10

11 **Abstract**

12 Winter fog and severe aerosol loading in the boundary layer over north India, especially in the Indo-
13 Gangetic Plain (IGP), cause disruption in the daily lives of millions of people in the region. To
14 understand better the role of atmospheric aerosols on the occurrence, spatial extent, and persistence of
15 winter fog in the IGP, several model simulations have been performed using the Weather Research and
16 Forecasting model coupled with chemistry (WRF-Chem). Results from WRF-Chem represented relative
17 humidity (RH) and fog formation in agreement with observations when using the ERA-Interim
18 reanalysis data as meteorological initial/boundary conditions and soil nudging were applied. WRF-
19 Chem successfully simulates the spatial distribution and magnitude of PM_{2.5} when evaluated with
20 observations from the Central Pollution Control Board of India (CPCB) monitoring network. However,
21 the aerosol composition predicted by WRF-Chem was quite different from measurements obtained
22 during the Winter Fog Experiment (WiFEX) in Delhi, with chloride aerosol fraction being strongly
23 underpredicted (~66.6%). By investigating a fog event on December 23-24, 2017 over central IGP, we
24 found that the aerosol-radiation feedback weakens turbulence, lowers the boundary layer height, and
25 increases PM_{2.5} concentrations and RH within the boundary layer. The increase in RH is found to be
26 important for fog formation and it promoted the growth of aerosol size and increased aerosol activation
27 in the polluted environment over IGP. Loss of aerosols through deposition of cloud droplets is found to
28 be a significant aerosol loss process during fog. The internal mixing of absorbing aerosols and
29 hygroscopic growth reduces the single scattering albedo impacting aerosol-radiation feedbacks.
30 Aqueous-phase chemistry increases the PM_{2.5} concentrations during fog events which subsequently
31 participates in aerosol-radiation feedback. With aerosol-radiation interaction and aqueous phase
32 chemistry, fog formation began 1-2 hours earlier and caused a longer fog duration than when these
33 processes were not included in the WRF-Chem simulation. These processes were also found to increase
34 RH, stabilize the boundary layer, increase PM_{2.5} promoting aerosol activation, and thus increasing the

35 fog water content over IGP. This suggests that the aerosol-radiation feedback and secondary aerosols
36 play an important role in the air quality and in the intensity and lifetime of fog over IGP.

37

38 **1 Introduction**

39 The Indo-Gangetic Plain (IGP; 21°35'-32°28'N latitude. and 73°50'-89°49'E longitude) in the
40 northern part of the Indian subcontinent is one of the most densely populated and heavily polluted
41 regions in South Asia. The rapid population and economic growth in the IGP region over the last decade
42 have increased air pollution over this region. This is evident from the increasing trend in AOD and NO_x
43 over India reported in recent studies (Dey and Di Girolamo, 2011; Ghude et al., 2013; Krishna Moorthy
44 et al., 2013), which has slowed and reversed only recently (Sarkar et al., 2019). The high concentration
45 of aerosols along the IGP and their adverse effects on human health and the environment are increasing
46 (Ghude et al., 2016). Consequently, more than 500 million people living in the IGP breathe air that
47 exceeds the National Ambient Air Quality (NAAQ) Standards, which has reduced the life expectancy
48 of the people (Debnath et al., 2022; Lelieveld et al., 2015). Lelieveld et al., (2015) estimated a very high
49 number of premature deaths (0.716 million per year) linked to aerosols (PM_{2.5}), thus making Southeast
50 Asia one of the largest regions affected by premature mortality globally.

51 One of the major environmental concerns in the IGP is the urban air quality during winter,
52 especially over the mega-cities, e.g., Delhi, located in the north-western part of IGP (Ghude et al., 2020;
53 Jena et al., 2021; Sengupta et al., 2022). Several urban air pollution hotspots along the IGP extend from
54 northwest to east with monthly average PM_{2.5} greater than 200 $\mu\text{g m}^{-3}$ (National Ambient Air Quality
55 Standards (NAAQS)=60 $\mu\text{g m}^{-3}$, 24 hr average) in the winter season (Bharali et al., 2019; Krishna et al.,
56 2019). IGP is dominated mainly by fine mode particulates, especially over central to eastern IGP, during
57 post-monsoon and winter (Kumar et al., 2018). Biomass burning (agricultural waste burning, domestic
58 heating, etc.) is an important contributor to the observed high PM_{2.5} loading over IGP during these
59 seasons (Kulkarni et al., 2020; Pant et al., 2015; Pawar and Sinha, 2022; Sharma et al., 2010; Yadav et
60 al., 2020). Delhi is affected substantially by the emissions from agricultural waste burning in the north-
61 western states of Punjab and Haryana during the post-monsoon (October-November) season
62 (Badarinath et al., 2009; Jethva et al., 2018; Kumar et al., 2021). Studies showed that PM_{2.5} increased
63 from ~50 $\mu\text{g m}^{-3}$ to as high as 300 $\mu\text{g m}^{-3}$ (Ojha et al., 2020), and AOD reached 0.98 with the presence
64 of absorbing aerosols (Singh et al., 2018) during the peak biomass burning in post-monsoon.

65 IGP experiences fog (both radiation and advection fog) every winter after the passage of the
66 synoptic wind system called the “Western Disturbances”. The number of low visibility days due to
67 haze/fog formation has been increasing significantly (Ghude et al., 2017; Jenamani, 2007; Singh and
68 Dey, 2012), impacting socio-economic activities, e.g., aviation (Kulkarni et al., 2019). The increase in
69 the intensity and regional extent of fog over IGP is consistent with the increasing trend in aerosol
70 concentration due to increasing anthropogenic emissions (Sarkar et al., 2006; Syed et al., 2012).

71 Several factors control the formation and persistence of fog in the IGP, e.g., stable boundary
72 layer, cold temperature, availability of moisture (supplied by the Western Disturbances and irrigation
73 activities), and the aerosol number and composition (Acharja et al., 2022; Dhangar et al., 2021). It has
74 also been suggested that the atmospheric rivers (moisture incursion from Arabian Sea) act as a source
75 of water vapor over IGP, which fuels the intensification of fog and haze (Verma et al., 2022) during
76 winter. The high aerosol concentration in the boundary layer influences fog formation (Gautam et al.,
77 2007; Safai et al., 2019) over the IGP by providing the needed cloud condensation nuclei (CCN) for
78 activation into fog droplets. In addition, aerosols induce surface cooling by reducing solar radiation at
79 the surface while warming the lower troposphere by absorption (Ding et al., 2016; Yu et al., 2002). A
80 reduction in surface-reaching solar radiation by ~19% has been reported during winter over Kanpur in
81 the IGP (Dey and Tripathi, 2007). The reduced solar flux affects the boundary layer stability and depth
82 by suppressing the thermals and thus further increasing the surface aerosol concentration via aerosol-
83 radiation feedback, which is very strong over the IGP (Bharali et al., 2019). Kumar et al., (2020) have
84 shown that aerosol-radiation feedback significantly improves the accuracy of PM_{2.5} and temperature
85 forecasts in Delhi. Srivastava et al., (2018) reported that the direct aerosol forcing over polluted regions
86 is very large with values up to $-80.0 \pm 7.2 \text{ W m}^{-2}$ over the IGP in the winter season.

87 Aerosol-radiation interaction determines that the aerosol distribution is critical for the evolution
88 of fog (Bodaballa et al., 2022; Steeneveld et al., 2015), while microphysics is important for fog
89 formation and dispersal (Boutle et al., 2018; Maalick et al., 2016). Although the relationship between
90 the aerosol chemical composition and aerosol activation to CCN has not been fully understood yet,
91 studies have found that the chemical composition and mixing state of aerosols affect the hygroscopicity
92 (κ) of aerosols (Bodaballa et al., 2022; Ma et al., 2013; Moore et al., 2012; Zhang et al., 2014a). Fog
93 processes involve a complex interplay between local meteorology, radiation, microphysics, and aerosol
94 chemistry, making it difficult to understand the fog lifecycle (Acharja et al., 2022; Maalick et al., 2016;
95 Zhang et al., 2014b). There is considerable heterogeneity in the spatial and temporal aerosol properties
96 over IGP and the poor estimates of their mixing state. Therefore, prediction of fog by weather models
97 is still challenging with biases in fog's onset and dispersal timings.

