ABSTRACT. Highly oxygenated organic molecules (HOMs) can participate in new particle formation (NPF) and enhance growth of newly formed particles partially because of their low volatility. Previous studies have shown formation of HOMs via autoxidation reactions of RO₂ intermediates generated by OH-initiated oxidation of anthropogenic volatile organic compounds (VOCs). It was also suggested that multi-generation OH oxidation could be an important source for aromatics-derived HOMs. However, our understanding on the generation of aromatics-derived HOMs are still insufficient, especially for their formation mechanisms, which determine molar yields of HOMs and are essential to the establishment of global chemical box models related to HOMs. In this study, with a potential aerosol formation oxidation flow reactor (PAM OFR), a series of OH-initiated oxidation experiments of 1,3,5-trimethylbenzene (1,3,5-TMB) were conducted to investigate the influences of the extent of OH exposure on the formation of aromatics-derived HOMs. The evolution of oxidation products of 1,3,5-TMB in an OH exposure range of $(0.5 - 5.0) \times 10^{10}$ molecules cm⁻³ s, equivalent to an OH exposure of 0.7 – 6.9 hours at an OH concentration of 2×10^6 molecules cm⁻³, was investigated by a nitrate-based chemical ionization mass spectrometer and a Vocus proton-transfer-reaction mass spectrometer, indicating significant secondary OH chemistry

37 during the ageing of stabilized first generation oxygenated products within an intraday OH
38 exposure and formation of various HOMs with more oxygen content and thus lower volatility.
39 In addition, organonitrates, formed after the introduction of NO_x into the reaction systems,
40 further confirmed the existence of such secondary reactions. Our study suggests an important
41 role of secondary OH chemistry in the oxidation of aromatics and elucidates detailed formation
42 mechanisms of certain HOM products.

43

44 **1 Introduction**

45 OH radicals can react with volatile organic compounds (VOCs) in the atmosphere,
46 converting primary pollutants to secondary ones. Generated from oxidation of VOCs,
47 oxygenated organic molecules (OOMs) are crucial in a variety of atmospheric chemical
48 processes, contributing efficiently to the formation of secondary organic aerosols (SOAs) and
49 ground-level O₃ (Ng et al., 2010; Wang et al., 2022; Qu et al., 2021). Among the enormous
50 number of oxygenated VOCs (OVOCs), highly oxygenated organic molecules (HOMs) have
51 recently attracted significant attention (Bianchi et al., 2019). Most of HOMs are low volatile
52 organic compounds (LVOCs) or extremely low volatile organic compounds (ELVOCs), and
53 thus are able to drive the initial formation of nucleated particles under certain conditions and
54 contribute to the subsequent growth of newly-formed particles, which finally enhance SOA
55 formation (Tröstl et al., 2016; Lehtipalo et al., 2018; Stolzenburg et al., 2018; Mohr et al., 2019;
56 Qiao et al., 2021).

57 Formation of HOMs is typically triggered by oxidation of VOCs in the gas phase. Peroxy
58 radicals (RO₂) are generated at the initial step and will undergo an intramolecular hydrogen
59 atom shift forming a hydroperoxide functionality and an alkyl radical. A molecular oxygen will
60 rapidly attach to this alkyl radical and form a new and more oxidized RO₂. This reaction is
61 called as autoxidation and the newly formed RO₂ can go through another autoxidation or
62 bimolecular termination reactions to form a stabilized product (Crouse et al., 2013).
63 Autoxidation is suggested to be responsible for widely detected HOMs in the atmosphere,
64 because it can form highly oxygenated RO₂ in a short time scale. In terms of bimolecular
65 reactions, RO₂ reacts appreciable only with hydroperoxyl radical (HO₂), NO, and another RO₂.
66 The RO₂ reaction chain in polluted areas is largely terminated by NO, which prohibits
67 generation of compounds with high oxidation levels and reduces yields of HOMs (Bianchi et
68 al., 2019).

69 Nevertheless, autoxidation reactions alone are not enough to explain the large numbers of
70 oxygen atoms in HOMs observed in laboratory experiments and ambient campaigns. [Take](#)
71 [alkylbenzenes as an example, previous studies suggest that the main products of OH-initiated](#)

72 oxidation of alkylbenzenes (C_xH_{2x-6} , $x=7, 8, \text{ or } 9$), i.e., bicyclic peroxy radicals (BPR, C_xH_{2x-6}
73 O_5^\bullet , $x=7, 8, \text{ or } 9$) (Jenkin et al., 2003), can undergo an autoxidation reaction and form a new
74 peroxy radical, $C_xH_{2x-6}O_7^\bullet$ ($x=7, 8, \text{ or } 9$) (Wang et al., 2017). Take alkylbenzenes as an example,
75 previous studies suggest that the main products of OH oxidation of alkylbenzenes (C_xH_{2x-6} , $x=7,$
76 $8, \text{ or } 9$), i.e., bicyclic peroxy radicals (BPR, $C_xH_{2x-6}O_5^\bullet$, $x=7, 8, \text{ or } 9$), can undergo an
77 autoxidation reaction and form a new peroxy radical, $C_xH_{2x-6}O_7^\bullet$ ($x=7, 8, \text{ or } 9$) (Jenkin et al.,
78 2003). The autoxidation of BPR could be fast if it has a favorable structure, as found in a
79 previous study The autoxidation reaction of BPR could be very fast because an allylic radical
80 will be formed after the hydrogen shift (Wang et al., 2017). On the other hand, the structure of
81 resulting $C_xH_{2x-6}O_7^\bullet$ is strongly different from that of BPR, whose autoxidation reaction rate
82 can be as low as the order of 0.001 s^{-1} , since it lacks enhancements from favorable transition
83 state geometries and substitutes or resonance structures (Bianchi et al., 2019; Otkjær et al.,
84 2018). Such a slow autoxidation reaction rate cannot explain the extensive existence of HOM
85 monomers with more than 7 oxygen atoms and HOM dimers with more than 10 oxygen atoms,
86 which are the maximum numbers of oxygen atoms in stabilized monomer and dimer products,
87 respectively, formed from $C_xH_{2x-6}O_7^\bullet$ (Molteni et al., 2018; Wang et al., 2020; Mentel et al.,
88 2015). Another possibility is the formation of a second oxygen bridge after the hydrogen shift
89 of BPR (Molteni et al., 2018), but this reaction pathway would not allow a further oxygenation
90 reaction without a breakage of the carbon ring, which is also unpromising. A very recent
91 investigation offers new insights into the formation mechanism of these products, indicating
92 the molecular rearrangement of BPR can initiate a series of autoxidation (Iyer et al., 2023).
93 However, the formation mechanism of HOMs with a large hydrogen atom number is still vague,
94 e.g., monomer products with 16 hydrogen atoms in the OH-initiated oxidation of TMB and
95 with 14 hydrogen atoms in the OH-initiated oxidation of xylene.

96 Multigeneration reactions of VOCs complicate HOMs' formation. Previous studies
97 indicate that HOMs can also be formed by sequential oxidation of stabilized first-generation
98 products of benzene and toluene (Garmash et al., 2020; Cheng et al., 2021). Garmash et al.
99 (2020) conducted OH oxidation experiments of benzene and toluene with an OH exposure
100 equivalent to atmospheric oxidation times of 10 hours – 15 days at OH concentrations of $\sim 10^6$
101 molecules cm^{-3} . Cheng et al. (2021) simulated oxidation of benzene and toluene with an OH
102 exposure equivalent to 2.4 – 19.4 days of atmospheric photochemical ageing. Certainly, such
103 extremely high OH exposures favor secondary OH chemistry and help to facilitate our
104 understanding on product distributions, but such a long timescale limits atmospheric
105 implications of their results, given the complex physical and chemical processes at night.

