring, summer, fall, and winter) and snow/sea ice (separated into permanent snow over Greenland and Antarctica, fresh snow, and sea ice). Over ocean and land, the coefficients for SW radiance unfiltering are derived separately for clear and cloudy conditions; over snow and sea ice, clear and cloudy scenes use the same coefficients. For LW and WN radiance unfiltering, one set of coefficients is used regardless of cloud coverage conditions. The coefficients derived from both clear and cloudy conditions are used if a scene lacks information of cloud coverage during the application.

## 3 Error analysis

The instantaneous errors in the unfiltered radiance are estimated by the same approach used in Loeb et al. (2001). A set of simulations (described in the following sub-sections) that differ from those used to construct the regression coefficients is generated, and it is assumed that they represent the true unfiltered radiances. The simulated radiances are convolved with CERES spectral response functions to obtain filtered radiances. The unfiltering regression coefficients are then applied to the filtered radiances to get unfiltered radiances to compare to the “true” simulated radiances. In the following discussion, without explicitly stating, the errors are evaluated at 9 SZAs, 6 VZAs and 5 RAZs (Table 7) in daytime and 6 VZAs and 5 RAZs at nighttime. The error analysis presented is based on CERES Terra FM1. The error analysis for Aqua FM3 can be found in the supplemental figures (Fig. S1-S8). Given that the errors for unfiltered WN radiances are negligible, only the errors for SW and LW radiances are presented. The unfiltered radiance errors for NPP FM5 and NOAA20 FM6 are available upon request.

### 3.1 Resolution in the number of angular bins

In the Edition 4 radiance unfiltering process, the regression coefficients were evaluated at 5 SZAs, 5 VZAs, and 5 RAZs. The SZAs are 0°, 41.4°, 60.0°, 75.5°, and 85.0°. To evaluate if the 5 SZAs are sufficient, we use clear-sky simulations with the same conditions to generate the regression coefficients but at different SZAs: 29°, 51.3°, 68°, and 80.3°. Figure 9 checks if the unfiltered radiance errors at the testing SZAs is comparable to the regression errors for SZAs at 0°, 41.4°, 60.0°, 75.5°, and 85.0°. The larger errors in the test cases suggest that the number of SZAs used in Edition 4 is insufficient. In this work, we increase the number of SZAs from 5 to 13 (Table 1). Same approach is used and shows that further increasing the number of SZAs is unnecessary.

With respect to the number of VZAs, we evaluate the unfiltering radiance errors for clear-sky conditions over ocean as the radiances are sensitive to viewing angles. Figure 10a estimates the errors in the solar plane as a function of VZA at two SZAs (16.6° and 41.4°) based on the regression coefficients evaluated at 6 VZA bins (0°, 30°, 45°, 60°, 70°, and 90°). It shows that the errors can be quite large for some VZAs. Taking the errors for SZA of 16.6° as an example, the magnitude of errors are 1.0% with a wind speed of 5 m/s and 1.7% with a wind speed of 12 m/s around VZA of 10° in the backward directions. To mitigate these errors, we

add a VZA of 15° when developing regression coefficients. Figure 10b shows that the errors are dramatically reduced, but the magnitude of the errors can still be greater than 1.0%. This will be addressed in the future by adding more VZA bins when developing regression coefficients. With respect to the number of RAZs, we verify that 5 RAZs are sufficient.

### 295 3.2 Errors due to wind speed over ocean

As mentioned in Section 2, the regression coefficients for ocean are generated by using radiative transfer simulations with a wind speed of 5 m/s and applied to oceanic scenes regardless of wind speed. Figure 11 shows that the SW unfiltered radiance errors for clear-sky scenes with wind speeds of 2 m/s and 12 m/s are comparable to the errors of the regression coefficients built with the wind speed of 5 m/s. Figure 10b further estimates the errors in the solar plane as a function of VZA at two SZAs (16.6° and 41.4°). It shows that for these cases, the magnitude of errors can be close to 1.2% with a wind speed of 2 m/s.

