20
21 **ABSTRACT.** Highly oxygenated organic molecules (HOMs) can participate in new particle
22 formation (NPF) and enhance growth of newly formed particles partially because of their low
23 volatility. Previous studies have shown formation of HOMs via autoxidation reactions of RO₂
24 intermediates generated by OH-initiated oxidation of anthropogenic volatile organic
25 compounds (VOCs). It was also suggested that multi-generation OH oxidation could be an
26 important source for aromatics-derived HOMs. However, our understanding on the generation
27 of aromatics-derived HOMs are still insufficient, especially for their formation mechanisms,
28 which determine molar yields of HOMs and are essential to the establishment of global
29 chemical box models related to HOMs. In this study, with a potential aerosol formation
30 oxidation flow reactor (PAM OFR), atwo series of OH-initiated oxidation experiments of 1,3,5-
31 trimethylbenzene (1,3,5-TMB) were conducted to investigate ~~the influences of the extent of~~
32 ~~OH exposure on~~ the formation of aromatics-derived HOMs. In the first series, ~~The~~the evolution
33 of oxidation products of 1,3,5-TMB in an OH exposure range of (0.5 – 5.0)×10¹⁰ molecules cm⁻³
34 s, equivalent to an OH exposure of 0.7 – 6.9 hours at an OH concentration ([OH]) of 2×10⁶
35 molecules cm⁻³, was investigated by a nitrate-based chemical ionization mass spectrometer and
36 a Vocus proton-transfer-reaction mass spectrometer, indicating significant secondary OH

37 chemistry during the ageing of stabilized first generation oxygenated products within an
38 intraday OH exposure and formation of various HOMs with lower double bond equivalence
39 (DBE) more oxygen content and thus lower volatility. In addition, organonitrates, formed after
40 the introduction of NO_x into the reaction systems, further confirmed the existence of such
41 secondary reactions. The second series of experiments was conducted with same residence time
42 but much lower [OH], which also shows the generation of multi-generation HOMs with an [OH]
43 as low as 1.06×10⁷ molecules cm⁻³ for 53 s, i.e., an OH exposure of around 5.86×10⁸ molecules
44 cm⁻³ s. Our study suggests an important role of secondary OH chemistry in the oxidation of
45 aromatics, if these oxygenated products survived long enough in the ambient, and elucidates
46 detailed formation mechanisms of certain HOM products.

47 **1 Introduction**

48 OH radicals can react with volatile organic compounds (VOCs) in the atmosphere,
49 converting primary pollutants to secondary ones. Generated from oxidation of VOCs,
50 oxygenated organic molecules (OOMs) are crucial in a variety of atmospheric chemical
51 processes, contributing efficiently to the formation of secondary organic aerosols (SOAs) and
52 ground-level O₃ (Ng et al., 2010; Wang et al., 2022; Qu et al., 2021). Among the enormous
53 number of oxygenated VOCs (OVOCs), highly oxygenated organic molecules (HOMs) have
54 recently attracted significant attention (Bianchi et al., 2019). Most of HOMs are low ~~volatile~~
55 volatility organic compounds (LVOCs) or extremely low ~~volatile-volatility~~ organic compounds
56 (ELVOCs), and thus are able to drive the initial formation of nucleated particles under certain
57 conditions and contribute to the subsequent growth of newly-formed particles, which finally
58 enhance SOA formation (Tröstl et al., 2016; Lehtipalo et al., 2018; Stolzenburg et al., 2018;
59 Mohr et al., 2019; Qiao et al., 2021).

60 Formation of HOMs is typically triggered by oxidation of VOCs in the gas phase. Peroxy
61 radicals (RO₂) are generated at the initial step and will undergo an intramolecular hydrogen
62 atom shift forming a hydroperoxide functionality and an alkyl radical. A molecular oxygen will
63 rapidly attach to this alkyl radical and form a new and more oxidized RO₂. This reaction is
64 called as autoxidation and the newly formed RO₂ can go through another autoxidation or
65 bimolecular termination reactions to form a stabilized product (Crouse et al., 2013).
66 Autoxidation is suggested to be responsible for widely detected HOMs in the atmosphere,
67 because it can form highly oxygenated RO₂ in a short time scale. In terms of bimolecular
68 reactions, RO₂ reacts appreciable only with hydroperoxyl radical (HO₂), NO, and another RO₂.
69 The RO₂ reaction chain in polluted areas is largely terminated by NO, which prohibits
70 generation of compounds with high oxidation levels and reduces yields of HOMs (Bianchi et
71 al., 2019).

72 Nevertheless, autoxidation reactions alone are not enough to explain the large numbers of
73 oxygen atoms and low double bond equivalence (DBE, calculated as $nC - \frac{nH+nN}{2} + 1$ where
74 nC , nH , and nN stand for number of containing carbon, hydrogen, and nitrogen, respectively)
75 in HOMs observed in laboratory experiments and ambient campaigns. Take alkylbenzenes as
76 an example, previous studies suggest that the main products of OH-initiated oxidation of
77 alkylbenzenes (C_xH_{2x-6} , $x=7, 8, \text{ or } 9$), i.e., bicyclic peroxy radicals (BPR, $C_xH_{2x-5}O_5\cdot$, $x=7, 8, \text{ or } 9$) (Jenkin et al., 2003), can undergo an autoxidation reaction and form a new peroxy radical,
78 $C_xH_{2x-5}O_7\cdot$ ($x=7, 8, \text{ or } 9$) (Wang et al., 2017). The autoxidation of BPR could be fast if it has a
79 favorable structure, as found in a previous study (Wang et al., 2017). On the other hand, the
80 structure of resulting $C_xH_{2x-5}O_7\cdot$ is strongly different from that of BPR, whose autoxidation
81 reaction rate can be as low as the order of 0.001 s^{-1} , since it lacks enhancements from favorable
82 transition state geometries and substitutes or resonance structures (Bianchi et al., 2019; Otkjær
83 et al., 2018). Such a slow autoxidation reaction rate cannot explain the extensive existence of
84 HOM monomers with more than 7 oxygen atoms and HOM dimers with more than 10 oxygen
85 atoms, which are the maximum numbers of oxygen atoms in stabilized monomer and dimer
86 products, respectively, formed from $C_xH_{2x-5}O_7\cdot$ (Molteni et al., 2018; Wang et al., 2020b;
87 Mentel et al., 2015). Another possibility is the formation of a second oxygen bridge after the
88 hydrogen shift of BPR (Molteni et al., 2018), but this reaction pathway would not allow a
89 further oxygenation reaction without a breakage of the carbon ring, which is also unpromising.
90 A very recent investigation offers new insights into the formation mechanism of these products,
91 indicating the molecular rearrangement of BPR can initiate a series of autoxidation (Iyer et al.,
92 2023). However, the formation mechanism of HOMs with a large hydrogen atom number, i.e.,
93 low DBE, is still vague. e.g., For example, monomer products with 16 hydrogen atoms in the
94 OH-initiated oxidation of TMB and with 14 hydrogen atoms in the OH-initiated oxidation of
95 xylene were observed in the laboratory, both with a DBE of 2 lower than their precursors'
96 (Molteni et al., 2018), but their formation mechanisms cannot be explained by any known
97 mechanisms with only one OH attack.