106 Compared to benzene and toluene, trimethylbenzene (TMB) is a precursor characterized
107 with much larger HOM molar yields when reacted with OH, and the abundance of TMB in the
108 atmosphere is unignorable (Molteni et al., 2018; Yuan et al., 2012). Previous laboratory
109 experiments on TMB-derived HOMs mainly focused on the autoxidation reactions of BPR and
110 the influences of NO_x, while the quantity of experiments was finite with a limited range of OH
111 exposure, bringing down the universality and applicability of conclusions (Tsiligiannis et al.,
112 2019; Wang et al., 2020). From the mechanism perspective, a number of HOM monomers with
113 more than 7 oxygen atoms detected in the OH-initiated oxidation of TMB were previously
114 assumed to be generated via multiple autoxidation reactions (Molteni et al., 2018). Nevertheless,
115 a subsequent OH oxidation of the first-generation oxygenated products might be more plausible
116 for the formation of HOM monomers with more than 7 oxygen atoms from the present point of
117 view. Indeed, laboratory experiments show that RO₂ formed during the second-generation OH
118 oxidation of the first-generation stabilized oxidation products can also undergo autoxidation
119 reactions, which entangles reaction mechanisms potentially involved in the formation of those
120 HOMs and justifies more investigations on the multigeneration OH oxidation of aromatics
121 (Wang et al., 2020). OH with an atmospheric concentration up to $6 \times 10^6 - 2.6 \times 10^7$ molecule
122 cm^{-3} , which is several times higher than the typical average atmospheric OH concentration,
123 1.5×10^6 molecule cm^{-3} (Jacob, 1999), has been frequently observed in both urban and suburban
124 environments in China (Tan et al., 2019; Lu et al., 2012).~~High atmospheric concentrations of~~
125 ~~OH have been frequently observed in both urban and suburban environments in China (Tan et~~
126 ~~al., 2019; Lu et al., 2012)~~, leading to a realistic implication of multigeneration OH oxidation.
127 Therefore, it is imperative to study chemical characteristics of formation reactions of HOMs at
128 different OH exposures, especially those fewer than or equivalent to one day of atmospheric
129 oxidation.

130 In this study, a series of laboratory experiments were conducted on the OH-initiated
131 oxidation of 1,3,5-TMB, selected as an example of anthropogenic VOCs with an OH exposure
132 equivalent to atmospheric oxidation times of roughly 0.7 – 6.9 hours at an average daytime OH
133 radical concentration of 2.0×10^6 molecules cm^{-3} . A nitrate-based chemical ionization mass
134 spectrometer (nitrate CIMS) and a Vocus proton-transfer-reaction mass spectrometer (Vocus
135 PTR) were deployed to measure the oxidation products and the precursor, respectively. From
136 the evolution of oxygenated products, we explored secondary OH chemistry of stabilized first-
137 generation oxygenated products generated by the oxidation of 1,3,5-TMB. Furthermore, the
138 influence of NO on the formation of HOMs was investigated by introducing N₂O into the
139 reaction system via formation of organonitrates.

140 **2 Methods**

141 OH-initiated oxidation of 1,3,5-TMB was investigated in a potential aerosol formation
142 oxidation flow reactor (PAM OFR) system at $T = 298 \pm 1$ K and a pressure of 1 atm (Lambe et
143 al., 2015). The experimental settings in this study differed slightly from what were used
144 previously (Wang et al., 2020). Forty OH experiments (Exp. 1 – 40) and twenty-eight NO_x
145 experiments (Exp. 41 – 68) were performed, the experimental conditions of which are
146 summarized in Table S1, including concentrations of the precursor, ozone, and NO and NO_2 .
147 The equivalent OH exposure in the OFR for each experiment was estimated according to the
148 precursor consumption, also listed in **Table S1**. OH exposures in the OFR were in the range of
149 $(0.5 - 5.0) \times 10^{10}$ molecules cm^{-3} s, equivalent to atmospheric oxidation times of roughly 0.7 –
150 6.9 hours for 1,3,5-TMB at an average daytime OH radical concentration of 2.0×10^6 molecules
151 cm^{-3} . In contrast, the OH oxidation lifetime for 1,3,5-TMB is around 2.4 hours at the
152 aforementioned atmospheric average daytime OH concentrations.

153 A home-made 1,3,5-TMB/ N_2 cylinder was used as a stable gaseous precursor source in the
154 experiments, from which the flow rate of 1,3,5-TMB/ N_2 varied between 1 – 3 sccm (standard
155 cubic centimeter per minute, standard to 0 °C, 1 atm), leading to 28.9 – 62.7 ppb of 1,3,5-TMB
156 in the OH oxidation experiments (**Table S1**). A total flow of 15 slpm (standard liters per minute,
157 standard to 0 °C, 1 atm) zero-gas generated by a zero-gas generator (model 737-13, Aadco
158 Instruments Inc.), together with the 1,3,5-TMB/ N_2 flow, was introduced into the OFR. The
159 reaction time in this series of experiments was kept at around 53 s. The flow in the PAM OFR
160 is laminar with a very low axial mixing, as characterized with a Taylor dispersion model in a
161 previous study (Lambe et al., 2011). Among the 15 slpm zero-gas, 6 slpm was initially passed
162 through a Nafion humidifier (Perma Pure Model FC100-80-6MSS) filled with ultra-pure water
163 and finally converged with the main flow into the OFR to achieve and keep a desired RH of
164 20.0 ± 2.5 % in the OFR throughout all the experiments, and 2 slpm was initially passed through
165 a separate ozone chamber, resulting in an initial ozone concentration of around 429 – 881 ppb
166 in the OFR. The OFR was operated with only the 254 nm lights on, under which the primary
167 oxidant production reactions in the OFR were $\text{O}_3 + h\nu (254 \text{ nm}) \rightarrow \text{O}_2 + \text{O}(^1D)$ and
168 $\text{O}(^1D) + \text{H}_2\text{O} \rightarrow 2\text{OH}$. After turning on of UV lights, a certain HOM compound is believed to
169 be generated if its signal is more than 3 standard deviations of its background signal. If the
170 fluctuations in the 1-min-averaged signals of both TMB in the Vocus PTR and typical HOMs
171 (i.e., $\text{C}_9\text{H}_{14}\text{O}_7(\text{NO}_3)^-$) in the nitrate CIMS are within 2% during a 10-min period, we assume
172 that a steady state has been reached. It usually took around no more than 2 minutes for the
173 signals of HOMs to stabilize after the adjustment of UV lights. We typically monitored the
174 reaction products for around 20 minutes for each experiment. An ozone monitor (Model 106-

175 M, 2B technologies) and a trace-gas analyzer for NO-NO₂-NO_x (Thermo, 42i-TL) were placed
176 at the exit of the OFR to measure concentrations of ozone and NO_x, respectively.

177 Non-tropospheric VOC photolysis is a typical issue that should be taken into account when
178 evaluating the settings of OFR laboratory experiments. Photolysis of the precursor and HOMs
179 were evaluated, showing that photolysis was not a contributor to our observation. The
180 photolysis rate of 1,3,5-TMB can be estimated based on the absorption cross-sections of 1,3,5-
181 TMB at 254 nm (Keller-Rudek et al., 2013) and UV photon fluxes estimated by a chemistry
182 model discussed in the following sections. The ratio of photolysis-to-OH reaction in our
183 experiments was merely 0.010 – 0.033. Hence, photolysis of 1,3,5-TMB was insignificant in
184 the OFR.

185 For stabilized products such as HOMs, the cross sections of organic molecules are usually
186 ~ 3.9×10⁻¹⁸ - 3.9×10⁻¹⁷ cm² (Peng et al., 2016), while the reaction rate between OH and the
187 stabilized first-generation products are estimated to be around 1.28×10⁻¹⁰ molecule⁻¹ cm³ s⁻¹, as
188 suggested by MCM (Jenkin et al., 2003). Hence, the ratio of photolysis rates of HOMs to their
189 secondary OH oxidation rates is estimated to be merely around 0.020 – 0.056.

190 For experiments with NO_x, 350 sccm N₂O (99.999%, Air Liquid) was added into the OFR
191 to produce and sustain NO_x mixing ratios at levels that were sufficiently high to be a competitive
192 sink for RO₂ radicals. NO and NO₂ were produced via the reaction $N_2O + O(^1D) \rightarrow 2NO$,
193 followed by the reaction $NO + O_3 \rightarrow NO_2 + O_2$. Two sets of irradiance intensities were chosen
194 for NO_x experiments, generally resulting in two NO_x levels, 1.8 ppb NO + 70 ppb NO₂ (Exp.
195 41 – 54) and 4.8 ppb NO + 120 ppb NO₂ (Exp. 55 – 68) at the exit of the OFR. With the aim to
196 slightly modify OH exposure but keep NO_x concentrations constant among each set of
197 experiments, the initial concentrations of 1,3,5-TMB were adjusted in a large range (16.7 – 84.1
198 ppb), as an increase in the precursor concentration corresponds to a larger sink for OH, while
199 RH and irradiances were not changed.