98 Previous studies have focussed on the impacts of meteorological conditions, topography, or
99 anthropogenic emissions on the poor air quality and intensification of fog during winter over IGP (e.g.
100 Hakkim et al., 2019). However, studies on the effect of feedback induced by the aerosols on the
101 meteorological conditions and thus on aerosol concentration are very limited over this region, except
102 for a few above-mentioned studies which discuss how the aerosol-radiation feedback favors haze and
103 fog during winter. Moreover, fog can provide a medium for aqueous-phase reactions. While several
104 earlier studies have reported an increase in secondary aerosols during fog over IGP, a sensitivity study
105 examining the impact of fog on aqueous phase chemistry has not yet been done over IGP.

106 In the present work, we aim to find the suitable chemistry/physics as well as the meteorology
107 initial/boundary conditions that lead to improved simulations of fog events in the Weather Research and

108 Forecasting model coupled with chemistry (WRF-Chem; (Fast et al., 2006; Grell et al., 2005; Powers et
109 al., 2017). We also explore the role of aerosol-radiation feedback on fog properties as the high aerosol
110 loadings in northern India can impact the heating rates, temperature inversions, and boundary layer
111 height. The role of aqueous chemistry on fog properties and vice-versa is also investigated.

112 2 Methodology

113 Fig. 1 shows the IGP study region for the simulations. Fog occurred on both 23rd and 24th
114 December 2017 (Fig. 1a, b). The fog region is located over an area with high PM_{2.5} anthropogenic
115 emissions (Fig. 1c). The IGP is a large region with varying meteorology and aerosol characteristics,
116 therefore, it is divided into three areas, northwest (NWIGP), central (CIGP), and east (EIGP) which are
117 marked by the black rectangles in Fig.1c. Although biomass burning and anthropogenic emissions
118 dominate throughout the IGP during post-monsoon and winter season, the north-westerly wind system
119 results in the gradient distribution of AOD over this region. The downwind regions, CIGP and EIGP
120 are influenced by the long-range transport from the NWIGP, resulting in high AOD with dominant fine
121 particulates over CIGP and EIGP, especially during post-monsoon and winter (Kedia et al., 2014;
122 Kumar et al., 2018). Therefore, representative stations from each region are considered for the
123 sensitivity analyses. Nine stations have been considered which include, Amritsar, IGI Airport (Indira
124 Gandhi International Airport, Delhi), IHBAS (Delhi), Dwarka (Delhi), RKP (Delhi) in the North-West
125 IGP; Kanpur, Lucknow in Central IGP and Patna, Muzaffarpur in East IGP.

126

127 2.1 Modeling

128 The WRF-Chem model version 4.0.3 has been used for this study. The model domain is
129 centered at Delhi (77.1°E, 28.7°N) with 300 grid points in the east-west, 170 grid points in the south-
130 north direction (Fig. 1c), and 50 vertical eta levels with the model top at 50 hPa. The horizontal grid
131 spacing of the domain is 10 km, while the vertical grid spacing varies from higher resolution (~200 m)
132 in the boundary layer to coarser resolution (~1200 m) near the model top. To quantify the impact of
133 aerosol-radiation (AR) feedback and aqueous chemistry on the fog properties, we conduct sensitivity
134 simulations (Table 1) for December 20–24, 2017. Three experiments (EXP1, EXP2, and EXP3) have
135 been designed with different combinations of meteorological initial/lateral boundary conditions and
136 planetary boundary layer (PBL) physics to identify the best configuration for meteorological
137 simulations. Experiment 1 (EXP1) uses the National Centers for Environmental Predictions (NCEP)
138 Final Analysis (GFS-FNL; 1° x 1°, 6 hourly) meteorology data for initial and boundary conditions and
139 the YSU (Yonsei University; (Hong et al., 2006) PBL scheme. Experiments 2 and 3 (EXP2, EXP3) use
140 ERA-Interim Project (1.125° x 0.703°, 6 hourly) for meteorology initial and boundary conditions, while
141 the PBL options were the YSU PBL scheme and ACM2 (Asymmetric Convective Model version 2)
142 scheme, respectively. ACM2 is a hybrid of the original nonlocal closure (Pleim and Chang, 1992) and
143 a local closure eddy diffusion scheme (Pleim, 2007a, 2007b). The YSU PBL option was coupled with
144 the Noah LSM while ACM2 was coupled with Pleim-Xiu LSM.

145 The advantage of Pleim-Xiu LSM (PX-LSM) is that it allows nudging of soil moisture and
146 temperature to improve the prediction of meteorology near the surface (Xiu and Pleim 2001; Pleim and
147 Xiu 2003; Gilliam et al. 2006) which Noah LSM does not include. The PX-LSM includes two-layer soil
148 (0–1 and 1–100 cm) model, canopy moisture, and aerodynamic and stomatal resistance. Ground surface
149 (1 cm) temperature is calculated from the surface energy balance using a force-restore algorithm for
150 heat exchange within the soil. Although the two-layer approach in PX-LSM is less detailed than the
151 multilayer soil models such as the Noah LSM (four soil layers; Chen and Dudhia 2001), it performs
152 well with realistic initialization for soil moisture and through dynamic adjustment in the model
153 simulation where soil moisture is indirectly nudged according to differences in 2-m temperature (T2)
154 and 2-m relative humidity (RH) between the model and observation (Pleim and Xiu, 2003). Soil moisture
155 nudging adjusts the surface evaporation (direct soil surface evaporation, vegetative evapotranspiration,
156 and evaporation from wet canopies) which then affects the partitioning of available surface energy into
157 latent and sensible heat flux and thus reduces errors in T2 and 2-m RH.

158 For EXP2, meteorological initial conditions were refreshed every 24 hours, while EXP3 was a
159 continuous run but soil moisture was nudged to the Era-Interim dataset to improve the prediction of
160 surface fluxes. All other physics and chemistry options are the same for all the experiments except the
161 surface physics option, which changes with the PBL scheme used. The deposition of cloud droplets is
162 an important moisture and aerosol sink during fog events. For all these simulations, the deposition
163 velocity of cloud droplets was reduced to 0.01 m s^{-1} based on Stoke's Law and previous studies (Katata
164 et al., 2015; Tav et al., 2018) because its default value (0.1 m s^{-1}), is large.

165 To examine the radiative effects of aerosols and aqueous phase chemistry additional simulations
166 have been done using the meteorological configuration in EXP3, with aerosol-radiation (wFB) feedback
167 plus aqueous chemistry (wAq.chem), without aerosol-radiation feedback (nFB) but with aqueous
168 chemistry, and without aqueous chemistry (noAq.chem) but with aerosol-radiation feedback. The
169 analysis has been done for the fog events on 23rd and 24th December 2017 as

170 *Impact of radiation feedback=wFB-nFB*

171 *Impact of aqueous phase chemistry= wAq.chem-noAq.chem*

172 Emissions used in the WRF-Chem simulations are from the EDGAR-HTAP v2 (*Emissions*
173 *Database for Global Atmospheric Research- Hemispheric Transport of Air Pollution*; $0.1^\circ \times 0.1^\circ$)
174 inventory for anthropogenic emissions and FINN v2.2 (*Fire INventory from NCAR*; $1 \text{ km} \times 1 \text{ km}$) fire
175 emission inventory (Wiedinmyer et al., 2011). Trash-burning emissions (Chaudhary et al., 2021) are
176 also included in the simulations. The model calculates the biogenic emissions online using MEGAN
177 v2.04 (*Model of Emissions of Gases and Aerosols from Nature*) (Guenther et al., 2006). The initial and
178 lateral boundary conditions for chemical constituents are from the global chemistry transport model
179 CAM-Chem (*Community Atmosphere Model with Chemistry*) (Emmons et al., 2020).

180 The MOZART (Model for Ozone and Related chemical Tracers) chemical mechanism
181 (Emmons et al., 2010) is used for gas-phase chemistry, which includes 85 gas-phase species, 39

182 photolysis, and 157 gas-phase reactions. It has been updated to include an explicit treatment of aromatic
183 compounds HONO, C₂H₂, and isoprene oxidation scheme (Knote et al., 2014). The lumped toluene used
184 by Emmons et al., (2010) has been speciated into benzene, toluene, and lumped isomers of xylenes
185 (Knote et al., 2014). For this study, HCl emissions, transport, dry, and wet deposition are represented.
186 However, HCl gas-phase reaction is not included in MOZART.

187 The Model for Simulating Aerosol Interactions and Chemistry (MOSAIC) with four size bins
188 (0.039–0.156, 0.156–0.625, 0.625–2.500, and 2.5–10.0 μm dry diameters) coupled with MOZART gas-
189 phase chemistry is used (Fast et al., 2006; Zaveri et al., 2008). The bin sizes are defined by their lower
190 and upper dry particle diameters, so there is no transfer of particles between bins during water uptake
191 or loss. It is assumed that aerosols in each bin are internally mixed with the same chemical composition
192 while they are externally mixed in different bins.