### 3.3 Errors due to aerosols for clear-sky scenes

Over ocean, maritime aerosols are used in radiative transfer simulations to generate regression coefficients (Table 2). We applied these regression coefficients to simulations with different aerosols for clear sky over ocean. Figure 12 shows the SW unfiltered radiance errors for dust and urban aerosols, and urban aerosol with larger AOD. Compared to the PDF of SW unfiltered radiance errors for scenes with maritime aerosols, the error PDFs for other aerosols are broader, and the PDF modes for dust and urban aerosols are shifted to negative and positive values, respectively. The mean biases are within  $\pm 0.35\%$  and RMS errors are below 0.47%. Over land, Fig. 13 shows the SW unfiltered radiance errors for scenes with larger AOD aerosols (varying from 0.5 to 2.0 depending on surface type, representing the 99th percentile in AOD climatology for each type) are larger than the scenes used to construct regression coefficients for land. As expected, the magnitude of errors become larger. The mean biases are within  $\pm 0.14\%$  and RMS errors are below 0.20%. Overall, errors due to aerosols for most scenes are within  $\pm 0.5\%$ .

### 3.4 Errors due to scene identification

The CERES radiance unfiltering process is scene-type dependent. Due to cloud mask uncertainties, a clear-sky scene may be mistakenly identified as a cloudy scene, and vice versa. Therefore, an actual clear-sky scene may use regression coefficients for cloudy scenes, and a cloudy scene may use regression coefficients for clear-sky scenes. Taking the simulations to derive the unfiltering regression coefficients of clear-sky scenes over ocean and land in July, Fig. 14 shows that the PDF of SW unfiltered radiance errors for clear-sky scenes unfiltered using the regression coefficients derived from cloudy scenes is wider than that based upon regression coefficients for clear-sky scenes. Overall, the errors are within  $\pm 0.5\%$ . Alternatively, an overcast scene with thin clouds or a broken cloudy scene might be identified as a clear-sky scene. Taking the simulations to derive regression coefficients for cloudy scenes over ocean and land in July, Fig. 15 compares PDFs of SW unfiltered radiance errors for overcast scenes of cirrus with a cloud optical depth (COD) of 2 unfiltered using the regression coefficients derived from clear-sky scenes and cloudy sky scenes. As expected, the errors for scenes become larger if its corresponding regression coefficients are not used. Most scenes are still within  $\pm 0.5\%$ , although the absolute errors can be as large as 1.0%. Figure 16 also compares PDFs of radiance errors for broken cloudy scenes with a cloud fraction of 10% unfiltered using the regression coefficients derived from clear-sky scenes. It shows that the PDFs of radiance errors are comparable with the mean errors near zero and RMS errors are less than 0.18%.

As discussed in Section 2, the regression coefficients over land are developed for 4 land surface groups (defined by IGBP types with similar SW spectral shapes) for each of the 4 seasons (Fig. 5 and Table 4). Here we further evaluate the SW unfiltered radiance errors for each land surface group unfiltered using the regression coefficients derived from a different land surface group. For example, Fig. 17a shows that the SW unfiltered radiance errors in January for Group 1, which contains land IGBP surface types 01, 02, 04, 05, 08, 12, and 14, caused by using the regression coefficients derived from all 4 groups. As expected, the smallest errors are found when the regression coefficients derived from its group are used. Particularly, the errors for Group 4, which contains IGBP surface type 16, can be up to 2.6% when the regression coefficients derived from other groups are used. Therefore, it is important to differentiate land surface types when developing the regression coefficients. Figure 18 provides strong evidence that the fluxes change substantially when the regression coefficients developed for a specific group are applied indiscriminately to all land surface types. Consistent with Fig. 17, the largest errors are found over desert regions if the unfiltering coefficients for Group 4 (bare soil and rocks: IGBP surface type 16) are not used (Figs. 18a-18c), but the errors are substantially larger for other regions if the unfiltering coefficients for Group 4 are used (Fig. 18d).