200 A nitrate CIMS (Ehn et al., 2014; Eisele and Tanner, 1993) and a Vocus PTR (Krechmer
201 et al., 2018) were deployed at the exit of the OFR to measure the oxidation products of 1,3,5-
202 TMB. These two mass spectrometers have been well characterized in a previous study (Wang
203 et al., 2020).

204 In this study, the sample flow rate for the nitrate CIMS was 8 slpm through a Teflon tube
205 with an outer diameter (OD) of 1/4 in. and a length of 70 cm. The sheath flow for the nitrate
206 CIMS was supplied by a zero-gas generator at a flow rate of 15 slpm. Mass resolution was
207 approximately 8000 for ions with m/z larger than 200 Th. HOMs generated from TMB
208 oxidation were charged in the ambient pressure interface region by collisions with nitrate
209 clusters, (HNO₃)_x·NO₃⁻ (x = 0 – 2), and detected by nitrate CIMS as clusters with NO₃⁻, i.e.,

210 HOM·NO₃⁻ (Hytinen et al., 2015). In addition, HOMs' signals were corrected with relative
211 transmission efficiencies of our nitrate CIMS obtained via a method reported previously
212 (Heinritzi et al., 2016). We followed the same sampling method of PAM OFR as those in
213 previous studies, in order to obtain a similar flow tube residence time distributions (RTDs) and
214 thus validate usage of a modified PAM chem v8 model to estimate concentrations of radicals
215 in the OFR as discussed below. We acknowledge that this is not a perfect sampling setting for
216 nitrate CIMS. However, the reduction in the sampling efficiencies of various HOMs is likely
217 to be close, if not identical, which keeps the distributions of HOMs.

218 Vocus PTR was applied to quantify precursor concentrations and measure volatile and
219 intermediate volatility oxidation products. The focusing ion-molecule reactor (FIMR) was
220 heated up and its temperature was maintained at 100 °C during the experiments. The FIMR can
221 be operated under 2.0 mbar without a strong interference from corresponding water clusters
222 when ionizing the neutral compounds. The Vocus front and back voltages were 650 V and 15
223 V, respectively, forming an axial voltage of 635V and a reduced electrical field (E/N , where E
224 is the electric field strength and N is the number density of the buffer gas in FIMR) of 180 Td.
225 The radio frequency (RF) voltages and frequency were set to be 450 V and 1.3 MHz,
226 respectively. The sample flow was introduced to the Vocus PTR through a Teflon tube with an
227 OD of 1/4 in. and a length of 120 cm from the OFR. A total sample flow of 1.4 slpm was
228 maintained by a pump with an orifice to minimize the delay time of sampling, from which
229 approximately 125 sccm was sampled into the FIMR through a capillary tube.

230 We did not quantify HOMs' concentrations. Since the inner diameters of PAM OFR,
231 sampling tube, and the nitrate CIMS inlet were different, and two reducing unions were used
232 during sampling, the estimation of the penetration efficiency and sampling efficiency of HOMs
233 are of a significant uncertainty. The initial concentrations of TMB utilized in the experiments
234 fluctuated slightly, which resulted from sample preparation processes, but generally were
235 around 50 ppbv. We tried to minimize potential influences of the differences in the initial TMB
236 concentrations on the signals of HOMs by normalizing the HOMs signals with the initial TMB
237 signal. To precisely illustrate changes in the abundance of HOMs at different OH exposures, a
238 normalized signal was chosen to present the abundance of detected HOMs, which is defined as
239 the ratio of the signals of HOMs in the nitrate CIMS normalized by the reagent ions and the
240 initial signal of 1,3,5-TMB, i.e., $S(HOMs)/S(TMB)$. $S(HOMs)$ is the signal of HOM detected
241 by the nitrate CIMS normalized with the signal of reagent ions, whereas $S(TMB)$ is the initial
242 signal of 1,3,5-TMB detected by the Vocus PTR.

243 ~~To further explore the secondary chemistry in the formation and evolution of HOMs, a~~
244 ~~nominal relative molar yield of HOMs, defined as $S(HOMs)/k[VOCs][OH]$, was used as a~~

245 substitute of molar HOM yields to reveal their changes under different OH exposures, which is
 246 similar to the definition from a previous study (Garmash et al., 2020). k , $[VOCs]$, and $[OH]$
 247 stand for the loss coefficient of HOMs in the OFR, the calibration factor of the nitrate
 248 CIMS and then divided by the OH oxidation reaction coefficient of 1,3,5-TMB, 1,3,5-TMB
 249 concentration detected at the exit of OFR, and calculated OH concentration in the OFR,
 250 respectively. The detailed derivation processes and calculation methods are provided in
 251 Supplementary Text S1.

252 To validate our settings, a PAM chemistry model (PAM chem v8), utilized widely in
 253 previous studies, were chosen with the latest updates to calculate radical profiles in our OFR
 254 (Li et al., 2015; Cheng et al., 2021; Wang et al., 2020; Mehra et al., 2020; Lambe et al., 2015,
 255 2018; Peng and Jimenez, 2020; Lambe et al., 2017). This model is based on a photochemical
 256 box model that includes chemistry of photolysis of oxygen, water vapor, and other trace gases
 257 by the primary wavelengths of mercury lamps, and simplified VOC and RO₂ chemistry (Table
 258 S2), but further reactions of the first-generation stabilized products and the second-generation
 259 organic radicals are not considered. The detailed reactions involved with RO₂ include:

270 R1, R2, and R3 are reactions of RO₂ + RO₂, forming alkoxy radicals, carbonyl termination
 271 products, and hydroxyl termination products, respectively. R4 is the accretion reaction,
 272 forming dimers via combination of two monomeric RO₂. R5 is the reaction between RO₂ and
 273 HO₂, forming hydroperoxyl radicals. R6 is the reaction between OH and RO₂, whose reaction
 274 channels/products are proposed according to previous studies (Table S3). R7 is the
 275 unimolecular reactions of RO₂ in the PAM OFR, among which the autoxidation reaction rate is
 276 the most significant. R8 and R9 are the reactions between NO and RO₂, generating alkoxy
 277 radicals and organonitrates, respectively. R10 is the physical loss of RO₂.

278 Kinetic data in the modified PAM chem v8 are obtained from the IUPAC (International
 279 Union of Pure and Applied Chemistry) dataset (<https://iupac-aeris.ipsl.fr>, last access: 26

309 [ranged between 4.9 and 47.9. In experiments with NO_x, the HO₂/OH ratio ranged between 3.7](#)
310 [and 17.9, whilst the RO₂/OH ratio ranged between 4.0 and 13.2. A recent comprehensive](#)
311 [ambient campaign conducted in the wintertime central Beijing reported mean daytime peak](#)
312 [concentrations of 8.8×10⁷, 3.9×10⁷, and 2.7×10⁶ molecule cm⁻³ for total RO₂, HO₂, and OH,](#)
313 [respectively \(Slater et al., 2020\), which corresponds to ambient RO₂/OH and HO₂/OH ratios of](#)

314 32.6 and 14.4 (Figure S1c), respectively. Therefore, radical ratios in our flow tube were
 315 generally in the same order of magnitude with the ambient conditions.