193 The aerosol composition includes sulfate (SO₄²⁻), ammonium (NH₄⁺), nitrate (NO₃⁻), aerosol
194 water, sea salt (Na⁺, Cl⁻), methanesulfonate (CH₃SO₃⁻), carbonate (CO₃²⁻), calcium (Ca⁺), black carbon
195 (BC), organic mass (OC), and unspecified inorganic species such as silica, inert minerals, and trace
196 metals lumped together as other inorganic mass (OIN). For OC, primary OC and secondary OC are
197 represented separately, where the latter is simulated using the volatility basis set (VBS) approach.
198 Reactive inorganic species such as potassium (K⁺) and magnesium (Mg⁺) are usually present in much
199 smaller amounts and are equivalent to Na⁺ since their sulfate, nitrate, and chloride salts are similar in
200 terms of their solubility in water.

201 MOSAIC treats condensation and evaporation of trace gases to/from particles, nucleation (new
202 particle formation), and coagulation. Aerosol coagulation (Brownian) is based on (Jacobson et al., 1994)
203 and nucleation is based on (Wexler et al., 1994) parameterization of H₂SO₄-H₂O homogeneous
204 nucleation. Sulfate, nitrate, chloride, and ammonium aerosols are mainly formed through oxidation and
205 neutralization/condensation of gas precursors. Gas-phase sulfuric acid (H₂SO₄) is produced by the gas-
206 phase oxidation of SO₂ by OH and nitric acid (HNO₃) formation is via the oxidation of NO₂ by OH.
207 HCl is a primary emission product. The neutralization/condensation of H₂SO₄, HCl, and HNO₃ with
208 NH₃ produces ammonium such as ammonium sulfate (NH₄)₂SO₄, ammonium bisulfate (NH₄HSO₄),
209 ammonium chloride (NH₄Cl) and ammonium nitrate (NH₄NO₃), respectively. The thermodynamic
210 modules in MOSAIC for the dynamic gas-particle partitioning of aerosols MTEM (Multicomponent
211 Taylor Expansion Method) and MESA (Multicomponent Equilibrium Solver for Aerosols) calculate the
212 activity coefficient in aqueous phase aerosols and compute the intraparticle solid-liquid phase
213 equilibrium respectively (Zaveri et al., 2005, 2008). The Adaptive Step Time-split Euler Method
214 (ASTEM) coupled with MESA-MTEM dynamically integrates the mass transfer equations.

215 Aqueous-phase chemistry uses a bulk water approach employing the Fahey and Pandis (2001)
216 mechanism. It calculates sulfate formation, formaldehyde oxidation, and non-reactive uptake of nitric
217 acid, hydrochloric acid, ammonia, and other trace gases (Chapman et al., 2009; Pye et al., 2020).
218 Aqueous-phase sulfate is produced via oxidation of SO₂ by H₂O₂, O₃, TMI (Transition metal Ion: Fe(III),

219 Mn(II) catalyzed O₂ and NO₂. TMI concentrations are prescribed in the model to 0.01 μg m⁻³ for Fe(III)
220 and 0.005 μg m⁻³ for Mn(II) (Martin and Good, 1991). The Fe(III) values are within the range of water
221 soluble iron in winter time aerosol reported in India (Kumar and Sarin, 2010). Wet removal
222 (scavenging), is represented by the (Neu and Prather, 2012) scheme for trace gases and Easter et al.,
223 (2004) for aerosols.

224 The WRF-Chem simulations include interactions with radiation, i.e., direct aerosol effect and
225 effect on photolysis rates. Aerosol cloud interactions are not possible when using the ACM2 PBL
226 scheme because the ACM2 PBL scheme does not provide the exchange coefficient for heat, which is
227 required to calculate the activation fraction for mass and number for each bin/mode.

228

229 2.2 Observations

230 To evaluate the model output, observations of aerosols and meteorology have been obtained
231 from several satellites as well as ground-based measurement platforms. To examine the aerosol loading
232 and spatial and temporal distribution, daily Level 2 Aerosol Optical Depth (AOD) retrievals from the
233 Moderate Resolution Imaging Spectroradiometer (MODIS) aboard Terra and Aqua satellites are
234 obtained at the spatial resolution of 10 km x 10 km (at nadir) pixel array. It provides aerosol properties
235 from the Dark Target (DT) algorithm applied over the ocean and dark land (e.g., vegetation) and Deep
236 Blue (DB) algorithms over the entire land areas, including both dark and bright surfaces. Each
237 MOD04_L2 (Terra) / MYD04_L2 (Aqua) products are available at a 5-minute time interval with an
238 output grid of 135 pixels in width by 203 pixels in length.

239 The Indian National Satellites (INSAT-3D) in the geostationary orbit at inclinations of 82°
240 longitude provide an imager fog product (3DIMG_L2C_FOG) with a spatial resolution of 4 km every
241 30 min (www.mosdac.gov.in). For daytime, the visible channel observation is used to detect fog,
242 whereas thermal infrared is used to reduce false alarms such as medium/high clouds and snow areas.
243 INSAT 3D's 'day microphysics' data component analyzes solar reflectance at three wavelengths: 0.5
244 μm (visible), 1.6 μm (shortwave infrared), and 10.8 μm (thermal infrared). Night-time fog is derived
245 from TIR-1 (12.0 μm and 10.0 μm) and MIR (10.8 μm and 3.9 μm) channel brightness temperature
246 over the Indian region. INSAT-3D provides fog intensity varying from 1 to 4 indicating SHALLOW
247 for visibility > 600 m; MODERATE, DENSE, and VERY_DENSE, respectively for visibility varying
248 from 0 to 500 m (Banerjee and Padmakumari, 2020). If the visibility is greater than 700 m it indicates
249 no fog while visibility > 1000 m represents very clear skies. Validation of INSAT-3D fog products over
250 the IGP shows a 66%-68% probability of detection and a 10% false alarm rate. It also captures the
251 entire life cycle of fog from formation to dissipation. However, detecting fog during multilayer clouds
252 is still challenging with INSAT-3D (Arun et al., 2018; Chaurasia and Gohil, 2015; Chaurasia and
253 Jenamani, 2017).

254 Ground-based monitoring sites provide hourly data of relative humidity, surface temperature,
255 and wind speed measured by the Central Pollution Control Board, CPCB (<http://cpcb.nic.in>). In
256 addition, measurements of several aerosols, trace gases, and meteorology at Delhi (IGI Airport) from
257 the Winter Fog Experiment (WiFEX) for the period December 10-31, 2017, have also been used to
258 validate the model output. The WiFEX, an initiative of the Ministry of Earth Sciences (MoES), India,
259 is a ground-based measurement campaign at the IGI Airport Delhi to understand fog's physical and
260 chemical features. Additional details of the WiFEX project and related publications can be found in
261 Ghude et al., (2017).

262

263 3 Meteorology Evaluation

264 Previous studies simulating fog highlight the importance of high model vertical resolution
265 (Pithani et al., 2019; Van Der Velde et al., 2010) for representing the fog formation and the growth of
266 the fog layer, model initialization (Yadav et al., 2022), initial relative humidity (Bergot and Guedalia,
267 1994; Pithani et al., 2020), and PBL schemes (Chen et al., 2020; Pithani et al., 2019). In the present
268 study, 2-m relative humidity (RH2), 2-m temperature (T2), and 10-m wind speed (WS) from WRF-
269 Chem have been validated using ground-based measurements from CPCB monitoring network and
270 WIFEX campaign for several stations across the IGP. The NWIGP stations include Amritsar, IGI (Indira
271 Gandhi International Airport), and RKP (Rama Krishna Puram) site in Delhi; Kanpur and Lucknow in
272 central IGP; and Patna in the East IGP. The comparison of WRF-Chem results with observations shows
273 that RH and T2 are sensitive to the choice of the meteorological initial and boundary conditions (Fig.
274 S1). WRF-Chem compares better with the observations for simulations driven by the ERA-Interim
275 reanalysis than with GFS-FNL reanalysis since ERA-Interim provides more realistic RH than GFS-FNL
276 (Figs. S2 a-f). For example, RH from EXP1 (GFS) varies from 10 to 50%, while RH from EXP2 and
277 EXP3 varies from 30 to 100%, which is closer to observation, especially for NWIGP and CIGP. For
278 EIGP, RH from EXP1 (GFS) compares better than ERA-Interim, which overestimates the observed RH.
279 ERA-Interim and YSU PBL scheme showed damping of RH continuously increasing the bias in RH
280 with time (not shown), which was corrected in EXP2 by refreshing meteorology every day at 00h UT
281 during the model simulation. In addition, maps of surface RH and T2 (Figs. S2 g-j) show that the GFS-
282 FNL dataset has lower relative humidity throughout the domain as compared to ERA-Interim. There are
283 differences in simulated 2-m temperature between these two datasets which are of smaller relative
284 magnitude compared to the RH.