99 Multigeneration reactions of VOCs complicate HOMs' formation. Previous studies
100 indicate that HOMs can also be formed by sequential oxidation of stabilized first-generation
101 products of benzene and toluene (Garmash et al., 2020; Cheng et al., 2021). Garmash et al.
102 (2020) conducted OH oxidation experiments of benzene and toluene with an OH exposure
103 equivalent to atmospheric oxidation times of 10 hours – 15 days at OH concentrations of $\sim 10^6$
104 molecules cm^{-3} . Cheng et al. (2021) simulated oxidation of benzene and toluene with an OH
105 exposure equivalent to 2.4 – 19.4 days of atmospheric photochemical ageing. Certainly, such
106 extremely high OH exposures favor secondary OH chemistry and help to facilitate our

107 understanding on product distributions, but such a long timescale limits atmospheric
108 implications of their results, given the complex physical and chemical processes at night.

109 Compared to benzene and toluene, trimethylbenzene (TMB) is a precursor characterized
110 with much larger HOM molar yields when reacted with OH, and the abundance of TMB in the
111 atmosphere is unignorable (Molteni et al., 2018; Yuan et al., 2012). Previous laboratory
112 experiments on TMB-derived HOMs mainly focused on the autoxidation reactions of BPR and
113 the influences of NO_x, while the quantity of experiments was finite ~~with a limited range of OH~~
114 ~~exposure, bringing down the universality and applicability of conclusions~~ restricting the
115 application of their conclusions to the more atmospheric relevant condition (Tsiligiannis et al.,
116 2019; Wang et al., 2020b). From the mechanism perspective, a number of HOM monomers
117 with more than 7 oxygen atoms detected in the OH-initiated oxidation of TMB were previously
118 assumed to be generated via multiple autoxidation reactions (Molteni et al., 2018). Nevertheless,
119 a subsequent OH oxidation of the first-generation oxygenated products might be more plausible
120 for the formation of HOM monomers with more than 7 oxygen atoms from the present point of
121 view. Indeed, laboratory experiments show that RO₂ formed during the second-generation OH
122 oxidation of the first-generation stabilized oxidation products can also undergo autoxidation
123 reactions, which entangles reaction mechanisms potentially involved in the formation of those
124 HOMs and justifies more investigations on the multigeneration OH oxidation of aromatics
125 (Wang et al., 2020b). OH with an atmospheric concentration ([OH]) up to $6 \times 10^6 - 2.6 \times 10^7$
126 molecule cm⁻³, which is several times higher than the typical average atmospheric ~~OH~~
127 ~~concentration [OH]~~, 1.5×10^6 molecule cm⁻³ (Jacob, 1999), has been frequently observed in both
128 urban and suburban environments in China (Tan et al., 2019; Lu et al., 2012), leading to a
129 realistic implication of multigeneration OH oxidation. Therefore, it is imperative to study
130 chemical characteristics of formation reactions of HOMs at different OH exposures, especially
131 those fewer than or equivalent to one day of atmospheric oxidation.

132 In this study, a series of laboratory experiments were conducted on the OH-initiated
133 oxidation of 1,3,5-TMB, selected as an example of anthropogenic VOCs with [OH] as high as
134 $9.32 \times 10^7 - 1.03 \times 10^9$ molecule cm⁻³ and an OH exposure equivalent to atmospheric oxidation
135 times of roughly 0.7 – 6.9 hours at an average daytime [OH] of 2.0×10^6 molecules cm⁻³. A
136 nitrate-based chemical ionization mass spectrometer (nitrate CIMS) and a Vocus proton-
137 transfer-reaction mass spectrometer (Vocus PTR) were deployed to measure the oxidation
138 products and the precursor, respectively. From the evolution of oxygenated products, we
139 explored secondary OH chemistry of stabilized first-generation oxygenated products generated
140 by the oxidation of 1,3,5-TMB. Furthermore, the influence of NO on the formation of HOMs
141 was investigated by introducing N₂O into the reaction system via formation of organonitrates.

142 In addition, another series of experiments under atmospheric relevant [OH] were conducted to
143 confirm the applicability of the above-developed multi-generation OH oxidation mechanisms
144 in the ambient atmosphere.

145 **2 Methods**

146 OH-initiated oxidation of 1,3,5-TMB was investigated in a potential aerosol formation
147 oxidation flow reactor (PAM OFR) system at $T = 298 \pm 1$ K and a pressure of 1 atm (Lambe et
148 al., 2015). Two series of experiments were conducted, one under high [OH] conditions and the
149 other under low [OH] conditions. Hereafter, we refer to the series of high [OH] experiments as
150 ‘the 1st-round experiments’ and the low [OH] as ‘the 2nd-round experiments’, respectively. The
151 i^{th} experiment in the 1st-round experiments is labelled as 1- i and the one in the 2nd-round
152 experiments as 2- i , where i stands for its serial number. The experimental settings in this study
153 differed slightly from what were used previously (Wang et al., 2020b). In the 1st-round
154 experiments, forty OH experiments without NO_x (Exp. 1-1 – 1-40) and twenty-eight NO_x
155 experiments with NO_x (Exp. 1-41 – 1-68) were performed. Seven experiments were conducted
156 in the 2nd-round, four without NO_x and three with NO_x. ~~The~~ The experimental conditions of
157 ~~which~~ are summarized in **Table S1**, including concentrations of the precursor, ozone, and NO
158 and NO₂. The equivalent OH exposure in the OFR for each experiment was estimated according
159 to the precursor consumption, also listed in **Table S1**. OH exposures in the OFR were in the
160 range of ~~(0.52 – 5.048.7) × 10¹⁰–10⁹~~ and $(0.6 – 5.5) \times 10^9$ molecules cm⁻³ s in the 1st-round and
161 2nd-round experiments, respectively. equivalent to atmospheric oxidation times of roughly 0.7
162 – 6.9 hours for 1,3,5-TMB at an average daytime OH radical concentration of 2.0×10^6
163 molecules cm⁻³. In contrast, the OH oxidation lifetime for 1,3,5-TMB is around 2.4 hours at the
164 aforementioned atmospheric average daytime OH concentrations.