316 **Figure 1.** Fates of RO₂ generated in the low NO_x experiment (Exp. 44), urban Beijing (Slater
 317 et al., 2020), low OH and zero NO_x experiment (Exp. 19), and high OH and zero NO_x
 318 experiment (Exp. 12). Note that RO₂ fates of RO₂, OH, HO₂, and accretion channels are blown
 319 up for a better comparison for urban Beijing and the high OH and zero NO_x experiment.
 320 Reactions and kinetic rate coefficients used in the calculations are provided in Table S2.
 321

322
 323 We take Exp. 12, 19 and 44 as representative examples and compare simulation results
 324 with those from the ambient environment (Slater et al., 2020). The RO₂ lifetime in urban Beijing
 325 (Slater et al., 2020), low NO_x experiment, low OH and zero NO_x experiment, and high OH and
 326 zero NO_x concentration experiment was 1.0, 0.7, 1.2, and 0.6 s, respectively. As shown in
 327 Figure 1, In the low NO_x experiment (Exp. 44), the fractions of RO₂ + RO₂ (R1 – R3), accretion
 328 reaction (R4), RO₂ + HO₂ (R5), RO₂ + OH (R6), autoxidation (R7), and RO₂ + NO (R8 – R9)
 329 were 0.06%, 12.1%, 0.9%, 0.07%, 82.9%, and 4.0%, respectively. Calculated based on the
 330 mean daytime peak concentrations of radicals in Beijing (Slater et al., 2020), the fractions of
 331 R1 – R3, R4, R5, R6, R7, and R8 – R9 were 0.0005%, 0.09%, 0.007%, 0.003%, 87.4%, and
 332 12.5%, respectively. For the experiment with low OH and zero NO_x (Exp. 19), the fractions of
 333 R1 – R3, R4, R5, R6, and R7 were 0.05%, 10.0%, 0.15%, 0.14%, and 89.7%, respectively. For
 334 the one with high OH and zero NO_x (Exp. 12), the fractions of R1 – R3, R4, R5, R6, and R7
 335 were 0.08%, 16.6%, 0.54%, 1.8%, and 81.0%, respectively. The overall lifetimes of RO₂ and
 336 the fractions of autoxidation together determine the significant and similar roles of
 337 autoxidation in both laboratory experiments and the ambient. Therefore, the autoxidation chain
 338 will run to a similar oxidation level between the laboratory and the ambient.

339 In experiments with NO_x (e.g., Exp. 44), though the yields of organonitrates were lower in
340 the laboratory experiments, the formation pathways of these compounds were the same as those
341 in the ambient. Based on the formulae of organonitrates, the detailed formulae for monomer
342 RO₂ could be probed, which helps to investigate the existence of multi-generation OH oxidation.
343 Alkoxy radicals generated in the NO termination channel will unlikely influence the
344 distributions of C₉ stabilized products since they tend to get decomposed in the subsequent
345 reactions, as discussed in the Supplementary **Text S1**.

346 In experiments in absence of NO_x (e.g., Exp. 12 and 19), the proportions of R₈ - R₉, i.e.,
347 the NO channel in urban environment were reassigned to termination reactions of R₁ - R₆, i.e.,
348 RO₂ + RO₂, accretion reaction, RO₂ + HO₂, and RO₂ + OH. Comparison of relative fractions of
349 RO₂ fates of RO₂, OH, HO₂, and accretion channels (**Figure 1**) shows similarities between
350 laboratory and ambient results. By expanding proportions of these termination reactions,
351 laboratory investigations on distributions of products can be facilitated, as the detection of
352 certain HOM products became more precise and the mass spectra became simplified. As
353 discussed in the “results” session, products of R₂, R₃, and R₅ channels of the main BPR were
354 not detected in our experiments due to their low oxygen contents, while secondary products
355 between products of R₂, R₃, and R₅ channels of the main BPR and OH were observed.
356 Together with stabilized products and secondary products from C₉H₁₃O₇· (the peroxy radical
357 formed from autooxidation of BPR), secondary products between products of R₂, R₃, and R₅
358 channels of the main BPR and OH help to elucidate the first- and multi-generation reaction
359 pathways in the 1,3,5-TMB+OH system, according to their molecular formulae.

360 On the other hand, the much-expanded proportion of HOM dimers through accretion
361 reactions makes it inadequate to compare yields of HOM dimers and HOM monomers.
362 However, identification of HOM dimers can help us identify the exact RO₂ in the OFR and
363 confirm the conditions of secondary OH oxidation according to the number of hydrogen atoms
364 in the molecules.

365 3.2 Oxidation products

366 A total of 33 HOM monomers with formulae of C₇₋₉H₈₋₁₆O₆₋₁₁ and 22 HOM dimers with
367 formulae of C₁₇₋₁₈H₂₄₋₃₀O₈₋₁₄ were observed in the gas phase OH-initiated oxidation of 1,3,5-
368 TMB in the OFR, as listed in **Table S2S4**. The relative signal contributions of HOMs to the
369 total signals of all HOMs at an OH exposure of 2.38×10¹⁰ molecules cm⁻³ s are listed as an
370 example in **Table S2S4**. The most abundant HOM products were also shown in stack in **Figure**
371 **2**. ~~Figure 1 illustrates how OH exposures in the OFR are related to the total normalized signals~~
372 ~~of HOM monomers and HOM dimers measured at the OFR exit, which is whose relationships~~
373 ~~with OH exposures are~~ superimposed by a gamma function ($f(x) = ax^m e^{-x}$) simulation line

374 to guide the eyes. The sum of normalized HOM monomers' abundance increased
 375 monotonically up to the highest OH exposure of 5×10^{10} molecule cm^{-3} s, whereas those of
 376 HOM dimers showed a non-monotonic dependence on OH exposure. The observed faster
 377 increase of accretion products than that of HOM monomers can be explained jointly by the fast
 378 second-order kinetics for accretion reactions of RO_2 (Berndt et al., 2018b) and the high
 379 concentrations of relevant radicals in this work. On the other hand, most of the first-generation
 380 HOM dimers formed from accretion reactions contain at least one C=C bond and have more
 381 functionalities than HOM monomers, and thus should be more reactive to OH radicals, which,
 382 together with a faster deposition loss of dimers, results in a faster consumption of HOM dimers
 383 than monomers in the OFR. The faster production and consumption of HOM dimers allowed
 384 their concentrations to summit at middle levels of OH exposures. Because of the inherent
 385 disadvantage of laboratory experiments, RO_2 concentrations are always too high in the OFR,
 386 which has been pointed out in a previous study (Bianchi et al., 2019). The accretion reactions
 387 in the OFR are relatively more significant than it should be in the ambient atmosphere. We do
 388 not mean to compare HOM monomer and HOM dimer signals crossly here, but to pay attention
 389 to their formulae.

390 (a)

391

392 (b)

Figure 2. Normalized signals of (a) HOM monomers and (b) HOM dimers versus OH exposure that are fitted via a gamma function and shown in stacked.

Theoretically, at a given RH and UV (i.e., a given OH), an increase in the initial TMB would lead to formation of more RO₂, which corresponds to a larger RO₂/OH. However, under our experimental conditions, the RO₂/OH/HO₂ channels of RO₂ radicals are always minor, and thus an increase in RO₂/OH would not have a significant impact on the relative distribution of products formed from these channels. We compared product MS for experiments with a similar OH exposure but different initial concentrations of TMB (e.g., Exp. 3 v.s. Exp. 19, and Exp. 12 v.s. Exp. 22). The OH exposures of Exp. 3 and Exp. 19 were estimated by the modified PAM_chem_v8 model to be 5.2 × 10⁹ and 5.3 × 10⁹ molecule cm⁻³ s, respectively, but the initial concentration of TMB of Exp. 3 was 25% more than that in Exp. 19. Meanwhile, the OH exposures of Exp. 12 and Exp. 22 were 4.5 × 10¹⁰ and 4.4 × 10¹⁰ molecule cm⁻³ s, respectively, but the initial concentration of TMB of Exp. 12 was 48% more than that in Exp. 22. Comparisons between the product MS of Exp. 3 and Exp. 19 (Figure S2), as well as of Exp. 12 and Exp. 22, show that increase in the initial concentration of precursors generally resulted in a minor increment in the absolute signals of HOMs. Clearly, the relative distributions of products in these experiments are quite similar, indicating a minor difference in the relative distributions of products caused by fluctuations of initial concentrations of TMB.