285 The GFS-FNL driven meteorology EXP1 has a warm bias in NWIGP and CIGP, especially
286 during night-time, while over EIGP, the model prediction agrees well with observations. EXP2 with the
287 ERA-Interim driven meteorology and YSU PBL scheme also shows good agreement between modeled
288 and observed T2 in EIGP. The ERA-Interim driven meteorology with the ACM2 PBL scheme in EXP3
289 has a cold bias of up to 7°C over EIGP during daytime from 22nd to 24th December. The wind speed
290 evaluation shows that WRF-Chem is over-predicting wind speed. However, it is also possible that some

291 CPCB stations (e.g., Amritsar and RK Puram) have a wind speed low bias due to the low measurement
292 height and obstructions such as tall trees near the monitoring station. Note that at other sites (e.g., over
293 IGI-Delhi and Kanpur) the model measurement agreement is better.

294 The WRF-Chem performance has been statistically assessed against observation using the
295 Taylor Diagram (Taylor, 2001), which provides a statistical summary of how well the model output
296 agrees with the observation in terms of the Pearson correlation, the root-mean-square error (RMSE),
297 and the ratios of their variances (Fig. 2). The percentage bias has also been included to further evaluate
298 the WRF-Chem results. In Fig. 2, better agreement of WRF-Chem results with observations are shown
299 by the marker's proximity to the "OBS" dashed black line. The WRF-Chem RH has a good correlation
300 for all three experiments with $r^2 > 0.75$ at all the locations in IGP for all the experiments. However, the
301 RMSE and the standard deviations are larger for the EXP1. The relative bias is also large (>20%) for
302 EXP1 (GFS-FNL) compared to EXP2 and EXP3 which lie closer to the dashed black line indicating
303 that the simulated RH variations are similar to observations. For all the experiments, WRF-Chem T2
304 agrees well with observations with a correlation between 0.8 and 0.95. The points are concentrated near
305 the dashed line showing a low RMSE and standard deviation for T2, signifying a good agreement of
306 simulated T2 with observation in terms of temporal variation but the T2 relative bias is large for EXP1
307 (>20%). The RMSE and relative bias for EXP1 are larger for several of the stations. The temporal
308 variability of T2 and RH are predicted well for all the combinations of inputs (Fig. S1), however, the
309 accuracy of simulated T2 and RH is sensitive to the choice of meteorological initial/boundary
310 conditions. WRF-Chem predicted RH and T2 agree better with observations when initialized with ERA-
311 Interim meteorology than with GFS-FNL.

312 The WRF-Chem runs driven by ERA-Interim with YSU (EXP2) and ACM2 PBL (EXP3)
313 schemes predicted the surface meteorology better over the IGP than the WRF-Chem run driven by GFS
314 (EXP1). By examining the modeled cloud water content in the lowest model level with the INSAT-3D
315 satellite fog intensity for the 23rd and 24th December 2017 (Fig. 3), it is apparent that WRF-Chem with
316 the ACM2 PBL scheme compared qualitatively well with observations obtained from INSAT-3D
317 satellite in terms of fog coverage over CIGP, while the WRF-Chem run with the YSU PBL scheme did
318 not produce widespread fog. However, there is also fog over EIGP in WRF-Chem with the ACM2 PBL
319 scheme although it is not observed by the satellite. This is because the model has a cold bias in T2 and
320 a high surface RH over East IGP with ACM2 PBL and Pleim-Xiu surface scheme as discussed earlier,
321 which favors the formation of fog in this region. The time series in Fig. 4 shows that EXP3 is capable
322 of predicting the duration of fog on 23rd and 24th December. There is a data gap from INSAT 3D
323 observations because it is unable to capture fog during daytime in the presence of mid and high-level
324 clouds.

325 In conclusion, EXP3 is the best configuration for predicting fog formation where the ERA-
326 Interim meteorology, the ACM2 PBL and surface schemes, and soil moisture nudging is used in the
327 WRF-Chem simulation. Therefore, the evaluation of predicting AOD, surface aerosol concentrations,

328 and aerosol composition as well as analysis of the impact of aerosols on fog formation uses the EXP3
329 configuration.

330

331 **4 Aerosol Evaluation**

332 Aerosol is an important factor in correct prediction of fog (Maalick et al., 2016; Stolaki et al.,
333 2015) as the number of fog droplets depends on the aerosol size distribution and concentration. Aerosols
334 as CCN can affect the liquid water content in fog and therefore an increase in aerosol concentration can
335 significantly affect fog lifetime (Stolaki et al., 2015; Zhang et al., 2014b). AOD retrievals from the
336 MODIS satellite have been used to validate the modeled AOD (Fig. 5). It is observed that the model
337 captures several important features of the MODIS retrieved AOD spatial distribution but at the same
338 time somewhat struggles to reproduce the observed AOD magnitude in some parts of the domain. One
339 possible reason for the underestimation would be the EDGAR-HTAP emission inventory, which has a
340 low bias for residential sector PM_{2.5} emissions in India (Sharma et al., 2022). For instance, the model
341 successfully predicts high aerosol loading seen by MODIS on 20 and 21 December over CIGP and
342 EIGP. This is the region with dense fog both in model and observation. Higher AOD (>0.5) over CIGP
343 and EIGP can be attributed to the accumulation of aerosols that are transported by north-westerly winds
344 to these regions from NWIGP (Dey and Di Girolamo, 2011; Jain et al., 2020; Jethva et al., 2018; Kumar
345 et al., 2018; Yadav et al., 2020). However, WRF-Chem underestimates AOD over the NWIGP
346 (AOD<0.3) throughout the simulation period and during 23-24 December over CIGP and EIGP where
347 the latter may be related to enhanced scavenging of aerosols by fog droplets.

348 The west to east gradient in aerosol loading over IGP is consistent with surface PM_{2.5}
349 distribution (Fig. 6a). Surface PM_{2.5} concentration is highest in EIGP (>100 µg/m³) and it decreases
350 gradually towards NWIGP (~60-80 µg/m³). The time series of PM_{2.5} from CPCB measurements and the
351 model at stations representative of each region in IGP shows that simulated PM_{2.5} compares well with
352 observation in terms of day-to-day variation over most of the locations in the IGP (Fig. 6 b-e). The
353 comparison is good over Amritsar (an NWIGP location), where PM_{2.5} is mostly primary aerosols from
354 local emissions e.g., residential heating related biomass burning. Agricultural waste burning is at its
355 peak during post monsoon months (Oct-Nov) whereas during winter burning for residential heating
356 increases and the stable boundary layer confines these emissions near the surface (Kumar et al., 2021;
357 Pawar and Sinha, 2022). PM_{2.5} at Amritsar shows a bimodal distribution with morning and evening
358 peaks whereas it is absent in the model likely due to the absence of diurnal variations in the WRF-Chem
359 anthropogenic emissions.

360 At Delhi, the daily variations are predicted well although WRF-Chem underestimates PM_{2.5}
361 observations during the first 4 days. Delhi experiences severe air pollution and haze with high PM
362 loading (> 500 µg m⁻³) (Bharali et al., 2019). The model is successful in predicting the high PM_{2.5}
363 episode on the 24th of Dec. However, it fails to predict the composition correctly (Fig. 7). Although
364 simulated SO₂ and NH₃ are comparable with observation, sulfate, and ammonium are underestimated

365 in the model. SO_4^{2-} is underestimated by $\sim 9 \mu\text{g m}^{-3}$, while NH_4^+ , NO_3^- and Cl^- are underestimated by
366 $\sim 30 \mu\text{g m}^{-3}$, $\sim 19 \mu\text{g m}^{-3}$ and $\sim 40 \mu\text{g m}^{-3}$ on average, respectively. This leads to the underestimation of
367 $\text{PM}_{2.5}$ over Delhi. Studies report very high chloride over the IGP with values exceeding $100 \mu\text{g m}^{-3}$
368 (Lalchandani et al., 2021) during winter emitted from increased trash burning and industrial emissions
369 (Pant et al., 2015; Patil et al., 2013). Our model includes HCl emissions from trash burning but emissions
370 from other sources (e.g., industries) are unaccounted for in the model which likely leads to the
371 underestimation in modeled chloride.