165 A home-made 1,3,5-TMB/N₂ cylinder was used as a stable gaseous precursor source in the
166 experiments, from which the flow rate of 1,3,5-TMB/N₂ varied between 1 – 3 sccm (standard
167 cubic centimeter per minute, standard to 0 °C, 1 atm), leading to 28.9 – 62.7 ppb of 1,3,5-TMB
168 in the ~~OH-oxidation~~ 1st-round experiments, and 30.8 or 34.5 ppb of 1,3,5-TMB in the 2nd-round
169 experiments, respectively (**Table S1**). A total flow of 15 slpm (standard liters per minute,
170 standard to 0 °C, 1 atm) zero-gas generated by a zero-gas generator (model 737-13, Aadco
171 Instruments Inc.), together with the 1,3,5-TMB/N₂ flow, was introduced into the OFR. The
172 reaction time in ~~this both~~ series of experiments was kept at around 53 s. and the flow reactor
173 was kept as a plug flow in both series. The flow in the PAM OFR is laminar with a very low
174 axial mixing, as characterized with a Taylor dispersion model in a previous study (Lambe et al.,
175 2011). Among the 15 slpm zero-gas, 6 slpm was initially passed through a Nafion humidifier

176 (Perma Pure Model FC100-80-6MSS) filled with ultra-pure water and finally converged with
177 the main flow into the OFR to achieve and keep a desired RH of 20.0 ± 2.5 % in the OFR
178 throughout all the experiments, and 2 slpm was initially passed through a separate ozone
179 chamber, resulting in an initial ozone concentration of around 429 – 881 ppb in the OFR in the
180 1st-round experiments and 123 – 152 ppb in the 2nd-round experiments, respectively. The OFR
181 was operated with only the 254 nm lights on, under which the primary oxidant production
182 reactions in the OFR were $O_3 + h\nu (254 \text{ nm}) \rightarrow O_2 + O(^1D)$ and $O(^1D) + H_2O \rightarrow 2OH$.
183 After turning on of UV lights, a certain HOM compound is believed to be generated if its signal
184 is more than 3 standard deviations of its background signal. If the fluctuations in the 1-min-
185 averaged signals of both TMB in the Vocus PTR and typical HOMs (i.e., $C_9H_{14}O_7(NO_3)^-$) in
186 the nitrate CIMS are within 2% during a 10-min period, we assume that a steady state has been
187 reached. It usually took around no more than 2 minutes for the signals of HOMs to stabilize
188 after the adjustment of UV lights. We typically monitored the reaction products for around 20
189 minutes for each experiment. An ozone monitor (Model 106-M, 2B technologies) and a trace-
190 gas analyzer for NO-NO₂-NO_x (Thermo, 42i-TL) were placed at the exit of the OFR to measure
191 concentrations of ozone and NO_x, respectively.

192 Non-tropospheric VOC and OVOC photolysis is a typical issue that should be taken into
193 account when evaluating the settings of OFR laboratory experiments, especially under the high
194 UV light dose settings in the 1st-round experiments. Photolysis of the precursor and HOMs were
195 evaluated, showing that photolysis was not a contributor to our observation. The photolysis rate
196 of 1,3,5-TMB can be estimated based on the absorption cross-sections of 1,3,5-TMB at 254 nm
197 (Keller-Rudek et al., 2013) and UV photon fluxes estimated by a chemistry model discussed in
198 the following sections. The ratio of photolysis-to-OH reaction in our 1st-round experiments was
199 merely 0.010 – 0.033. Hence, photolysis of 1,3,5-TMB was insignificant in the OFR. For
200 stabilized products such as C9 and C18 HOMs, the cross sections of organic molecules are
201 usually $\sim 3.9 \times 10^{-18} - 3.9 \times 10^{-17} \text{ cm}^2$ (Peng et al., 2016), while the reaction rate between OH and
202 the stabilized first-generation products are estimated to be around $1.28 \times 10^{-10} \text{ molecule}^{-1} \text{ cm}^3 \text{ s}^{-1}$,
203 as suggested by MCM (Jenkin et al., 2003). Hence, the ratio of photolysis rates of C9 and
204 C18 HOMs to their secondary OH oxidation rates is estimated to be merely around 0.020 –
205 0.056 in the 1st-round experiments. In the 2nd-round, the influences of photolysis should be even
206 lower due to the much lower light intensity.

207 For experiments with NO_x in the 1st-round experiments, 350 sccm N₂O (99.999%, Air
208 Liquid) was added into the OFR to produce and sustain NO_x mixing ratios at levels that were
209 sufficiently high to be a competitive sink for RO₂ radicals. NO and NO₂ were produced via the
210 reaction $N_2O + O(^1D) \rightarrow 2NO$, followed by the reaction $NO + O_3 \rightarrow NO_2 + O_2$. Two sets of

211 irradiance intensities were chosen for NO_x experiments, generally resulting in two NO_x levels,
212 1.8 ppb NO + 70 ppb NO₂ (Exp. 1-41 – 1-54) and 4.8 ppb NO + 120 ppb NO₂ (Exp. 1-55 – 1-
213 68) at the exit of the OFR. With the aim to slightly modify OH exposure but keep NO_x
214 concentrations constant among each set of experiments, the initial concentrations of 1,3,5-TMB
215 were adjusted in a large range (16.7 – 84.1 ppb), as an increase in the precursor concentration
216 corresponds to a larger sink for OH, while RH and irradiances were not changed. In the 2nd-
217 round experiments, due to the lower (O¹D) in the PAM OFR, 2.5 slpm pure N₂O was utilized
218 instead, whereas the total flow rate was kept the same as that in the 1st-round. We lowered the
219 light intensity to obtain less lower [OH] in the PAM OFR, which also resulted in fluctuations in
220 the NO concentrations ([NO]) from 1.3 to 7.1 ppb and the NO₂ concentrations ([NO₂]) from 11
221 to 38 ppb.

222 A nitrate CIMS (Ehn et al., 2014; Eisele and Tanner, 1993) and a Vocus PTR (Krechmer
223 et al., 2018) were deployed at the exit of the OFR to measure the oxidation products of 1,3,5-
224 TMB in the 1st-round experiments. These two mass spectrometers have been well characterized
225 in a previous study (Wang et al., 2020b).

226 In this study, †The sample flow rate for the nitrate CIMS in the 1st round-experiments was
227 8 slpm through a Teflon tube with an outer diameter (OD) of 1/4 in. and a length of 70 cm. The
228 sheath flow for the nitrate CIMS was supplied by a zero-gas generator at a flow rate of 15 slpm.
229 Mass resolution was approximately 8000 for ions with m/z larger than 200 Th. HOMs generated
230 from TMB oxidation were charged in the ambient pressure interface region by collisions with
231 nitrate clusters, (HNO₃)_x·NO₃⁻ (x = 0 – 2), and detected by nitrate CIMS as clusters with NO₃⁻,
232 i.e., HOM·NO₃⁻ (Hyttinen et al., 2015). In addition, HOMs' signals were corrected with relative
233 transmission efficiencies of our nitrate CIMS obtained via a method reported previously
234 (Heinritzi et al., 2016). We followed the same sampling method of PAM OFR as those in
235 previous studies, in order to obtain a similar flow tube residence time distributions (RTDs) and
236 thus validate usage of a modified PAM_chem_v8 model to estimate concentrations of radicals
237 in the OFR as discussed below. We acknowledge that this is not a perfect sampling setting for
238 nitrate CIMS. However, the reduction in the sampling efficiencies of various HOMs is likely
239 to be close, if not identical, which keeps the distributions of HOMs.