3.2.1 HOM monomers in the absence of NO_x

414 Previous studies indicate that oxidation products derived from the peroxide-bicyclic
415 pathway represent a main fraction of HOMs (Wang et al., 2017; Zaytsev et al., 2019). For 1,3,5-
416 TMB, this pathway, as recommended by Master Chemical Mechanism (MCM), starts from a
417 BPR, $C_9H_{13}O_5\cdot$ (MCM name: TM135BPRO2) (Molteni et al., 2018). Scheme 1 has been
418 proposed to provide a good understanding of this reaction system and the structures of oxidation
419 products. Molteni et al. (2018) suggested that $C_9H_{13}O_7\cdot$, i.e., peroxy radical formed from
420 autooxidation of $C_9H_{13}O_5\cdot$ has two isomers, ~~which are referred as C9H13O7A and C9H13O7B~~
421 ~~for clarity in this study. The structures of these two isomers have been provided in Scheme 1.~~
422 ~~Their termination products are nominated according to the name of these two isomers,~~
423 ~~respectively. A second-step of endo-cyclization is required in the formation of one of the isomer,~~
424 ~~which is extremely slow and not competitive as shown in several previous studies using both~~
425 ~~experimental and theoretical approaches (Wang et al., 2017; Xu et al., 2020). Even if such a~~
426 ~~second O_2 bridging to a double bond is assumed to be possible, the abundance of this isomer~~
427 ~~should be significantly smaller than the other one, because of the much faster reaction rate of~~
428 ~~H-shift reaction. Therefore, we do not take the $C_9H_{13}O_7\cdot$ isomer containing a double endo-~~
429 ~~cyclization into consideration in this work. The majority of HOM monomers is generated from~~
430 ~~subsequent reactions of $C_9H_{13}O_5\cdot$ and newly formed $C_9H_{13}O_7\cdot$. A second-step of endo-~~
431 ~~eyelization is required in the formation of C9H13O7B, which is extremely slow and not~~
432 ~~competitive as shown in several previous studies using both experimental and theoretical~~
433 ~~approaches (Wang et al., 2017; Xu et al., 2020). Even if such a second O_2 bridging to a double~~
434 ~~bond is assumed to be possible, the abundance of C9H13O7B should be significantly smaller~~
435 ~~than C9H13O7A, because of the much faster reaction rate of H shift reaction in the reaction~~
436 ~~route for C9H13O7A. Therefore, the majority of HOM monomers are generated from~~
437 ~~subsequent reactions of $C_9H_{13}O_5\cdot$ and C9H13O7A, both of which contain one C=C bond in the~~
438 carbon backbone and thus have a feasible site for OH addition. Meanwhile, the autoxidation
439 reaction rate for newly formed $C_9H_{13}O_7\cdot$ C9H13O7A should be significantly smaller than
440 $C_9H_{13}O_5\cdot$, as there is no hydrogen atom in $C_9H_{13}O_7\cdot$ that is able to undergo a hydrogen atom
441 shift at an appreciable rate based on our current understanding. Therefore, the subsequent
442 autoxidation reaction should not be able to generate large amounts of more oxidized RO_2 .

443

444 **Scheme 1.** Oxidation pathways of the bicyclic peroxy radical $C_9H_{13}O_5\cdot$ (MCM name:
 445 **TM135BPRO2**) in the OH-initiated oxidation of 1,3,5-TMB. Green, blue, and black formulae
 446 denote alkyl peroxy radicals, alkoxy radicals and stabilized products, respectively. Black
 447 arrows denote the autoxidation pathway. MCM names for HO_2 - and RO_2 -termination products
 448 of **TM135BPRO2** are present.

449

450 The monomeric termination products of BPR, as shown in **Scheme 1**, were not detected
 451 by nitrate CIMS due to their own low oxygen content and thus relative low detection efficiency
 452 in nitrate CIMS, which has been investigated in a previous study (Riva et al., 2019). ~~were not~~
 453 ~~detected by nitrate CIMS because of their low oxygen content, whereas t~~ Those of
 454 $C_9H_{13}O_7\cdot$ were all observed clearly, including $C_9H_{12}O_6$, $C_9H_{14}O_6$, and $C_9H_{14}O_7$. Especially,
 455 $C_9H_{14}O_7$ was the most abundant one among all of the HOM monomer products (**Figure 2a**). As
 456 proved by a previous study, these three species should be typical first-generation stabilized
 457 products derived from autoxidation (Wang et al., 2020). ~~Their nominal relative molar yields~~

458 ~~increased with the OH exposures in the OFR, as shown in Figure S1, which implies that the~~
459 ~~secondary OH reactions of stabilized products can also produce these HOM monomers~~
460 ~~otherwise the observed yields would remain constant or decline (, the latter of which is due to~~
461 ~~the consumption of the products).~~ These HOM monomers ~~thus~~ should consist of several isomers
462 bearing the same formula, because products from the secondary reactions cannot share the same
463 structure as that of the one from the first-generation reaction. However, limited by the inherent
464 disadvantages of mass spectrometers, we could not distinguish isomers here and further
465 illustrate their different chemical behaviors.

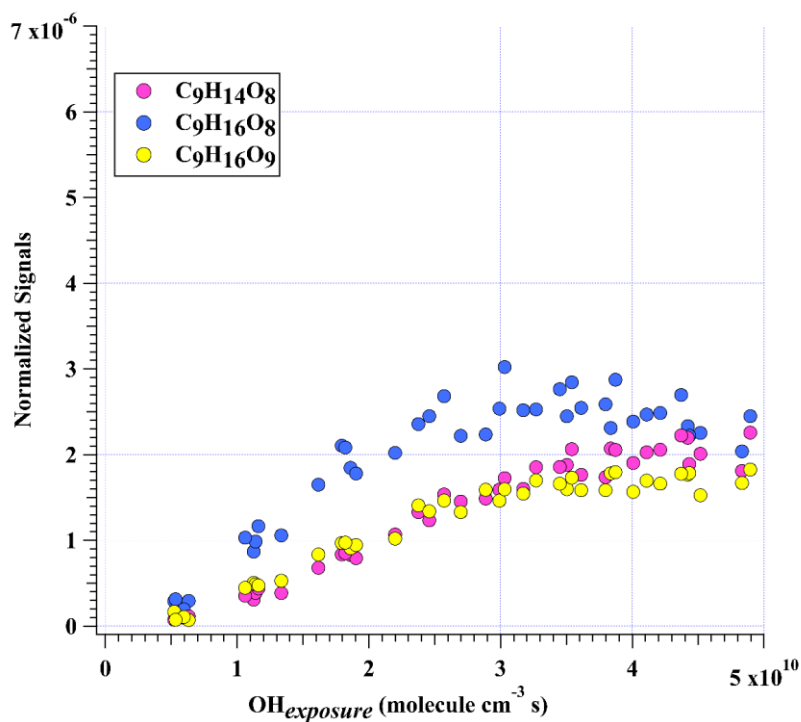

466 In addition to these three ones, the ~~nominal relative molar yields of other HOM monomers~~
467 ~~also showed an increase trend with more OH exposures.~~ The next most prominent products to
468 $C_9H_{14}O_7$ were $C_9H_{16}O_7$ and $C_9H_{16}O_8$ (Figure 2a3a), which are produced from multi-generation
469 oxidation according to their hydrogen content (Molteni et al., 2018; Cheng et al., 2021). Based
470 on the formulae of these three HOM monomers, they ($C_9H_{14}O_7$, $C_9H_{16}O_7$, and $C_9H_{16}O_8$) could
471 be formed from the bimolecular termination reactions of $C_9H_{15}O_8^*$, which can be generated by
472 an OH attack to $C_9H_{14}O_5$ (Scheme 2), the hydroperoxyl termination product of the BPR
473 $C_9H_{13}O_5^*$. The other HOM monomers characterized with high signals were $C_9H_{14}O_8$ and
474 $C_9H_{16}O_9$ (Figure 2b3b). These two HOM monomers ($C_9H_{14}O_8$ and $C_9H_{16}O_9$), together with
475 $C_9H_{16}O_8$, correspond to the monomeric termination products of $C_9H_{15}O_9^*$, which is highly likely
476 the peroxy radical generated by an OH attack to $C_9H_{14}O_6$ (Scheme 3), i.e., the hydroxyl
477 termination product of $C_9H_{13}O_7^*$. As discussed earlier, $C_9H_{13}O_7^*$ is a typical autoxidation
478 reaction product of the BPR of $C_9H_{13}O_5^*$. Therefore, detected signals of $C_9H_{16}O_8$ should be the
479 sum of two isomers' signals at least. Other HOM monomers were generally observed at much
480 lower signals and thus were not plotted individually.