372 Over the CIGP and EIGP, the underestimation in $\text{PM}_{2.5}$ is mostly observed at the east IGP
373 locations during the dense fog. It is well known that the hygroscopic aerosols grow in size and are
374 deposited to the surface during fog (Gupta and Mandariya, 2013; Kaul et al., 2011). $\text{PM}_{2.5}$ shows an
375 increase initially with the onset of fog and then it decreases as the aerosols grow and get deposited
376 through fog droplets. A two order higher deposition rate (Fig. 6 f, g) during fog compared to the
377 deposition rate of dry aerosol results in the lower $\text{PM}_{2.5}$ over CIGP and EICP during fog events.

378 Previous studies have reported that models tend to underestimate the AOD observation (David
379 et al., 2018; Pan et al., 2015) during the post-monsoon and winter when agricultural waste burning and
380 anthropogenic emissions dominate. While anthropogenic emissions include a contribution from the
381 residential sector, the emissions from small-scale burning for residential heating over IGP especially
382 during winter are likely underestimated in the current emission inventory (Sharma et al., 2022). This
383 leads to an underestimation of aerosol concentration in the model. Other possible causes for the
384 underestimation are the biases in the simulated meteorology (Govardhan et al., 2015; Kumar et al., 2015;
385 Pan et al., 2015) which affects the aerosol concentration. We corrected some of the biases in
386 meteorology as discussed earlier however there are still residual biases in the simulated meteorology
387 e.g., overestimation of wind speed by WRF-Chem. We also observe underestimation of secondary
388 aerosols over NWIGP which contribute significantly to the aerosol loading over IGP. Secondary aerosol
389 formation is substantial over CIGP and EIGP in the model compared to NWIGP which will be discussed
390 in a later section. Several modeling studies have shown significant improvements in forecasting surface
391 $\text{PM}_{2.5}$ by assimilation of satellite AOD and $\text{PM}_{2.5}$ (Ghude et al., 2020; Jena et al., 2020; Kumar et al.,
392 2020) suggesting the importance of correct initialization of the model in simulating aerosols over IGP.

393

394 **5 Effect of Aerosol Radiation feedback**

395 Interactions of aerosols with radiation affects temperature and surface heat fluxes, thereby
396 weakening the turbulence in the PBL and stabilizing the boundary layer height (Fig. 8b) compared to
397 the clean environment (Fig. 8a). In the presence of well mixed aerosols within the PBL, the radiative
398 effect of aerosols lowers the noontime PBL height (Fig. 8b). However, the presence of absorbing
399 aerosols in the PBL warms the air and changes the thermodynamics. Three cases are shown in Fig. 8(c-
400 e) where increases of scattering aerosol concentrations at the top of PBL (Fig. 8c) increases scattering
401 of radiation by the aerosol layer and reduces the surface reaching solar radiation similar to Fig. 8b.

402 Higher concentrations of absorbing aerosols at the top of PBL (Fig. 8d) warms the air above the
403 boundary layer and strengthens the capping inversion stabilizing the PBL and suppressing its growth.
404 The shallow PBL and weakened daytime vertical mixing confines aerosols and water vapor near the
405 surface and worsens the air quality of a region. The aerosols trapped in the stagnant PBL further affects
406 the radiation flux at the surface and creates a positive feedback loop wherein the PBL is continually
407 suppressed until interrupted by some synoptic weather phenomenon, such as the western disturbances
408 in the IGP. On the other hand, higher concentration of absorbing aerosols within the PBL (Fig. 8e)
409 warms the air in the PBL and this results in the higher PBL height. The raised PBL decreases the aerosol
410 concentration near the surface which is termed as a negative feedback effect.

411 The aerosol radiation feedback can affect shortwave heating rates (SWHR). The high aerosol
412 loading over the IGP (Fig. 6 and Fig. 7) allows the AR feedback to reduce the PBL height by more than
413 140 m throughout the IGP compared to the surrounding region with AR feedback (Fig. 9a). The
414 difference in PBL height with and without aerosol radiation feedback is largest during noontime. The
415 suppressed PBL is due to the decrease in the surface heating flux and the consequent weakening of
416 turbulence in the PBL. The surface solar radiation flux (SWF) decreases by 5-35 % while the surface
417 latent heat (LH) and sensible heat (HFX) fluxes decrease by 5-35 % and 10-60 %, respectively (Fig.
418 S3). The stable, shallow PBL reduces the vertical mixing of aerosols and moisture and confines them
419 near the surface, resulting in increased $PM_{2.5}$ concentrations and RH near the surface with AR feedback
420 (Fig. 9). Although T_2 should decrease with the reduction in surface SWF, T_2 shows mixed signals with
421 both cooling and warming over IGP. While surface cooling is observed over NWIGP and EIGP, T_2
422 increases with AR feedback over most of CIGP. The response of AR feedback to T_2 varies in these
423 three regions probably due to differences in the distribution and types of aerosols and the presence of
424 fog. Increase in surface concentration of $PM_{2.5}$ occurs more over NWIGP and EIGP with increase in BC
425 and OIN over NWIGP, and sulfate aerosol over EIGP which results in the surface cooling due to positive
426 AR feedback in these two regions.

427 Over the CIGP, the AR feedback causes a depletion of surface $PM_{2.5}$ (Fig. 9d). Examining
428 further, the time variation of the changes in PBL height, T_2 , and RH between the simulations with and
429 without aerosol-radiation feedback (Fig. 9g) shows an increase in T_2 while the surface fluxes, sensible
430 heat flux, latent heat flux, and downward shortwave radiation flux decrease over CIGP (Fig. 9h). AR
431 feedback affects mostly the lower atmosphere at multiple levels; however, our finding suggests that the
432 decreased shortwave radiation flux decreases the surface fluxes and thus the turbulence in the boundary
433 layer resulting in a reduced PBL height on both days. Figure 9 g and h clearly show a decrease in HFX
434 and LH following the decrease in SWF. Moreover, we observe that the PBL height is sensitive to latent
435 heat flux likely due to its strong dependence on moisture availability (Xiu and Pleim, 2001; Zhang and
436 Anthes, 1982).

437 The impact of AR feedback on T_2 depends on factors such as the presence of absorbing aerosols
438 and their vertical distribution via heating or increased SWF (as observed in CIGP, Fig. S3). Absorbing

439 aerosols in WRF-Chem include BC and OIN (other inorganic aerosols), which both increase near the
440 surface (Fig. 9e, Fig. S4) due to their confinement in the stable PBL. Some areas in the fog-affected
441 region show a decrease in BC as well as SO_4^{2-} which is likely due to their hygroscopic growth, increase
442 in activation to fog droplets, and then dry deposition in dense fog. The increase in RH favours the growth
443 of aerosols in size by the uptake of water and also the formation of secondary aerosols. As a result, AR
444 feedback changes the absorbing to scattering ratio of aerosols over IGP indicated by the decrease in
445 SSA (Single Scattering Albedo; Fig. S5). A decrease in SSA is found in CIGP throughout the boundary
446 layer while it is negligible in NWIGP. SSA increases in EIGP in the PBL and decreases near the top of
447 PBL. Similar observation has been made by Ramachandran et al., (2020) where SSA decreases with
448 increasing altitude due to absorbing carbonaceous aerosols at higher elevations which contributes $\geq 75\%$
449 to the aerosol absorption over IGP. Increased shortwave heating (Fig. 10) is probably caused by the
450 increased absorbing aerosols near the surface which overwhelms the surface cooling due to reduced
451 shortwave radiation at the surface.

452 The increase in 2-m RH is substantial over CIGP on 24th December (Fig. 9g) compared to the
453 previous day following the decrease in PBL height which constrains the moisture near the surface. The
454 decrease in RH by 2% or more when aerosol-radiation feedback is included compared to no aerosol-
455 radiation feedback is likely due to increase in T2. However, the increase in RH in the afternoon
456 associated with a decrease in LH and PBL height is important for the air to saturate which then favors
457 the formation of fog in a polluted environment. Note that the increase in T2 with AR feedback is very
458 small ($<0.5^\circ\text{C}$) which reduces further after noon (~12:30 pm IST) on both days.