240 Vocus PTR was applied to quantify precursor concentrations and measure volatile and
241 intermediate volatility oxidation products. The focusing ion-molecule reactor (FIMR) was
242 heated up and its temperature was maintained at 100 °C during the experiments. The FIMR can
243 be operated under 2.0 mbar without a strong interference from corresponding water clusters
244 when ionizing the neutral compounds. The Vocus front and back voltages were 650 V and 15
245 V, respectively, forming an axial voltage of 635V and a reduced electrical field (E/N , where E

246 is the electric field strength and N is the number density of the buffer gas in FIMR) of 180 Td.
247 The radio frequency (RF) voltages and frequency were set to be 450 V and 1.3 MHz,
248 respectively. The sample flow was introduced to the Vocus PTR through a Teflon tube with an
249 OD of 1/4 in. and a length of 120 cm from the OFR. A total sample flow of 1.4 slpm was
250 maintained by a pump with an orifice to minimize the delay time of sampling, from which
251 approximately 125 sccm was sampled into the FIMR through a capillary tube.

252 In the 2nd-round experiments, a Vocus CI-TOF (Towerk AG, Switzerland) equipped with
253 a Vocus Aim inlet and the same nitrate-ion chemical ionization source as adopted in the 1st-
254 round experiments was utilized to measure oxidation products, hereafter referred as nitrate CI-
255 TOF. The nitrate CI-TOF was characterized with a flat transmission efficiency between m/z 60
256 Th and m/z 500 Th, as well as a mass resolution of 10000 at m/z 200 Th.

257 In this series of experiments, the reaction products were sampled from the PAM OFR via
258 a 30 cm-long Teflon tube with a 1/2 in. OD to our nitrate CI-TOF. The Vocus PTR and the
259 ozone monitor were connected to the PAM OFR from a separate port via a 120 cm-long Teflon
260 tube with a 1/4 in. OD.

261 We did not quantify HOMs' concentrations. Since the inner diameters of PAM OFR,
262 sampling tube, and the nitrate CIMS inlet were different, and two reducing unions were used
263 during sampling, the estimation of the penetration efficiency and sampling efficiency of HOMs
264 are of a significant uncertainty. The initial concentrations of TMB utilized in ~~the both sets of~~
265 experiments fluctuated slightly, which resulted from sample preparation processes, ~~but~~
266 generally were around 50 ppbv, and were more obvious in the 1st-round experiments. Therefore,
267 in the discussion on the data of the 1st-round experiments, we tried to minimize potential
268 influences of the differences in the initial TMB concentrations on the signals of HOMs by
269 normalizing the HOMs signals with the initial TMB signal. To precisely illustrate changes in
270 the abundance of HOMs at different OH exposures, a normalized signal was chosen to present
271 the abundance of detected HOMs, which is defined as the ratio of the signals of HOMs in the
272 nitrate CIMS normalized by the reagent ions and the initial signal of 1,3,5-TMB, i.e.,
273 $S(HOMs)/S(TMB)$. $S(HOMs)$ is the signal of HOM detected by the nitrate CIMS normalized
274 with the signal of reagent ions, whereas $S(TMB)$ is the initial signal of 1,3,5-TMB detected by
275 the Vocus PTR.

276 To ~~validate our settings~~ compare chemical regimes of the two series of experiments and the
277 ambient atmosphere, a PAM chemistry model (PAM_chem_v8), utilized widely in previous
278 studies, were chosen with the latest updates to calculate radical profiles in our OFR (Li et al.,
279 2015; Cheng et al., 2021; Wang et al., 2020b; Mehra et al., 2020; Lambe et al., 2015, 2018;
280 Peng and Jimenez, 2020; Lambe et al., 2017). This model is based on a photochemical box

281 model that includes chemistry of photolysis of oxygen, water vapor, and other trace gases by
 282 the primary wavelengths of mercury lamps, and simplified VOC and RO₂ chemistry (Table S2),
 283 but further reactions of the first-generation stabilized products and the second-generation
 284 organic radicals are not considered. The detailed reactions involved with RO₂ include:

295 R1, R2, and R3 are reactions of RO₂ + RO₂, forming alkoxy radicals, carbonyl termination
 296 products, and hydroxyl termination products, respectively. R4 is the accretion reaction,
 297 forming dimers via combination of two monomeric RO₂. R5 is the reaction between RO₂ and
 298 HO₂, forming hydroperoxyl radicals. R6 is the reaction between OH and RO₂, whose reaction
 299 channels/products are proposed according to previous studies (Table S3). R7 is the
 300 unimolecular reactions of RO₂ in the PAM OFR, among which the autoxidation reaction rate is
 301 the most significant. R8 and R9 are the reactions between NO and RO₂, generating alkoxy
 302 radicals and organonitrates, respectively. R10 is the physical loss of RO₂.

303 Kinetic data in the modified PAM_chem_v8 are obtained from the IUPAC (International
 304 Union of Pure and Applied Chemistry) dataset (<https://iupac-aeris.ipsl.fr>, last access: 26
 305 October 2023) and the MCM dataset (MCM v3.3.1, <https://mcm.york.ac.uk/MCM/>, last access:
 306 9 October 2023), except for those that are specifically discussed in details in the supplement.
 307 Note that the total RO₂ concentration is simplified to be the sum of concentrations of BPR and
 308 C₉H₁₃O₇[•]. In this work, the autoxidation reaction and the accretion reaction of 1,3,5-TMB-
 309 derived BPR, as well as the subsequent reactions of the autoxidation product of BPR, i.e.,
 310 C₉H₁₃O₇[•], are newly implemented or modified in this model (Reaction No. ~~41-46~~ – ~~57-62~~ in
 311 Table S2). The newly implemented or modified reactions in this model are discussed in
 312 Supplementary Text S1. NO_x-related reactions are also included in the model. When we
 313 simulate experiments without NO_x, these reactions do not contribute to the simulation results.

314 For the 1st-round experiments, the input parameters of temperature, mean residence time,
 315 water vapor concentration, O₃ concentration, and the initial 1,3,5-TMB concentration are 25 °C,

316 53 s, 0.863%, 500 ppbv, and 50 ppbv, respectively, as measured directly ~~in the experiments.~~
317 ~~For the 2nd-round experiments, the input parameters of O₃ concentration and the initial 1,3,5-~~
318 ~~TMB concentration were updated as 150 ppbv and 30.8 ppbv, respectively. In the NO_x~~
319 ~~experiments, the input flow rate of N₂O is 350 sccm in the 1st-round experiments and 2.5 slpm~~
320 ~~in the 2nd-round experiments, respectively.~~ The actinic flux at 254 nm, I_{254} , is constrained by
321 comparing OH exposures by model output and OH exposures estimated by the consumption of
322 1,3,5-TMB as measured by a Vocus PTR. Consumption of O₃ estimated by the model agrees
323 well with the measured results, with discrepancies being always within 10% at different OH
324 exposures.