481 (a)

482

483 (b)

484

485 **Figure 3.** Normalized signals of (a) $C_9H_{14}O_7$, $C_9H_{16}O_7$, and $C_9H_{16}O_8$ and (b) $C_9H_{14}O_8$, $C_9H_{16}O_8$,
 486 and $C_9H_{16}O_9$ measured at the exit of OFR in experiments without NO_x as a function of OH
 487 exposure. $C_9H_{16}O_8$ are shown in both plots to better illustrate the chemical profiles of different
 488 compound groups.

489

490 **Scheme 2.** Proposed formation pathways of $\text{C}_9\text{H}_{14}\text{O}_7$, $\text{C}_9\text{H}_{16}\text{O}_7$, and $\text{C}_9\text{H}_{16}\text{O}_8$ via the secondary
 491 OH oxidation of TM135BPOOH.

492

493 **Scheme 3.** Proposed formation pathways of $\text{C}_9\text{H}_{14}\text{O}_8$, $\text{C}_9\text{H}_{16}\text{O}_8$, and $\text{C}_9\text{H}_{16}\text{O}_9$ via the secondary
 494 OH oxidation of TM135BPOOH.

495 We further examined the nominal relative molar yields of HOM products with 12, 14, and
 496 16 hydrogen atoms, i.e., the common HOM monomers in our system. Based on the number of
 497 hydrogen atoms, $\text{C}_9\text{H}_{12}\text{O}_m$ (m refers to the oxygen atom number in a molecule) are presumably
 498 derived from first generation radicals of $\text{C}_9\text{H}_{13}\text{O}_m^\cdot$, and $\text{C}_9\text{H}_{16}\text{O}_m$ are from second generation
 499 radicals of $\text{C}_9\text{H}_{15}\text{O}_m^\cdot$, whereas $\text{C}_9\text{H}_{14}\text{O}_m$ can be either products of the first generation or second-
 500 generation OH oxidation (Molteni et al., 2018). Therefore, compounds with more hydrogen
 501 atoms are expected to increase more rapidly. However, the actual observation in our laboratory

502 ~~experiments conflicted with our preconceived expectations. The nominal relative molar yields~~
503 ~~of HOM monomers are shown in Figure 3. For clarity, only the 3 most abundant species with~~
504 ~~(a) 12, (b) 14, and (c) 16 hydrogen atoms, respectively are plotted. A prominent linear increase~~
505 ~~in the nominal molar yields of $C_9H_{14}O_m$ with larger oxygen atom numbers and $C_9H_{16}O_m$ was~~
506 ~~observed with the increase of OH exposure, whereas $C_9H_{14}O_m$ with fewer oxygen atoms and~~
507 ~~$C_9H_{12}O_m$ increased convexly. This is likely because the concentrations of RO_2 in the OFR~~
508 ~~increased with the increment of consumed precursors, which promoted the carbonyl and~~
509 ~~hydroxyl channels and favored formation of $C_9H_{12}O_m$ and $C_9H_{14}O_m$ with fewer oxygen atoms~~
510 ~~in the molecule.~~

511 It is worth noting that HOM monomers with 18 hydrogen atoms were never observed in
512 our experiments, including a potential stabilized hydroperoxyl products formed from $C_9H_{17}O_m\cdot$.
513 This is expected, since $C_9H_{17}O_m\cdot$ should be in really low concentrations, if ever existed. As
514 indicated by its hydrogen number, a $C_9H_{17}O_m\cdot$ was formed by at least two OH additions to the
515 C=C bond of a $C_9H_{13}O_m\cdot$, but the main BPR, $C_9H_{13}O_5\cdot$, and its autoxidation product ($C_9H_{13}O_7\cdot$),
516 are characterized with one C=C bond on the ring, which makes this formation pathway
517 impossible. Other ring-breakage pathways should not contribute to the formation of this radical
518 ($C_9H_{17}O_m\cdot$) because of their low branching ratio as determined by recent studies (Zaytsev et al.,
519 2019; Xu et al., 2020).

520 Scheme 4 shows the NO termination pathways of the main BPR $C_9H_{13}O_5\cdot$ and its
521 autoxidation product, $C_9H_{13}O_7\cdot$. After introducing N_2O into PAM OFR, quantities of
522 organonitrates were generated, including both C9 and C18 organonitrates. The averaged mass
523 spectrometry of nitrate CIMS in the 1.8 ppb NO experiment and 4.8 ppb NO experiment is
524 shown in Figure S3. Organonitrates were formed via the $NO + RO_2$ reaction, called as NO
525 termination reactions. The distribution of oxidation products under these two NO settings were
526 similar.

527

528 **Scheme 4.** NO termination reactions of the bicyclic peroxy radical $\text{C}_9\text{H}_{13}\text{O}_5\cdot$ (MCM name:
 529 **TM135BPRO2**) and its autoxidation reaction products. Green, blue, and black formulae denote
 530 alkyl peroxy radicals, alkoxy radicals and stabilized products, respectively. Black arrows
 531 denote the autoxidation pathway. MCM names of NO-termination products of **TM135BPRO2**
 532 are present.

533

534 As discussed above, most of the first-generation HOMs should contain a C=C bond in the
 535 carbon backbone. The ubiquitous existence of organonitrates that contain two nitrogen atoms
 536 exactly confirms the extensive secondary OH oxidation in the systems, because the NO
 537 termination reaction of RO_2 is the only pathway that can generate organonitrates in our
 538 experiments and this pathway can only introduce one nitrogen atom at a time, as indicated in

539 Scheme 4. RO₂ can react with NO₂ to form peroxy nitrates (ROONO₂) but these species are
540 thermally unstable except at very low temperatures or when the RO₂ is an acylperoxy radical
541 (Orlando and Tyndall, 2012), neither of which were not met in our experiments. The
542 concentrations of NO₃ were estimated to be lower than 1 pptv by our modified PAM chem v8
543 because of the existence of decent concentrations of NO, which would consume NO₃ at a rapid
544 reaction rate, i.e., 2.7×10⁻¹¹ molecule⁻¹ cm³ s⁻¹ (IUPAC dataset, <https://iupac-aeris.ipsl.fr>, last
545 access: 26 October 2023). Therefore, NO₂ and NO₃ were not likely to react with RO₂ to form
546 large amounts of organonitrates in our experiments. Taking the most abundant organonitrate,
547 C₉H₁₄N₂O₁₀, as an example, it was exactly the NO termination product of C₉H₁₄NO₉[•], which
548 was generated from an OH attack and a subsequent O₂ addition to C₉H₁₃NO₆, the NO
549 termination product of C₉H₁₃O₅[•]. For other organonitrates, C₉H₁₃NO₈, the second most
550 abundant organonitrate, could be either a NO termination product of C₉H₁₃O₇[•] or, together with
551 other most abundant organonitrates, C₉H₁₅NO₇ and C₉H₁₅NO₈, classical termination products
552 of C₉H₁₄NO₉[•].

553 The NO:RO₂ ratio in the PAM OFR is lower than typical values in the ambient atmosphere,
554 which is due to the existence of O₃ that was utilized to generate O(¹D) in the OFR and its rapid
555 reaction rate with NO. However, due to rapid reaction rate constants between NO and RO₂, i.e.,
556 around 8.5×10⁻¹² molecule⁻¹ cm³ s⁻¹, the reaction rate for the NO termination channel of RO₂
557 was as fast as around 0.3 – 1.0 s⁻¹. Large amounts of organonitrates would still be formed. Our
558 conclusion is also valid because of detection of compounds with multiple nitrogen atoms.