459 Another important factor that can affect the extent of change in PBL height is the distribution
460 of aerosols in the vertical (illustrated in Fig. 8). The pressure-time cross-sections of differences in T,
461 $\text{PM}_{2.5}$, BC, and SO_4^{2-} between aerosol radiation (AR) feedback (wFB) and no aerosol radiation feedback
462 (nFB) for three regions, NWIGP, CIGP, and EIGP are shown in Fig. 11. The difference in the PBL
463 height reaches a maximum with the AR feedback during midday (12:30-15:30 IST). Increase in
464 temperature in the boundary layer is observed with AR feedback particularly at the upper PBL in all the
465 regions of IGP. This induces a temperature inversion resulting in a stable and suppressed PBL. In all
466 the regions the decrease in PBL height (100-200 m) is larger on 24th December compared to 23rd
467 December. The difference in the PBL height on 23rd and 24th December with AR feedback on these days
468 is possibly controlled by the aerosol distribution during the previous day or early morning on the same
469 day. For example, in all the regions an increase in $\text{PM}_{2.5}$ is observed the previous night (23:30 onwards)
470 till ~11:30 of December 24, with increased BC over NWIGP and CIGP whereas both BC and SO_4^{2-} over
471 EIGP. The increased $\text{PM}_{2.5}$ concentrations suppress the development of the PBL after sunrise with AR
472 feedback on December 24 compared to that on December 23, leading to the observed differences in
473 ΔPBL height on these two days. Increase in BC concentrations in NWIGP and CIGP are found above
474 the PBL on 24th December whereas BC concentrations decrease within the PBL. This BC concentration
475 gradient creates a temperature inversion, for example between 10:30-14:30 IST. The increase in BC

476 warms the air in the PBL; however, the warming is not strong enough to cause negative feedback over
477 CIGP. On 23rd December a small increase in BC is uniform throughout the PBL, while there is a decrease
478 in SO_4^{2-} concentrations, resulting in a warmer PBL (Fig. 11) with AR feedback.

479 In EIGP, BC distribution is similar to that in CIGP with AR feedback while there is a substantial
480 increase in sulfate aerosol in the PBL. This results in the strongest extinction in EIGP as evident from
481 the largest difference in PBL height and surface cooling with AR feedback among the three regions.
482 Although ΔPBL is small on 23rd December, it still results in the accumulation of aerosols during night-
483 time (~23:30 pm onwards) which further strengthens the AR feedback effect the next day in NWIGP
484 and CIGP. Thus, AR feedback stabilizes the PBL, increases $\text{PM}_{2.5}$ and RH in the PBL making conditions
485 favourable for persistence of fog over IGP.

486

487 **6 Effect of Aqueous phase chemistry**

488 In this section we discuss the impact of aqueous phase chemistry on aerosol composition and
489 its interaction with meteorology. There is a considerable difference in the surface concentration of $\text{PM}_{2.5}$
490 ($>16 \mu\text{g m}^{-3}$) in the absence of aqueous chemistry over CIGP and EIGP where fog occurs (Fig. 12a)
491 while the difference is negligible over NWIGP where fog does not occur. This is due to the formation
492 of secondary aerosols through aqueous phase chemistry and the hygroscopic growth of aerosols during
493 fog in these regions with the inclusion of aqueous chemistry in the model. In the region between CIGP
494 and EIGP (83E-84E; marked by the box in Fig. 12a), $\text{PM}_{2.5}$ concentration is less in the simulation with
495 aqueous-phase chemistry than without aqueous-phase chemistry because deposition of fog water
496 aerosols to the surface increases as the fog thickens (Fig. 13, Fig. S6). Figure 13 shows the relation
497 between formation of secondary aerosols, deposition flux of $\text{PM}_{2.5}$, and fog with and without aqueous
498 phase chemistry. During the fog event, the secondary aerosols (SO_4^{2-} , NH_4^+) increase significantly by
499 $4\text{-}10 \mu\text{g m}^{-3}$ due to aqueous phase chemistry adding to the $\text{PM}_{2.5}$ burden over IGP. The intensity of fog
500 is high around midnight December 24-25 compared to that on 23rd and 24th (1:30-11:30 IST) which
501 increases the dry deposition flux of $\text{PM}_{2.5}$ causing a sharp drop in the $\text{PM}_{2.5}$ concentration on 24th
502 December compared to the previous night's fog event. The observed change in $\text{PM}_{2.5}$ over a region is
503 the net result of the formation of secondary aerosols and its deposition with fog droplets.

504 The composition distribution of $\text{PM}_{2.5}$ (Fig. 12b) has a similar distribution for the simulations
505 with and without aqueous phase chemistry over NWIGP where fog did not occur. The primary aerosols
506 are higher (BC $> 9\%$, OC $\sim 16\text{-}30\%$, OIN $> 50\%$), than the secondary aerosols ($<5\%$). While the model
507 requires fog for accelerated formation of secondary inorganic aerosol, experimental data (Fig. 7)
508 supports significant formation of secondary inorganic aerosol at elevated RH levels even in haze aerosol
509 (Acharja et al., 2022). On the other hand, the central and east IGP stations are fog-covered and therefore,
510 there is an increase in secondary aerosols esp. SO_4^{2-} and NH_4^+ when aqueous phase chemistry is included
511 in the simulation. SO_4^{2-} is chemically produced via aqueous phase chemistry in cloud water, hence the
512 abrupt increase whereas NH_4^+ maintains a gas-aerosol and gas-cloud equilibrium with NH_3 and SO_4^{2-}

513 via neutralizing the drop or aerosol. NO_3^- is high in the model compared to SO_4^{2-} and NH_4^+ and it
514 decreases by ~1-2 % with aqueous phase chemistry. We observe a small increase in NO_3^- during fog,
515 however it drops as fog intensifies, more rapidly than that without aqueous phase chemistry likely due
516 to increase in dry deposition. This results in lower average NO_3^- to $\text{PM}_{2.5}$ ratio with aqueous phase
517 chemistry. Moreover, NO_3^- is high over the fog covered CIGP and EIGP compared to NWIGP
518 suggesting that transport and chemistry of NO_x in CIGP and EIGP produce more HNO_3 . Aerosol NO_3^-
519 is also in equilibrium with HNO_3 and it is formed only if excess NH_3 is available beyond the sulfate
520 neutralization. Thus, NH_4^+ and NO_3^- changes are likely due to changing the partitioning between gas
521 and liquid based on the production of sulfate.

522 $\text{PM}_{2.5}$ is mostly composed of organic aerosols (OA) over CIGP and EIGP whereas it is OIN
523 (dust) and OA over NWIGP. Although observational studies report Cl^- as one of the largest contributors
524 (12-17%) to $\text{PM}_{2.5}$ after the organics (Lalchandani et al., 2021; Pant et al., 2015) during winter, Cl^- is
525 largely underestimated by the model as discussed in section 4 and contributes only ~3%. A small
526 increase (2-4%) in secondary organic aerosols (SOA) from glyoxal production in aerosols occurs for
527 the simulation with aqueous phase chemistry included during intense fog, suggesting there are feedbacks
528 between cloud chemistry (without glyoxal aqueous chemistry) and aerosol chemistry. However, similar
529 to NO_3^- , average SOA (ASOA (anthropogenic)+BSOA (biogenic) + GlySOA) shows a decrease when
530 aqueous phase chemistry is included. SOA contributes significantly to organic aerosol loading over IGP
531 (Kaul et al., 2011; Mandariya et al., 2019).

532 The WRF-Chem results on aerosol composition behave similarly to observational studies. For
533 example, Ram et al., (2012) reported an increase of EC, OC, and WSOC concentrations by ~30% during
534 fog and haze events at Allahabad, a location in the Central IGP, and a marginal increase of these
535 constituents at Hisar (NWIGP). Several studies report an increase in inorganic ions (NH_4^+ , NO_3^- , and
536 SO_4^{2-}) during fog over IGP and elsewhere (Gundel et al., 1994; Ram et al., 2012). Recent studies suggest
537 that a significant fraction of atmospheric particulate matter in the IGP is comprised of carbonaceous
538 aerosol (~30–35% of the PM) and water-soluble inorganic species (~10–20% of the PM) during
539 October–January when emissions from biomass burning (including residential heating) are dominant
540 over IGP (Ram et al., 2014; Rengarajan et al., 2007; Tare et al., 2006).

541 Both the simulations with and without aqueous-phase chemistry include the AR feedback. The
542 increased $\text{PM}_{2.5}$ with aqueous phase chemistry interacts with radiation and adds to the AR feedback.
543 Since the secondary inorganic aerosols are scattering aerosols, the increased scattering of radiation
544 further reduces the solar radiation reaching the surface (Fig. 14a). Over CIGP the presence of higher
545 aerosol loading reduces the T2 during daytime, particularly on the 24th of December which then reduces
546 the PBL height and increases RH near the surface (Fig. 14b). These conditions favor fog formation over
547 the CIGP. Further, the fog water content with aqueous-phase chemistry is higher than that without
548 aqueous-phase chemistry on 24th December post-midnight (Fig. 13b). This is likely due to saturation of

549 air due to increase in RH and lower T₂, induced by the AR feedback caused by the increase in PM_{2.5}.
550 Although the difference in T₂ is small (<0.4), favourable conditions mentioned above are conducive to
551 fog formation. Another reason for increase in fog water content is the increase in the size of aerosols
552 such as sulfate which grows in size by water uptake and are activated to form fog.