326 **3 Results and discussion**

327 **3.1 Validation of experiment settings** Comparison of chemical regimes

328 Concentration profiles of OH, RO₂, and HO₂ as a function of OH exposures in our high
329 [OH] experiments without NO_x, i.e., the 1st-round experiments, are illustrated in Figure S1a.
330 According to the modified PAM_chem_v8, when [OH] increased from $4.099.32 \times 10^8 - 10^7$ to
331 1.5703×10^9 molecule cm⁻³, [HO₂] increased from $7.727.25 \times 10^8$ to $3.482.79 \times 10^9$ molecule cm⁻³
332 ³, whereas [RO₂] concentrations increased from $4.835.17 \times 10^9$ to $8.489.5 \times 10^9$ molecule cm⁻³.
333 The radical concentrations in high [OH] experiments with NO_x (Figure S1b) varied in a similar
334 range, with [RO₂] ranging from $3.894.38 \times 10^9$ to $9.349.13 \times 10^9$ molecule cm⁻³, HO₂ ranging
335 from $3.664.47 \times 10^9$ to $6.826.47 \times 10^9$ molecule cm⁻³, and OH ranging from $4.833.86 \times 10^8$ to
336 $9.057.82 \times 10^8$ molecule cm⁻³, respectively. The ratios between HO₂/OH and RO₂/OH in ~~our the~~
337 1st-round experiments were generally in the same order of magnitude with the ambient
338 atmosphere (Whalley et al., 2021). ~~are displayed in Figure S1c. The HO₂/OH ratio ranged~~
339 ~~between 1.9 and 7.1 in our PAM OFR experiments without NO_x, and the RO₂/OH ratio ranged~~
340 ~~between 4.9 and 47.9. In experiments with NO_x, the HO₂/OH ratio ranged between 3.7 and 17.9,~~
341 ~~whilst the RO₂/OH ratio ranged between 4.0 and 13.2. A recent comprehensive ambient~~
342 ~~campaign conducted in the wintertime central Beijing reported mean daytime peak~~
343 ~~concentrations of 8.8×10^7 , 3.9×10^7 , and 2.7×10^6 molecule cm⁻³ for total RO₂, HO₂, and OH,~~
344 ~~respectively (Slater et al., 2020), which corresponds to ambient RO₂/OH and HO₂/OH ratios of~~
345 ~~32.6 and 14.4 (Figure S1c), respectively. Therefore, radical ratios in our flow tube were~~
346 ~~generally in the same order of magnitude with the ambient conditions.~~

347
 348 **Figure 1.** Fates of RO₂ generated in the low NO_x experiment (Exp. 44), urban Beijing (Slater
 349 et al., 2020), low OH and zero NO_x experiment (Exp. 19), and high OH and zero NO_x
 350 experiment (Exp. 12). Note that RO₂ fates of RO₂, OH, HO₂, and accretion channels are blown
 351 up for a better comparison for urban Beijing and the high OH and zero NO_x experiment.
 352 Reactions and kinetic rate coefficients used in the calculations are provided in [Table S2](#).

353 Radical concentrations were also estimated by the PAM chem v8 model to illustrate the
 354 chemical regimes in the 2nd-round experiments ([Table S4](#)). The average [HO₂], [OH], and [RO₂]
 355 were 9.7×10⁷, 1.64×10⁷, and 1.69×10⁹ molecule cm⁻³, respectively, in Exp. 2-3, and were
 356 6.7×10⁷, 1.04×10⁷, and 1.34×10⁹ molecule cm⁻³, respectively, in Exp. 2-4, both of which
 357 generally differ by no more than a factor of 3 from the summer daytime ambient ones in polluted
 358 atmosphere (Tan et al., 2017, 2018, 2019; Whalley et al., 2021; Lu et al., 2012). The average
 359 [HO₂], [OH], and [RO₂], as well as the NO and NO₂ concentrations in Exp. 2-7 are generally
 360 very close to those in the same environment (Tan et al., 2019).

Figure 1. (a) The fraction of monomeric termination reactions and (b) monomeric termination products of BPR in a representative high [OH] experiment without NO_x (Exp. 1-12), a representative low [OH] experiment without NO_x (Exp. 2-3), and summertime, urban Beijing (Whalley et al. 2021). NO_x related reactions and products for the Beijing study are not included for a better comparison. (c) The fraction of monomeric reactions (R1 - R3 and R5 - R9) and (d) monomeric termination products of BPR in a representative high [OH] experiment with NO_x (Exp. 1-48), a representative low [OH] experiment with NO_x (Exp. 2-7), and summertime,

376 urban Beijing (Whalley et al. 2021). Reactions and kinetic rate coefficients used in the
377 calculations are provided in Table S2.

378 We take Exp. 1-12 ([OH] = $\sim 8.47 \times 10^8$ molecule cm^{-3} and $\text{NO}_x = 0$) and Exp. 2-3 ([OH] =
379 $\sim 1.64 \times 10^7$ molecule cm^{-3} and $\text{NO}_x = 0$) as representative examples and compare simulation
380 results with those from the ambient atmosphere, since NO_x in the ambient is believed not to
381 impact relative ratios for $R1 - R3$, $R5$, and $R6$. In the ambient atmosphere, the average [HO₂],
382 [OH], and [RO₂] were 2.7×10^8 , 8.0×10^6 , and 1.4×10^9 molecule cm^{-3} , respectively, around
383 summertime noon in urban Beijing (Whalley et al. 2021), and $(4 - 28) \times 10^8$, $(0.8 - 2.4) \times 10^7$, and
384 1.2×10^9 molecule cm^{-3} (modeled) at a suburban site in Yangtze River Delta (Ma et al. 2022).
385 As shown in Figure 1a, for the most important RO₂, BPR, the fractions of monomeric
386 termination reactions of RO₂ + RO₂ ($R1 - R3$), RO₂ + HO₂ ($R5$), and RO₂ + OH ($R6$) were
387 6.2%, 29.3%, and 64.5%, respectively, in Exp.1-12. In contrast, the fractions were 32.5%,
388 31.8%, and 35.7%, respectively, in Exp. 2-3, whereas the values were 20.3%, 66.6%, and 13.2%,
389 respectively, for summertime, urban Beijing.