### 3.5 Errors for cloudy scenes

Four cloud properties over land and ocean are used in radiative transfer simulations of overcast scenes to derive regression coefficients for cloudy scenes (Table 5). One of the simulations represents stratus overcast scenes with a COD of 5.6. Simulations with the same conditions but using a different COD of 38 are used to evaluate the SW unfiltered radiance errors. Another simulation represents cirrus overcast scenes with a COD of 4. Simulations with the same conditions but with a COD of 1 are used to evaluate

345 the errors. Figure 19 shows that the errors for stratus are similar; while the error PDF for cirrus with COD of 1 are broader than that with a COD of 4, but the errors are still within 0.5%.

### 3.6 Errors due to surface and cloud top temperatures

350 As mentioned in Section 2, to derive regression coefficients for LW, the surface temperatures varying from 280 to 320 K over ocean are used in simulations; over land, the median values of surface temperature in a 5-year climatologies are used; and over snow/sea ice, the 25<sup>th</sup>, 50<sup>th</sup>, and 75<sup>th</sup> percentile of the surface temperatures are used. For clear-sky conditions, we use simulations with the minimum and maximum surface temperatures from climatologies, keeping all other conditions the same to evaluate the unfiltered LW radiance error. For overcast conditions, the unfiltered radiance errors are evaluated from simulations with clouds placed at different altitudes (Table 8) as compared to that used to generate the regression coefficients (Table 5). Both tests show that the errors are within 0.1%.

## 4 Impact of unfiltering algorithm on instantaneous fluxes

355 The newly updated regression coefficients are applied to the filtered radiances to obtain the unfiltered SW, LW and WN radiances of CERES Terra FM1 and Aqua FM3 instruments. With CERES Edition 4 ADMs (Su et al. 2015), the unfiltered radiances are converted to corresponding instantaneous fluxes. Figures 20 to 24 show the SW, daytime and nighttime LW flux differences between the newly calculated fluxes and the CERES Edition 4 fluxes for Aqua FM3 in January, April, July, and October in 2010 (the corresponding analyses for Terra FM1 are shown in Fig. S9 to S13).

360 For SW fluxes (Figs. 20 and 21) over ocean, the difference pattern correlates with the cloud coverage distribution. Negative value regions covered with high clouds can be associated with the changes in the cloud microphysical properties used in MODTRAN simulations (Section 2.2.6), while the new implementation of the Cox-Munk ocean model has less of an impact on clear-sky conditions over ocean. Over land, SW flux differences are geographically dependent, as expected, which further justifies the development of a surface type dependent unfiltering process. The SW flux differences vary seasonally, supporting the need for seasonal stratification in the unfiltering process. The fluxes decrease in January and increase in July over desert regions, while the flux changes over vegetation covered regions are relatively small. In January and April over the middle to high latitudes in the north hemisphere, the large negative values are associated with surfaces covered by fresh snow. In all months, positive values are found over permanent snow and sea ice (except sea ice in April). Both should be due to the changes in snow/ice model in the simulations (Section 2.2.5). Given that the new simulations over snow or sea ice are better than that used in Edition 4 (Section 2.2.5), we believe that the new process should be more realistic, even though the simulations over snow or sea ice are still far from closely matching the observations (Fig. 8). Quantitatively, the SW global mean instantaneous fluxes for Aqua FM3 are reduced by 0.34 to 0.45 Wm<sup>-2</sup>, and there are 4.0%, 0.9%, 0.4%, 2.5% of 1°×1° grids in January, April, July, and October in 2010, respectively, that have differences with a magnitude greater than 2.0 W/m<sup>2</sup>. In terms of the relative differences, the fluxes are reduced by 0.06% to 0.20%. For Terra FM1 (Figs. S9 and S10), the global mean instantaneous flux is reduced by 0.24 to 0.34 Wm<sup>-2</sup> with the differences showing similar regional patterns as Aqua FM3 but with smaller magnitudes.