559 3.2.2 HOM dimers ~~in the absence of NO_x~~

560 Accretion reaction RO₂ + RO'₂ → ROOR' + O₂ is a source of gas-phase dimer
561 compounds from highly oxidized, functional RO₂ radicals. (Ehn et al., 2014; Berndt et al., 2018b;
562 Zhao et al., 2018; Berndt et al., 2018a) C₁₈H₂₆O₈ and C₁₈H₂₆O₁₀ are two typical accretion
563 reaction products in the 1,3,5-TMB + OH system, whose formation pathways have been
564 elucidated. (Berndt et al., 2018b) C₁₈H₂₆O₈ can only be formed via the accretion reaction of two
565 C₉H₁₃O₅[•]. C₉H₁₃O₃[•] is not likely to react with C₉H₁₃O₇[•] to form large amounts of C₁₈H₂₆O₈.
566 C₉H₁₃O₃[•] can only be formed after addition of a hydroxyl radical to the aromatic ring of 1,3,5-
567 TMB and a subsequent O₂ addition to the newly formed hydroxyl-substituted cyclohexadienyl
568 radical (Vereecken, 2019). However, the lifetime of this radical is extremely short, as C₉H₁₃O₃[•]
569 will undertake a ring-closure reaction and get attached by a O₂ very rapidly, forming BPR,
570 C₉H₁₃O₅[•]. Its short lifetime and low concentration, as indicated by Berndt et al. (2018), lead to
571 its insignificant role in the accretion reactions. In contrast, C₁₈H₂₆O₁₀ can be formed either by
572 the accretion reaction between C₉H₁₃O₅[•] and C₉H₁₃O₇[•] or via a second OH attack to C₁₈H₂₆O₈.
573 These two HOM dimers are so far the only ones that are confirmed to be formed via the

574 accretion reactions (Berndt et al., 2018b; Bianchi et al., 2019). There are currently no evidences
575 supporting that $C_9H_{15}O_m\cdot$ radicals can participate in the formation of HOM dimers with 28
576 hydrogens. Therefore, it hints that one could attribute the formation of $C_{18}H_{28}O_m$ to multi-
577 generation OH oxidation of $C_{18}H_{26}O_m$.

578 $C_{18}H_{26}O_{10}$ was characterized with the highest dimer signals for experiments with OH
579 exposures under 3.5×10^{10} molecule cm^{-3} s. Nevertheless, $C_{18}H_{26}O_{10}$, together with $C_{18}H_{28}O_{12}$,
580 $C_{18}H_{26}O_{12}$, $C_{18}H_{28}O_{11}$, $C_{18}H_{28}O_{13}$, and $C_{18}H_{28}O_{10}$ contributed more than 50% of total HOM
581 dimer signals at any OH exposure levels (Figure S22b). These six most abundant HOM dimers
582 correspond exactly to the hydroperoxyl, hydroxyl, and carbonyl termination products of
583 $C_{18}H_{27}O_{11}\cdot$ and $C_{18}H_{27}O_{13}\cdot$, respectively. These two RO_2 ($C_{18}H_{27}O_{11}\cdot$ and $C_{18}H_{27}O_{13}\cdot$), on the
584 other hand, could be generated by OH attacks to $C_{18}H_{26}O_8$ and $C_{18}H_{26}O_{10}$, respectively, which
585 strongly suggests the significant role of secondary OH chemistry in the formation of HOMs in
586 our experiments. In addition, $C_{18}H_{28}O_x$ can also be formed through accretion of a $C_9H_{13}O_m\cdot$
587 radical and a $C_9H_{15}O_m\cdot$ radical, as suggested by previous studies (Molteni et al., 2018; Wang et
588 al., 2020; Tsiligiannis et al., 2019). However, since a $C_9H_{15}O_m\cdot$ radical, as suggested by its
589 hydrogen atom number, can only be formed via an OH addition to the stabilized $C_9H_{14}O_m$
590 products through multi-generation OH reactions, our conclusion that $C_{18}H_{28}O_x$ are multi-
591 generation OH oxidation products still holds. Figure 4 shows the normalized signals of these
592 abundant HOM dimers at different OH exposures. ~~These HOM dimers increased under low OH
593 exposure levels but decreased with the increasing OH exposure that corresponds to 2.8—6.9
594 hours' atmospheric equivalent photochemical age.~~

595 (a)

596

597

(b)

598

599 **Figure 4.** Normalized signals of (a) $C_{18}H_{26}O_{12}$, $C_{18}H_{28}O_{12}$, and $C_{18}H_{28}O_{13}$, and (b) $C_{18}H_{26}O_{10}$,
 600 $C_{18}H_{28}O_{10}$, and $C_{18}H_{28}O_{11}$ measured at the exit of OFR in experiments without NO_x as a function
 601 of OH exposure.

602

603 This decrease of dimer at relatively high OH exposures are likely due to the accelerated
 604 accretion reactions in the OFR, resulted by the high RO_2 concentrations. The HOM dimers are

605 formed earlier compared to under ambient conditions and then can go through the further
606 oxidation reactions. Note that this does not mean the maximum concentrations of HOM dimers
607 will also accurately occur at the same OH exposures in the atmosphere, because the detailed
608 appearance time of the maximum concentrations of HOM dimers is dependent on their
609 formation rate and loss rate. In our experiments, the formation rate and loss rate were not
610 accelerated equally. On the other hand, the loss pathways of HOM dimers were not exactly the
611 same as the ambient due to the lack of aerosols in the OFR. With the decrease of particulate
612 pollution and thus condensation sinks in the polluted areas, the physical loss of HOMs might
613 be lower and the chemical process can be more important. This series of experiments are not
614 meant to specifically find out the detailed OH exposures when the maximum concentrations of
615 HOM dimers will occur, but try to indicate how HOM dimers evolve with the increase of OH
616 exposures. This work can be regarded as an indicator for the potential chemical fates of HOM
617 dimers in the atmosphere.*

618 ~~The nominal relative molar yields of the abovementioned HOM dimers are shown in~~
619 ~~Figure 5 as a function of OH exposure, except for $C_{18}H_{28}O_{11}$. The nominal relative molar yields~~
620 ~~of $C_{18}H_{28}O_{11}$ are not plotted in the Figure 5, since they overlapped quite closely with those of~~
621 ~~$C_{18}H_{26}O_{10}$, as can be deduced from Figure 4b. Compared with HOM monomers, variation~~
622 ~~tendencies of the nominal relative molar yields of HOM dimers are more diverse. Especially,~~
623 ~~the nominal relative molar yield of $C_{18}H_{26}O_8$ (Fig. S3) kept declination under growing OH~~
624 ~~exposure conditions, whereas that of $C_{18}H_{26}O_{10}$ (Fig. 5) appeared to reduce after a slight growth~~
625 ~~in the OH exposure range studied. The changes in the nominal relative molar yields of these~~
626 ~~two HOM dimers along with the OH exposure confirm the combined influences of accretion~~
627 ~~reactions and multi-generation OH oxidation reactions on their formation and evolution, i.e.,~~
628 ~~further OH oxidation consumed $C_{18}H_{26}O_8$ and $C_{18}H_{26}O_{10}$, and produced $C_{18}H_{26}O_{10}$, $C_{18}H_{26}O_{12}$,~~
629 ~~$C_{18}H_{28}O_{10}$, $C_{18}H_{28}O_{11}$, $C_{18}H_{28}O_{12}$ and $C_{18}H_{28}O_{13}$. These six HOM dimers contributed the~~
630 ~~majority of the total HOM dimer signals as mentioned above, while most of them were HOM~~
631 ~~dimers with 28 hydrogen atoms.~~

632 ~~The nominal relative molar yields of dimer compounds with 28 hydrogen atoms tended to~~
633 ~~increase with extended OH exposures, except that $C_{18}H_{28}O_{10}$ appeared to keep constant when~~
634 ~~OH exposure was larger than 1×10^{10} molecules $cm^{-3} \cdot s$. This again indicates that these H28~~
635 ~~products might be formed by an OH addition to a C=C bond in the accretion products, and then~~
636 ~~the newly formed alkyl radical further reacted and would go through the typical RO_2~~
637 ~~termination reactions.~~

638 It should be noted that the gas-phase chemistry in the PAM OFR cannot be exactly the
639 same as that in the ambient. Reactions of OH with OVOCs often lead to HO_2 formation,