390 Our NO_x -free experiments are characterized with an inherent drawback that the proportion
391 of the HO₂ termination pathway ($R5$) is actually lower than that under ambient conditions,
392 which is similar to most other laboratory experiments (Bianchi et al., 2019). In our high [OH]
393 experiments without NO_x , the reaction rates of unimolecular reactions e.g., autoxidation
394 reaction ($R7$) and condensation ($R10$) did not change with [OH] that increased in our
395 experiments relative to that in the ambient. As a result, relative proportions of autoxidation and
396 condensation are lowered. On the other hand, 1,3,5-TMB-derived BPR was suggested to
397 undergo autoxidation ($R7$) at a reaction rate of 0.078 s^{-1} (Wang et al., 2017), which represents
398 36.8%, 94.4%, and 92.8% of the overall rates of $R1 - R3$ and $R5 - R7$ in Exp. 1-12, Exp. 2-3,
399 and summertime, urban Beijing, respectively. Because of its dominant proportion in Exp. 2-3
400 and the ambient, the autoxidation channel is not included for clarity in Figure 1a. Autoxidation
401 does possess a lower significance in our high [OH] experiments due to the other accelerated
402 bimolecular reactions. However, it would only influence the oxygen content of our products
403 but would not change the DBE. Both accretion reaction ($R4$) and condensation ($R10$) have been
404 taken into account in the model, but they would not influence the distributions of monomeric
405 stabilized products. We will specifically discuss these two pathways in the following sections
406 because of their complexity between the laboratory and ambient conditions.

407 RO₂ other than BPR and $\text{C}_9\text{H}_{13}\text{O}_7\cdot$ existed in the PAM OFR, which were not included in
408 the model simulation. Their reaction rates of the accretion reaction ($R4$) and the autoxidation
409 reaction ($R7$) should be different from BPR and $\text{C}_9\text{H}_{13}\text{O}_7\cdot$ due to the strong dependence of these
410 two reaction rates on the molecular structure. Rates for the other channels, on the other hand,

411 should be the same as those of BPR and $C_9H_{13}O_7^*$. Therefore, their fates in terms of the
412 monomeric termination reactions ($R1 - R3$, $R5 - R6$, and $R8 - R9$) should be similar as BPR
413 and $C_9H_{13}O_7^*$.

414 Calculated from yields of stabilized monomeric termination products of BPR, the fractions
415 of monomeric termination reaction products in Exp. 1-12, Exp. 2-3, and summertime, urban
416 Beijing (Whalley et al. 2021) are presented in Figure 1b, showing a lot of similarities between
417 these conditions. The fractions of R=O, ROH, ROOH, and ROOOH in Exp. 1-12 were 3.1%,
418 14.1%, 71.7%, and 11.1%, respectively. These fractions were 13.0%, 18.1%, 63.9%, and 5.0%,
419 respectively, in the Exp. 2-3, whereas the values were 5.3%, 6.5%, 87.0%, and 1.2%,
420 respectively, in the summertime Beijing case. Among them, the majority of products are always
421 ROOH and ROH, with ROOH being the most abundant. Therefore, the monomeric termination
422 products of BPR in our experiments are atmospheric relevant. In addition, only the R=O product
423 has a DBE higher than the reacted RO_2 , but merely accounted for a limited proportion. All the
424 other stabilized termination products have a DBE that is 1 lower than the precursor, and are the
425 majority in both laboratory and ambient conditions. This indicates that the majority of the first-
426 generation products typically have a DBE that is 1 lower than that of 1,3,5-TMB, whereas the
427 majority of subsequent-generation products typically have a DBE that is 2 lower than that of
428 1,3,5-TMB. Once a monomeric compound with a DBE that is ≥ 2 lower than that of 1,3,5-TMB
429 was observed, multi-generation OH reactions have happened in the system.

430 We take Exp. 12, 19 and 44 as representative examples and compare simulation results
431 with those from the ambient environment (Slater et al., 2020). The RO_2 -lifetime in urban Beijing
432 (Slater et al., 2020), low NO_x -experiment, low OH and zero NO_x -experiment, and high OH and
433 zero NO_x -concentration experiment was 1.0, 0.7, 1.2, and 0.6 s, respectively. As shown in
434 Figure 1, In the low NO_x -experiment (Exp. 44), the fractions of $RO_2 + RO_2$ ($R1 - R3$), accretion
435 reaction ($R4$), $RO_2 + HO_2$ ($R5$), $RO_2 + OH$ ($R6$), autooxidation ($R7$), and $RO_2 + NO$ ($R8 - R9$)
436 were 0.06%, 12.1%, 0.9%, 0.07%, 82.9%, and 4.0%, respectively. Calculated based on the
437 mean daytime peak concentrations of radicals in Beijing (Slater et al., 2020), the fractions of
438 $R1 - R3$, $R4$, $R5$, $R6$, $R7$, and $R8 - R9$ were 0.0005%, 0.09%, 0.007%, 0.003%, 87.4%, and
439 12.5%, respectively. For the experiment with low OH and zero NO_x (Exp. 19), the fractions of
440 $R1 - R3$, $R4$, $R5$, $R6$, and $R7$ were 0.05%, 10.0%, 0.15%, 0.14%, and 89.7%, respectively. For
441 the one with high OH and zero NO_x (Exp. 12), the fractions of $R1 - R3$, $R4$, $R5$, $R6$, and $R7$
442 were 0.08%, 16.6%, 0.54%, 1.8%, and 81.0%, respectively. The overall lifetimes of RO_2 -and
443 the fractions of autooxidation together determine the significant and similar roles of
444 autooxidation in both laboratory experiments and the ambient. Therefore, the autooxidation chain
445 will run to a similar oxidation level between the laboratory and the ambient.

446 In experiments in absence of NO_x (e.g., Exp.1-12), the proportions of R8 - R9, i.e., the
447 NO channel in the urban atmosphere were attributed to termination reactions of R1 - R6, i.e.,
448 RO₂ + RO₂, accretion reaction, RO₂ + HO₂, and RO₂ + OH. By expanding proportions of these
449 termination reactions, laboratory investigations on product distributions can be facilitated, as
450 the detection of certain HOM products became more precise and the mass spectra became
451 simplified.

452 In experiments with NO_x, the chemical fates of BPR in high [OH] experiments (Exp. 1-48
453 as an example, [OH] = ~6.77×10⁸ molecule cm⁻³, NO = ~1.93 ppb. NO₂ = ~68 ppb), low [OH]
454 experiments (Exp. 2-7 as an example, [OH] = ~1.69×10⁷ molecule cm⁻³, NO = ~1.30 ppb. NO₂
455 = ~11 ppb), and the summertime, urban Beijing are compared. As shown in Figure 1c, in all
456 three conditions, RO₂ reactions with NO were always the most significant pathway, with
457 autoxidation being the second most significant.

458 Accounting for at least 52% of monomeric termination products under all conditions,
459 organonitrates were always the most important termination products, as shown in Figure 1d.
460 On the other hand, based on the formulae of organonitrates, the detailed formulae for monomer
461 RO₂ could be probed, which can help us better understand the chemical reactions inside the
462 system. In experiments with NO_x (e.g., Exp. 44), though the yields of organonitrates were lower
463 in the laboratory experiments, the formation pathways of these compounds were the same as
464 those in the ambient. Based on the formulae of organonitrates, the detailed formulae for
465 monomer RO₂ could be probed, which helps to investigate the existence of multi-generation
466 OH oxidation. Alkoxy radicals generated in the NO termination channel will unlikely influence
467 the distributions of C9 stabilized products since they tend to get decomposed in the subsequent
468 reactions, as discussed in the Supplementary Text S1.