375 The daytime LW flux differences also show regional dependences (Figs. 22 and 23). The locations of positive LW flux differences correspond to locations of negative SW flux differences and vice versa. Given that the nighttime LW flux differences (Fig. 24) are nearly negligible (with a ~ 0 W/m<sup>2</sup> global mean and less than 0.04 W/m<sup>2</sup> root mean square error), the correlations are largely due to the subtraction of the SW component from the TOT radiances. In other words, the daytime LW radiance unfiltering is critically related to the performance of the SW radiance unfiltering process. Quantitatively, the global mean instantaneous fluxes are increased by 0.25 to 0.46 Wm<sup>-2</sup> for Aqua FM3, and there are 0.2%, 1.5%, 0.5%, and 0.8% of 1°×1° grids in January, April, July, and October in 2010, respectively, that have differences with a magnitude greater than 2.0 W/m<sup>2</sup>. In terms of the relative differences, the fluxes are increased by 0.03% to 0.11%. For Terra-FM1, the global mean fluxes are increased by 0.08 to 0.28 Wm<sup>-2</sup> (Figs. S11 and S12).

## 5 Summary

390 CERES instruments measure filtered reflected solar and emitted thermal infrared radiances from the earth-atmosphere system. For use in science applications, the filtered radiances must be converted to unfiltered radiances, which are equivalent to the radiances arriving at the instrument prior to entering its optical system. The unfiltered radiances are then converted to radiative fluxes for scientific research. This paper describes an update to the existing Edition 4 CERES unfiltering algorithm (Loeb et al., 2001) by incorporating the most recent developments in radiative transfer modeling, ancillary input datasets, and increased computational and storage capabilities during the past 20 years. A few of the improvements in the new version are:

- 395 (1) Simulations are performed with MODTRAN 5.4 with many updates as compared to MODTRAN 3.7, such as a newer HITRAN dataset, adopting the correlated-K algorithm to calculate absorptions, allowing finer spectral resolution, and with an improved incorporation of DISORT to calculate multiple scattering radiations [Berk 2004, 2016].
- (2) Over ocean, the implementation of the Cox-Munk BRDF model in the 6S radiative transfer code replaces the implementation in Takashima (1985) used in simulations for the Edition 4 radiance unfiltering process. The newer version matches the CERES observed angular variation of the SW radiances better.
- 400 (3) For simulations over land and snow, surface BRDFs are characterized by MODIS retrieved RossThick-LiSparse kernel-based BRDF model fitting parameters for each IGBP surface type, instead of the Lambertian surface used in simulations for the Edition 4 CERES radiance process. The hot spot features for vegetation are further modeled by using the approach described in Maignan et al. [2004].
- (4) Over land, unfiltering regression coefficients are derived separately into 4 surface groups to characterize spectral differences among different surface types. The regression coefficients are also separated into 4 seasons to characterize the seasonal variation of the surfaces.
- 405 (5) The regression coefficients are calculated at more SZA bins, increased to 13 from 5 in SZA as used in the Edition 4, to reduce the unfiltered radiance errors.
- (6) Climatological surface temperatures from Goddard Earth Observing System reanalysis were used in simulations over land, snow, and sea ice. Climatological AODs derived from MODIS over land are also used in the simulations.
- 410

Instantaneous unfiltered radiance errors were estimated using radiative transfer simulations. The simulated filtered radiances are converted to unfiltered radiances and compared to the simulated unfiltered radiances. Overall, the instantaneous relative errors are mostly within  $\pm 0.5\%$  for SW radiances, within  $\pm 0.2\%$  for daytime LW radiances, and negligible for nighttime LW and WN radiances. However, the errors are larger for some extreme cases, such as very large AODs for clear-sky, miss-classified cloudy or clear-sky scenes, and for scenes with radiances that are very sensitive to the sun-viewing geometry.

415

The unfiltered radiances with the newly updated unfiltering regression coefficients are converted to fluxes and compared to fluxes in Edition 4. The global mean instantaneous fluxes for Aqua FM3 are reduced by 0.34 to 0.45  $\text{Wm}^{-2}$  for SW and are increased by 0.25 to 0.46  $\text{Wm}^{-2}$  for daytime LW; while for Terra FM1, the global mean instantaneous fluxes are reduced by 0.24 to 0.34  $\text{Wm}^{-2}$  for SW and increased by 0.08 to 0.28  $\text{Wm}^{-2}$  for daytime LW, though the regional differences can be greater than 2.0  $\text{Wm}^{-2}$ . For nighttime LW fluxes, the differences are negligible for both instruments.