640 resulting in a HO₂:RO₂ ratio larger than 1 in the real atmosphere (Bianchi et al., 2019). A recent
641 campaign conducted at a rural site in the Yangtze River Delta estimated that the local ratio of
642 HO₂:RO₂, the latter of which was presumably derived from longer chain alkanes (> C₃), alkenes,
643 and aromatic compounds, was around 1.66 (Ma et al., 2022). Such a high HO₂:RO₂:OH:HO₂
644 ratio condition is typically difficult to be simulated in the laboratory experiments, as the
645 precursors are usually hydrocarbons without any OVOCs (Peng and Jimenez, 2020). This is
646 exactly the case for our experiments, ~~but its influences on our conclusion were tiny, as have
647 been discussed in the Section 3.1, and the lower ratio of OH:HO₂ in our experiments than that
648 in the ambient atmosphere was confirmed by a photochemical model in our previous study
649 (Wang et al., 2020). In addition, high concentrations of radicals might also terminate the RO₂
650 chain earlier, which inhibits the autoxidation reactions in the PAM OFR. Therefore, the
651 difference in the distribution of products will not change our conclusion. However, these could
652 only influence the distribution of oxidation products at most, and would not affect the chemical
653 behaviors of HOMs under different OH exposures.~~

654 Such an active secondary OH chemistry is consistent with the fast OH reaction rates of
655 HOMs. We take C₁₈H₂₆O₈ ~~whose plausible structure is shown in Figure S4~~ as an example,
656 which is the accretion product of two C₉H₁₃O₅[•]. Its OH reaction rate constant is estimated to be
657 around $2.07 \times 10^{-10} \text{ cm}^3 \text{ molecule}^{-1} \text{ s}^{-1}$ according to the structure-activity relationship (Jenkin et
658 al., 2018b, a), whose details are provided in Supplementary **Text S2**. This rate is several times
659 larger than that of 1,3,5-TMB, which enables a very active secondary OH chemistry in the
660 system. MCM recommended an OH reaction rate of $1.28 \times 10^{-10} \text{ cm}^3 \text{ molecule}^{-1} \text{ s}^{-1}$ for
661 TM135BPOOH (C₉H₁₄O₅) and $1.00 \times 10^{-10} \text{ cm}^3 \text{ molecule}^{-1} \text{ s}^{-1}$ for TM135OBPOH (C₉H₁₂O₄)
662 (Jenkin et al., 2003). ~~The OH reaction rate for C₁₈H₂₆O₈ should also be fast due to the C=C
663 bonds in its structure, which is activated by the adjacent functionalities. The OH reaction rate
664 for C₁₈H₂₆O₈ should be around twice of these values, as there are two C=C bonds in its structure.~~
665 Our calculation result is consistent with this estimation.

666 ~~The distributions of C18 organonitrates also verified the extensive secondary reactions.~~
667 ~~The most abundant C18 organonitrate, C₁₈H₂₇NO₁₂ was a NO termination product of radical
668 C₁₈H₂₇O₁₁[•], which, as mentioned above, was the radical generated from the OH reaction with
669 C₁₈H₂₆O₈. C₁₈H₂₇NO₁₂ can also be formed either by accretion between a C₉H₁₅O_m[•] radical and
670 a C₉H₁₂NO_m[•] radical or accretion between a C₉H₁₃O_m[•] radical and a C₉H₁₄NO_m[•] radical. Both
671 C₉H₁₅O_m[•] and C₉H₁₄NO_m[•] radicals are a typical multi-generation RO₂ and thus prove
672 C₁₈H₂₇NO₁₂ is a multi-generation OH oxidation product. Other C18 organonitrates are believed
673 to be formed in a similar pathway. Hence, plenty of organonitrates have been formed via the
674 multi-generation OH reactions of first-generation stabilized products.~~

3.3 Products in the presence of NO_x

Scheme 2 shows the NO termination pathways of the main BPR C₉H₁₃O₅[•] and its autoxidation product, C₉H₁₃O₇[•]. After introducing N₂O into PAM OFR, quantities of organonitrates were generated, including both C9 and C18 organonitrates. The averaged mass spectrometry of nitrate CIMS in the 1.8 ppb NO experiment and 4.8 ppb NO experiment is shown in Figure S4. Organonitrates were formed via the NO + RO₂ reaction, called as NO termination reactions. The distribution of oxidation products under these two NO settings were similar.

As discussed above, most of the first generation HOMs should contain a C=C bond in the carbon backbone. The ubiquitous existence of organonitrates that contain two nitrogen atoms exactly confirms the extensive secondary OH oxidation in the systems, because the NO termination reaction of RO₂ is the only pathway that can generate organonitrates and this pathway can only introduce one nitrogen atom at a time, as indicated in Scheme 2. Taking the most abundant organonitrate, C₉H₁₄N₂O₁₀, as an example, it was exactly the NO termination product of C₉H₁₄NO₉[•], which was generated from an OH attack and a subsequent O₂ addition to C₉H₁₃NO₆, the NO termination product of C₉H₁₃O₅[•]. For other organonitrates, C₉H₁₃NO₈, the second most abundant organonitrate, could be either a NO termination product of C₉H₁₃O₇[•] or, together with other most abundant organonitrates, C₉H₁₅NO₇ and C₉H₁₅NO₈, classical termination products of C₉H₁₄NO₉[•].

The distributions of C18 organonitrates also verified the extensive secondary reactions. The most abundant C18 organonitrate, C₁₈H₂₇NO₁₂ was a NO termination product of radical C₁₈H₂₇O₁₄[•], which, as mentioned above, was the radical generated from the OH reaction with C₁₈H₂₆O₈. Other C18 organonitrates are believed to be formed in a similar pathway since no evidence supports that a nitrogen-containing monomeric RO₂ can go through accretion reactions. Hence, plenty of organonitrates have been formed via the multi-generation OH reactions of first-generation stabilized products.

4 Atmospheric Implications

This study highlights the influences of OH exposure on the distribution and evolution of 1,3,5-TMB-derived HOMs. Secondary OH reactions can influence HOMs' composition by directly reacting with the stabilized first-generation oxidation products, leading to enhanced formation of HOMs. Organonitrates generated in the NO experiments further confirmed this. Due to the elevated abundance and the reduced volatility of HOMs, growth rates of newly formed nanoparticles in the presence of HOMs should be raised, especially in high-OH environments, which prevails in the summer noon. Substantially high concentrations of OH

710 have been frequently observed in polluted environments during summer, e.g., megacities in
711 China (Tan et al., 2019), and thus more active secondary OH reactions are expected compared
712 to wintertime. As a plausible consequence, seasonal differences of HOMs and new particle
713 formation (NPF) are resulted (Qiao et al., 2021; Yao et al., 2018; Guo et al., 2022). Furthermore,
714 previous studies suggest that high concentrations of NO can suppress the formation of HOMs
715 via the suppression of autoxidation (Pye et al., 2019), but the influences of such a suppression
716 could have been overestimated, since secondary OH reactions can continue to oxidize the
717 stabilized organonitrates. Our conclusions help to explain the existing gap between model
718 prediction and ambient measurement on the HOMs concentrations (Qi et al., 2018), and to build
719 a global HOMs simulation model.

Scheme Captions

Scheme 1. Oxidation pathways of the bicyclic peroxy radical $C_9H_{13}O_5$ (MCM name: TM135BPRO2) in the OH-initiated oxidation of 1,3,5-TMB. Green, blue, and black formulae denote alkyl peroxy radicals, alkoxy radicals and stabilized products, respectively. Red arrows denote the autoxidation pathway. MCM names for HO_2 and RO_2 termination products of TM135BPRO2 are present, whereas MCM names for termination products of $C_9H_{13}O_7$ are unavailable and thus named according to the autoxidation intermediates.

Scheme 2. NO termination reactions of the bicyclic peroxy radical $C_9H_{13}O_5$ (MCM name: TM135BPRO2) and its autoxidation reaction products. Green, blue, and black formulae denote alkyl peroxy radicals, alkoxy radicals and stabilized products, respectively. Red arrows denote the autoxidation pathway. MCM names of NO-termination products of TM135BPRO2 are present, whereas MCM names for termination products of $C_9H_{13}O_7$ are unavailable and thus named according to the autoxidation intermediates.