553

554 **7 Effect of AR feedback and aqueous chemistry on the duration of fog**

555 Aerosol and its radiative effects impact the lifetime of fog over a region and hence its
556 distribution. Figure 15(a) shows the time-series of fog liquid water content (LWC) from WRF-Chem
557 and fog intensity from INSAT-3D satellite similar to Fig. 4, for all three experiments with aqueous
558 chemistry plus AR feedback, aqueous chemistry without AR feedback, and without aqueous chemistry
559 but with AR feedback). The fog starts forming one hour earlier with AR feedback than without AR
560 feedback. In the simulation without aqueous phase chemistry, fog formation is delayed by an hour or
561 two compared to the simulation with aqueous chemistry plus AR feedback. Fog cover occurs for both
562 the simulations with and without aqueous chemistry, however the fog water content is greater with
563 aqueous chemistry than without aqueous chemistry. Fog dissipation usually occurs after sunrise when
564 the shortwave radiative warming at the surface warms the air, which results in PBL mixing. In addition,
565 absorbing aerosols like BC affect fog dissipation by increasing the radiative heating in and above the
566 fog. We find an increase in BC and shortwave heating in the PBL with AR feedback (Fig. 10,11) and
567 warming over CIGP with AR feedback. Fog intensity starts to decrease after 01 UTC (06:30 IST),
568 however, in our study, we find that the fog dissipates completely in the afternoon (~10 UTC or 15:30
569 IST) for both the simulations with AR feedback and no aqueous chemistry while an hour later without
570 AR feedback. The AR feedback induces radiative cooling of the surface and increases surface PM_{2.5},
571 which contributes to fog as CCN. Increase in CCN at 0.02% supersaturation, a value typical of fog, is
572 observed on 24th December with AR feedback as compared to no AR feedback (Fig. 15b). As discussed
573 in earlier sections the impact of AR feedback is more on 24th December than that on 23rd which increases
574 RH and CCN on 24th. This facilitates the growth of aerosol and their activation to form fog droplets.
575 Thus, AR feedback produces more fog droplets in polluted conditions and makes fog dense as indicated
576 by the rapid increase in LWC with AR feedback. Shao et al. (2023) examined aerosol-fog interactions
577 for two consecutive fog events by comparing WRF-Chem results with current emissions strengths to
578 those with low emission strengths. They show that the first fog event promotes formation of the second
579 fog event leading to wider fog distribution, and longer fog lifetime favoured by multiple feedbacks
580 including AR feedback i.e., low temperature, high humidity and high stability similar to our study.
581 While Shao et al. (2023) observe a delay in dissipation of the first event and early formation of second
582 fog event, we find an early dissipation and early formation of fog with AR feedback as discussed earlier
583 in this section. Dry deposition (ddmass) also increases in dense fog which causes rapid loss in CCN and
584 activated aerosols during fog with AR feedback as in Fig. 15 (b and c). Thus, aqueous phase chemistry

585 together with AR feedback promotes early formation of fog while AR feedback alone promotes early
586 dissipation of fog and plays a critical role in the formation and evolution of the fog over IGP.

587

588 **8 Conclusions**

589 The effects of aerosol-radiation (AR) feedback and aqueous chemistry in air quality and fog
590 have been assessed over IGP. We carried out three experiments using WRF-Chem testing different
591 combinations of PBL schemes and meteorology initial and boundary conditions. The best representation
592 of surface meteorology for the IGP region for the case study (December 20-25, 2017) used ERA-Interim
593 reanalysis to drive the meteorology and ACM2 PBL scheme with soil moisture nudging to ERA-Interim.
594 With this meteorology configuration for WRF-Chem, evaluation of aerosol concentrations with
595 measurements and the impact of aerosols on atmospheric processes during fog were examined. AOD
596 regional distribution is predicted well by the model for most of the IGP. However, AOD is
597 underestimated over NWIGP likely due to an underestimation of fugitive emissions during wintertime
598 cold spells. $PM_{2.5}$ daily variation concentrations are predicted well over IGP however secondary
599 aerosols are underestimated. Increased dry deposition of $PM_{2.5}$ with cloud water droplets is observed
600 during fog.

601 The AR interactions showed a significant impact on meteorology and air quality over IGP. A
602 WRF-chem simulation with AR interactions resulted in a lower PBL height by ~50-270 m compared to
603 a simulation without AR interactions leading to accumulation of aerosols and moisture near the surface.
604 Reduced surface shortwave radiation flux and the surface sensible and latent heat fluxes due to aerosol
605 radiative effect suppressed the turbulence resulting in a stable PBL. The shallow PBL further increased
606 surface $PM_{2.5}$ ($> 8 \mu g m^{-3}$) and RH (2-8%) over IGP and this positive feedback mechanism promoted
607 thickening of fog over IGP. However, an increase in absorbing aerosols in the PBL gave negative
608 feedback, increasing the shortwave heating and temperature particularly over CIGP. Fog forms when
609 air is saturated which occurs when the surface temperature is reduced or the moisture content increases
610 causing saturation of air. This study suggests that increase in RH saturated the air and the increase in
611 aerosols favoured fog formation as depicted by the thickening of fog intensity. Aqueous phase chemistry
612 on the other hand contributed significantly to secondary aerosols in the fog, especially sulfate aerosols,
613 indicating substantial formation of secondary aerosols in the cloud. The underpredicted secondary
614 aerosols over NWIGP where no fog occurred implies underestimation of formation of aerosols through
615 gas and aerosol chemistry in the model. This underestimation could also be linked to an underestimation
616 of pH in the default MOSAIC scheme (Ruan et al., 2022) which slows the secondary aerosol formation,
617 or an underestimation of the aqueous sulfur oxidation in haze aerosol at $> 80\%$ RH before the onset of
618 fog (Acharja et al., 2022), or missing multiphase oxidation processes (Wang et al., 2022). We also
619 observed that AR feedback with aqueous chemistry initiated the fog formation 1-2 hours earlier than
620 the initiation time in the simulation without AR feedback and without aqueous phase chemistry whereas
621 AR feedback alone led to early dissipation of fog. In addition, fog acted as an important sink of aerosols

622 in a polluted environment with increased dry deposition with cloud water. Thus, AR feedback and
623 aqueous chemistry play a significant role in modulating the distribution and concentration of aerosols
624 and evolution of fog in the PBL.

625 The large emission of aerosols and trace gases in the IGP makes the atmospheric dynamics as
626 well as chemistry complex, suggesting the need for more studies using both models and ground-based
627 measurements to better understand the processes. While all aerosol types interact with solar radiation
628 and reduce the surface reaching flux, presence of absorbing aerosols in the boundary layer and its
629 vertical distribution plays an important role in modulating the meteorology over IGP. It is therefore
630 crucial to improve the simulation of absorbing aerosols e.g., BC in the vertical as well as at the surface
631 to increase the accuracy in predicting formation as well as the dissipation of fog in this region. Emissions
632 from burning for residential heating are an important source of aerosols in IGP during post-monsoon
633 and winter and the inclusion of these sources in the emission inventory would improve the prediction
634 of wintertime aerosols. For example, the underestimation of chloride aerosol in the model indicates
635 unaccounted emission sources over IGP. Additionally, more detailed modeling studies are required to
636 understand the missing chemical processes if any in the model which leads to biases in sulfate-nitrate
637 and ammonium partitioning between gas and aerosol phases. We find that the change in PBL height
638 with AR feedback is sensitive to changes in LH, signifying the role of soil moisture in PBL dynamics.
639 Several studies have reported cooling over IGP due to an increase in irrigation (Kumar et al., 2017;
640 Mishra et al., 2020). Further investigations into the role of irrigation in the increasing fog events over
641 NWIGP would help in better understanding the formation and persistence of fog over this region. It can
642 be concluded that fog forecasting is a complex process due to the multiple factors involved and this
643 work suggests that AR feedback is important in fog forecasting while aqueous phase chemistry plays
644 an important role in defining the composition of aerosols over IGP.