420

The instantaneous unfiltered radiance errors for CERES NPP FM5 and NOAA20 FM6 are similar to those of Terra FM1 and Aqua FM3 (not shown). As for the regional distribution of flux differences, NOAA20 FM6 is similar to Terra FM1 and Aqua FM3, but with a smaller magnitude of differences. However, while the regional SW fluxes are mostly reduced (Figs. 20 and 21) and daytime LW fluxes are increased (Figs. 22 and 23) for Aqua FM3, the regional SW fluxes are mostly increased and daytime LW fluxes are decreased for NPP FM5, both to a lesser degree than Terra FM1 or Aqua FM3 (Figs. S13 and 14). Further investigations are needed as how the spectral response functions impact the unfiltering process to answer these changes.

425

#### 430 **Author contribution:**

NL initialized and implemented the previous edition of unfiltering algorithm. LL and WS designed the algorithm improvements with contributions from SS and ZE. LL carried model simulations and implemented algorithm. LL, WS, SS, and ZE conducted analysis and prepared the manuscript. All authors contributed to the reviewing of the manuscript.

435

Figure 17. SW unfiltered radiance errors for land surface (a) Group 1, (b) Group 2, (c) Group 3, and (d) Group 4 unfiltered using regression coefficients derived from all 4 land surface types, respectively, for CERES Terra FM1 in January. In January, Group 1 contains land surface IGBP types 01, 02, 04, 05, 08, 12, and 14, Group 2 contains land IGBP surface types 03, 11, and 13, Group 3 contains land IGBP surface types 06, 07, 09, 10, and 18, and Group 4 contains land IGBP surface type 16.

Figure 18. Clear-sky land SW Flux differences between fluxes retrieved from the unfiltered radiances by using the unfiltering coefficients developed for (a) Group 1, (b) Group 2, (c) Group 3, and (d) Group 4, respectively, and that by using corresponding coefficients for each land surface type. Figures show the results for Aqua FM3 in January, 2010.

720

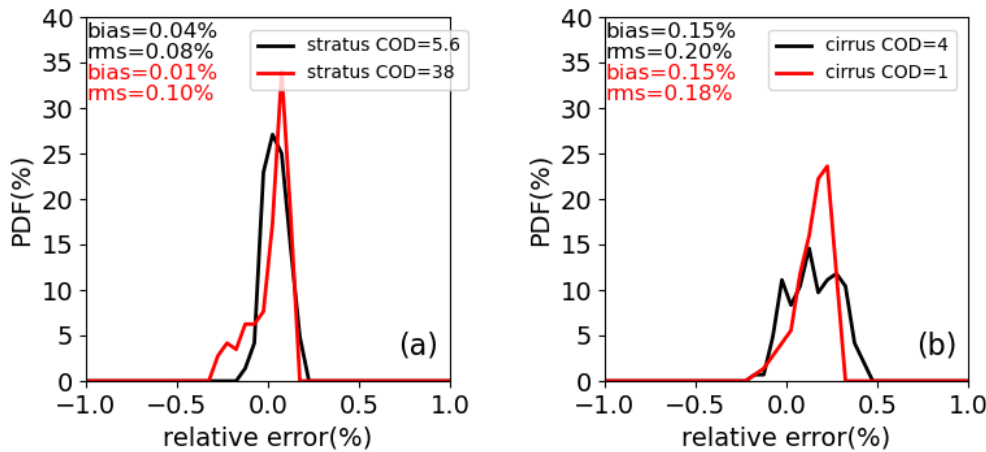

Figure 19. (a) SW unfiltered radiance errors for CERES Terra FM1 in cloudy sky scenes covered by stratus with COD of 38 as compared to that covered by stratus with COD of 5.6 unfiltered using regression coefficients derived from cloudy sky scenes over ocean. (b) Same as (a) but for comparing the errors for cirrus clouds with CODs of 1 and 4.