469 ~~In experiments in absence of NO_x (e.g., Exp. 12 and 19), the proportions of R8 - R9, i.e.,~~
470 ~~the NO channel in urban environment were reassigned to termination reactions of R1 - R6, i.e.,~~
471 ~~RO₂ + RO₂, accretion reaction, RO₂ + HO₂, and RO₂ + OH. Comparison of relative fractions of~~
472 ~~RO₂ fates of RO₂-OH, HO₂, and accretion channels (Figure 1) shows similarities between~~
473 ~~laboratory and ambient results. By expanding proportions of these termination reactions,~~
474 ~~laboratory investigations on distributions of products can be facilitated, as the detection of~~
475 ~~certain HOM products became more precise and the mass spectra became simplified. As~~
476 ~~discussed in the “results” session, products of R2, R3, and R5 channels of the main BPR were~~
477 ~~not detected in our experiments due to their low oxygen contents, while secondary products~~
478 ~~between products of R2, R3, and R5 channels of the main BPR and OH were observed.~~
479 ~~Together with stabilized products and secondary products from C₉H₁₃O₇· (the peroxy radical~~
480 ~~formed from autoxidation of BPR), secondary products between products of R2, R3, and R5~~

481 channels of the main BPR and OH help to elucidate the first and multi-generation reaction
482 pathways in the 1,3,5-TMB+OH system, according to their molecular formula.

483 On the other hand, due to the complexity of ambient RO₂ pool, it is difficult to estimate
484 the detailed fraction of accretion reactions R4. In the laboratory experiments, RO₂ pool mainly
485 consists of BPR and its autoxidation reaction product C₉H₁₃O₇·, which both can undergo
486 accretion reaction rapidly (Berndt et al., 2018b). The concentrations of these two radicals were
487 estimated by PAM_chem_v8 according to the kinetics discussed in Supplementary Text S1. The
488 reaction rate of accretion (R4) for BPR was around 1.61 s⁻¹ in Exp.1-12, being 61.8% of R1 –
489 R7, and was 0.29 s⁻¹ in Exp.2-3, equivalent to 21.1% of R1 – R7. Certain uncertainties exist
490 in the estimation of the proportions of accretion reactions, as the PAM_chem_v8 model only
491 includes the first-generation reactions of precursors, whereas the subsequential fragmentation
492 and re-initiation of stabilized products can generate a series of new RO₂ that will influence the
493 proportions of accretion reactions. We are only certain that the significance of accretion
494 reactions in both Exp. 1-12 and Exp. 2-3 is larger than the ambient. The much-expanded
495 proportion of HOM dimers through accretion reactions makes it inadequate to compare yields
496 of HOM dimers and HOM monomers. However, this deviation will not influence our
497 conclusion on multi-generation OH oxidation and identification of HOM dimers can help us
498 identify the exact RO₂ in the OFR and confirm the conditions of secondary OH oxidation
499 according to the number of hydrogen atoms in the molecules.

500 In addition, certain compounds might have condensed onto pre-existing particles in the
501 real atmosphere before an appreciable fraction of such compounds undergoes the re-initiated
502 OH oxidation. Therefore, even the same product can be generated both in the laboratory
503 experiments and the ambient atmosphere, the relative significance of this product is not
504 completely identical. Though OOMs might have the potential to undergo multi-generation OH
505 oxidation, the exact proportion of this reaction in the ambient strongly depends on their
506 volatility, in other words, condensation sink of these OOMs. The typical monomeric
507 termination products of 1,3,5-TMB-derived BPR, C₉H₁₂O₄, C₉H₁₄O₄, C₉H₁₄O₅, and C₉H₁₃NO₆,
508 are estimated to have saturation vapor concentrations (C*) of 30.20, 30.20, 0.85, and 3.39 μg/m³
509 at 300 K with the volatility parameterization developed in the CLOUD chamber oxidation
510 experiments of aromatics, respectively (Wang et al., 2020a). From the perspective of volatility,
511 they all belong to semi-volatile organic compounds (SVOC, 0.3 < C* < 300 μg/m³) and are
512 expected to exist in both the condensed and the gas phases at equilibrium in the atmosphere
513 (Bianchi et al., 2019). Compared to ambient conditions, their condensation rates in the
514 laboratory were biased to be lower due to the accelerated bimolecular reactions. However, this
515 will not prevent the high [OH] experiments from showing the potential and ability of these

516 compounds to go through re-initiated OH oxidation, as these compounds would exist in
517 significant fractions in the gas phase in the real atmosphere.

518 However, the conditions are completely distinct for other HOM monomer products and
519 HOM dimer products with much lower volatility. It is difficult for a HOM dimer, e.g., C₁₈H₂₆O₁₀
520 estimated with a C* of 7.24×10⁻¹³ μg/m³ at 300 K, to survive long enough to experience an
521 appreciable re-initiated photochemical ageing. The lifetime of HOMs that can be classified as
522 LVOCs (3×10⁻⁵ < C* < 0.3 μg/m³) and ELVOCs (C* < 3×10⁻⁵ μg/m³) can be estimated
523 according to the condensation sink (CS) in the atmosphere, as they are lost irreversibly onto
524 surfaces. The median value of CS in urban Beijing was reported to be around 0.019 s⁻¹ and
525 0.057 s⁻¹ during NPF days and non-NPF days, respectively, whereas the values in Shanghai
526 were reported to be around 0.013 s⁻¹ and 0.017 s⁻¹, respectively (Deng et al., 2020; Yao et al.,
527 2018), which are all much higher than the physical loss in our PAM OFR, i.e., 0.0023 s⁻¹, as
528 stated in the **Supplementary Text S1**. LVOCs and ELVOCs are believed to be lost irreversibly
529 to the surface in both the laboratory and ambient because of their low volatility. However, by
530 assuming a similar diffusion coefficient of LVOCs and ELVOCs to that of sulfuric acid, the
531 lifetimes of LVOCs and ELVOCs in the ambient still can be as high as 77 s for the condensation
532 loss, which is close to the residence time of our PAM OFR. Therefore, LVOCs and ELVOCs
533 should at least have the potential to experience the same OH exposures in the ambient as those
534 in our low [OH] experiments, i.e., at least 5.86×10⁸ molecule cm⁻³ s, if they were generated. On
535 the other hand, the detailed proportions of LVOCs and ELVOCs after a large OH exposure
536 should be lower than those in the lab due to their magnified physical loss in the ambient. This
537 means that if the multi-generation products of those compounds were observed in the ambient
538 air, they should have been generated via a reaction that happened very recently.