1056 Figure 1 The MODIS reflectance (true color) map over Indo Gangetic Plains, India (study region)
1057 showing fog and haze cover on 23rd December (a) and 24th December (b)2017. (c) Anthropogenic
1058 emission of PM_{2.5} over IGP for December 2017 obtained from EDGAR-HTAP. The boxes represent the
1059 regions Northwest IGP (NWIGP), Central IGP (CIGP), and East IGP (EIGP).

1060

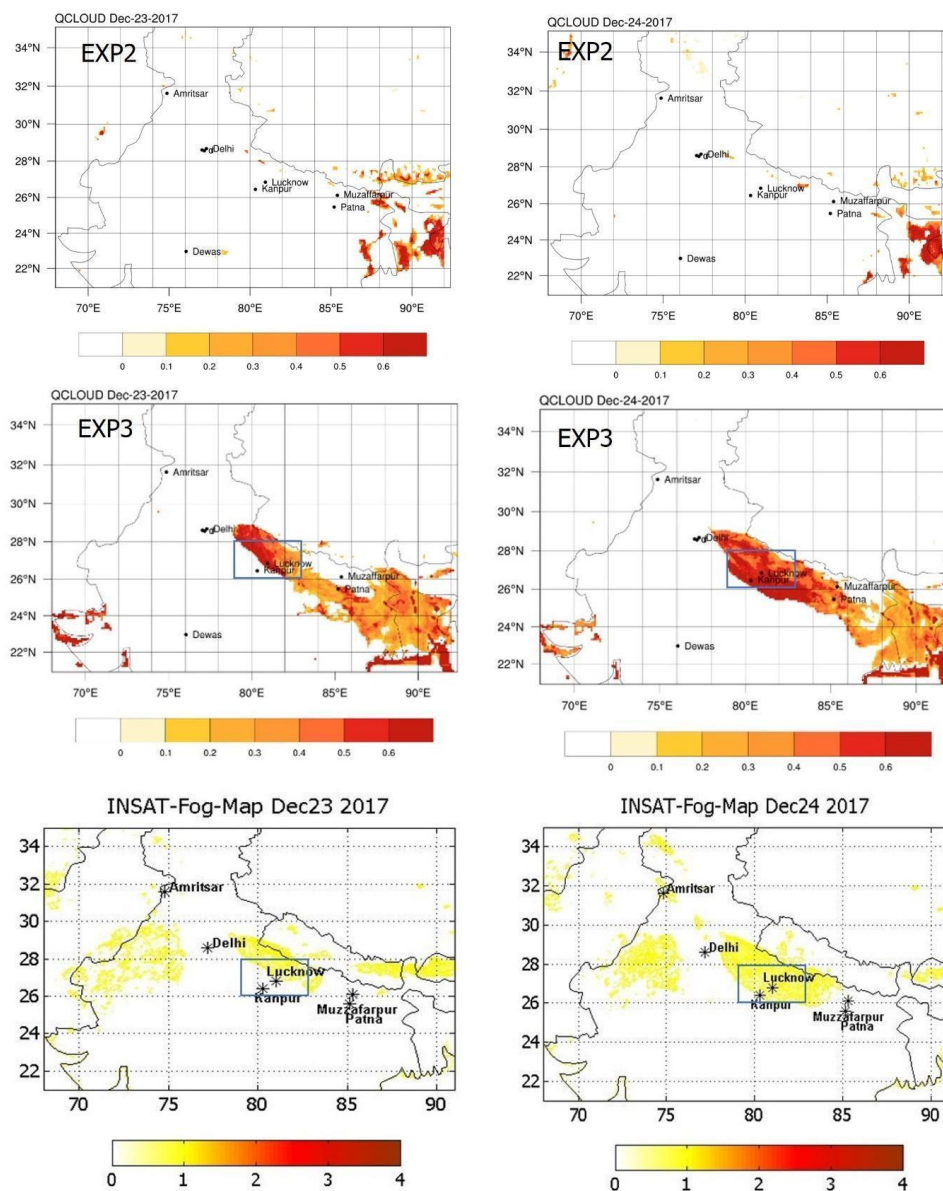

1061

1062

1063 Figure 2 Taylor Diagram of simulated (WRF-Chem) and observed (CPCB) relative humidity (left) and
 1064 2-m temperature (right) over IGP. The colors indicate the experiments. The marker (triangles) size
 1065 varies with a mean bias between the experiments and observation. Upside-down triangles represent
 1066 positive bias (exp-obs) and vice versa. The stations over IGP are denoted by number 1. Amritsar, 2.
 1067 IGI Airport (Delhi), 3. IHBAS (Delhi), 4. Dwarka (Delhi), 5. RKP (Delhi), 6. Kanpur, 7. Lucknow, 8.
 1068 Patna, 9. Muzaffarpur. The locations are marked in Fig. 1a.

1069

1070

1071 Figure 3 Comparison of fog coverage from WRF-Chem and INSAT-3D satellite for 23 and 24 Dec

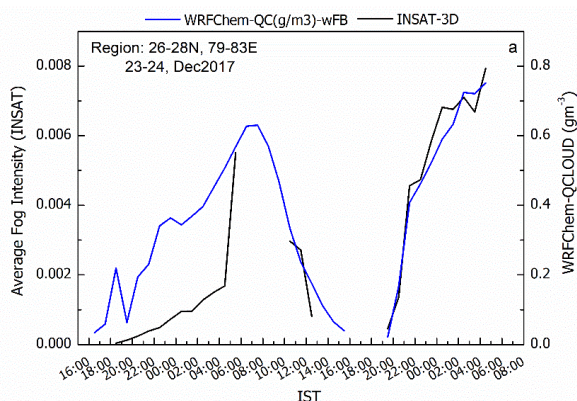

1072 2017. WRF-Chem fog is represented by surface layer cloud water mixing ratios (in g m^{-3}) whereas

1073 INSAT-3D provides fog intensity which varies from 0 to 4 indicating SHALLOW, MODERATE,

1074 DENSE, and VERY_DENSE, respectively. The rectangle in central IGP is the region for the time

1075 series analysis.

1076

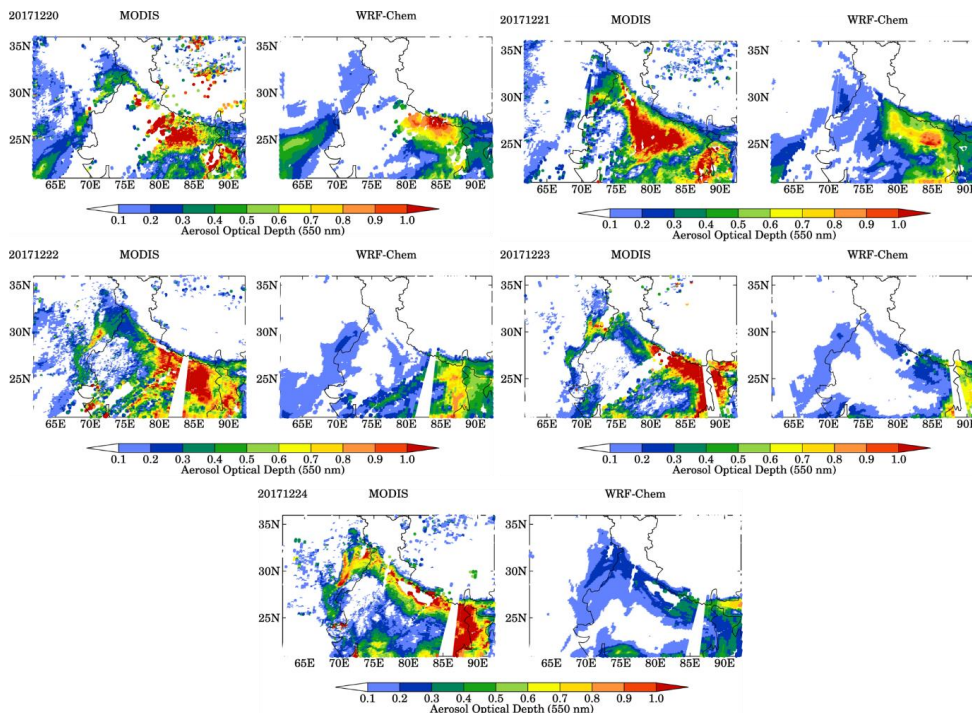

1077

1078 Figure 4 Average Hourly variation of fog on 23 and 24 December 2017 from WRF-Chem EXP3
1079 simulation and INSAT-3D satellite between 26°N-28°N,79°E-83°E (region shown in Fig 3). The time
1080 is in IST (Indian Standard Time; IST is 5.5 hours ahead of Universal Time Coordinate (UTC).

1081

1082