539 **3.2 Oxidation products in high [OH] experiments**

540 A total of 33 HOM monomers with formulae of C₇₋₉H₈₋₁₆O₆₋₁₁ and 22 HOM dimers with
541 formulae of C₁₇₋₁₈H₂₄₋₃₀O₈₋₁₄ were observed in the 1st-round experiments of gas phase OH-
542 initiated oxidation of 1,3,5-TMB in the OFR, i.e., high [OH] experiments, as listed in **Table**
543 **S4S5**. The relative signal contributions of HOMs to the total signals of all HOMs at an OH
544 exposure of 2.38×10¹⁰ molecules cm⁻³ s are listed as an example in **Table S4S5**. The most
545 abundant HOM products were also shown in **stack in Figure 2**, whose relationships with OH
546 exposures are superimposed by a gamma function ($f(x) = ax^m e^{-x}$) simulation line to guide
547 the eyes. The sum of normalized HOM monomers' abundance increased monotonically up to
548 the highest OH exposure of 5×10¹⁰ molecule cm⁻³ s, whereas those of HOM dimers showed a
549 non-monotonic dependence on OH exposure. The observed faster increase of accretion
550 products than that of HOM monomers can be explained jointly by the fast second-order kinetics

551 for accretion reactions of RO₂ (Berndt et al., 2018b) and the high concentrations of relevant
552 radicals in this work. On the other hand, most of the first-generation HOM dimers formed from
553 accretion reactions contain at least one C=C bond and have more functionalities than HOM
554 monomers, and thus should be more reactive to OH radicals, which, together with a faster
555 deposition loss of dimers, results in a faster consumption of HOM dimers than monomers in
556 the OFR. The faster production and consumption of HOM dimers allowed their concentrations
557 to summit at middle levels of OH exposures. As stated in Section 3.1, Bbecause of the inherent
558 disadvantage of laboratory experiments, [RO₂]-concentrations are-is always too high in the OFR,
559 which has been pointed out in a previous study (Bianchi et al., 2019). The accretion reactions
560 in the OFR are relatively more significant than it should be in the ambient atmosphere. We do
561 not mean to compare HOM monomer and HOM dimer signals crossly here, but to pay attention
562 to their formulae.

563 (a)

564

565 (b)

566
 567 **Figure 2.** Normalized signals of (a) HOM monomers and (b) HOM dimers versus OH exposure
 568 in the high [OH] experiments, which that are fitted via a gamma function and shown in stacked.

569
 570 Theoretically, at a given RH and UV (i.e., a given [OH]), an increase in the initial TMB
 571 would lead to formation of more RO₂, which corresponds to a larger RO₂/OH. However, under
 572 our high [OH] experimental conditions, the RO₂/OH/HO₂ channels of RO₂ radicals are always
 573 minor, and thus an increase in RO₂/OH would not have a significant impact on the relative
 574 distribution of products formed from these channels. We compared product MS for experiments
 575 with a similar OH exposure but different initial concentrations of TMB (e.g., Exp. 1-3 v.s. Exp.
 576 1-19, and Exp. 1-12 v.s. Exp. 1-22). The OH exposures of Exp. 1-3 and Exp. 1-19 were
 577 estimated by the modified PAM_chem_v8 model consumption of precursors to be 5.2 × 10⁹ and
 578 5.3 × 10⁹ molecule cm⁻³ s, respectively, but the initial concentration of TMB of Exp. 1-3 was
 579 25% more than that in Exp. 1-19. Meanwhile, the OH exposures of Exp. 1-12 and Exp. 1-22
 580 were 4.5 × 10¹⁰ and 4.4 × 10¹⁰ molecule cm⁻³ s, respectively, but the initial concentration of TMB
 581 of Exp. 1-12 was 48% more than that in Exp. 1-22. Comparisons between the product MS of
 582 Exp. 1-3 and Exp. 1-19 (Figure S2), as well as of Exp. 1-12 and Exp. 1-22, show that increase
 583 in the initial concentration of precursors generally resulted in a minor increment in the absolute
 584 signals of HOMs. Clearly, the relative distributions of products in these experiments are quite
 585 similar, indicating a minor difference in the relative distributions of products caused by
 586 fluctuations of initial concentrations of TMB.

587 3.2.1 HOM monomers

588 Previous studies indicate that oxidation products derived from the peroxide-bicyclic
589 pathway represent a main fraction of HOMs (Wang et al., 2017; Zaytsev et al., 2019). For 1,3,5-
590 TMB, this pathway, as recommended by Master Chemical Mechanism (MCM), starts from a
591 BPR, $C_9H_{13}O_5^\bullet$ (MCM name: TM135BPRO2) (Molteni et al., 2018). [According to MCM and](#)
592 [Molteni et al. \(2018\)](#). Scheme 1 has been proposed to provide a good understanding of this
593 reaction system and the structures of oxidation products. Molteni et al. (2018) suggested that
594 $C_9H_{13}O_7^\bullet$, i.e., peroxy radical formed from autooxidation of $C_9H_{13}O_5^\bullet$ has two isomers. A
595 second-step of endo-cyclization is required in the formation of one of the isomer, which is
596 extremely slow and not competitive as shown in several previous studies using both
597 experimental and theoretical approaches (Wang et al., 2017; Xu et al., 2020). Even if such a
598 second O_2 bridging to a double bond is assumed to be possible, the abundance of this isomer
599 should be significantly smaller than the other one, because of the much faster reaction rate of
600 H-shift reaction. Therefore, we do not take the $C_9H_{13}O_7^\bullet$ isomer containing a double endo-
601 cyclization into consideration in this work. The majority of HOM monomers is generated from
602 subsequent reactions of $C_9H_{13}O_5^\bullet$ and newly formed $C_9H_{13}O_7^\bullet$, both of which contain one C=C
603 bond in the carbon backbone and thus have a feasible site for OH addition. Meanwhile, the
604 autoxidation reaction rate for newly formed $C_9H_{13}O_7^\bullet$ should be significantly smaller than
605 $C_9H_{13}O_5^\bullet$, as there is no hydrogen atom in $C_9H_{13}O_7^\bullet$ that is able to undergo a hydrogen atom
606 shift at an appreciable rate based on our current understanding. Therefore, the subsequent
607 autoxidation reaction should not be able to generate large amounts of more oxidized RO_2 .

608

609 **Scheme 1.** Oxidation pathways of the bicyclic peroxy radical $C_9H_{13}O_5 \cdot$ (MCM name:
 610 TM135BPRO2) in the OH-initiated oxidation of 1,3,5-TMB. Green, blue, and black formulae
 611 denote alkyl peroxy radicals, alkoxy radicals and stabilized products, respectively. Black
 612 arrows denote the autoxidation pathway. MCM names for HO_2 - and RO_2 -termination products
 613 of TM135BPRO2 are present.

614 Monomeric termination products of BPR, as shown in Scheme 1, were not detected by
 615 nitrate CIMS in this round of experiments, which might be due to the fast sub-sequential OH
 616 oxidation of these products under high [OH] environment due to their own low oxygen content
 617 and thus relative low detection efficiency in nitrate CIMS, which has been investigated in a
 618 previous study (Riva et al., 2019) since they were observed under low [OH] environments as
 619 shown in Section 3.3. Monomeric termination products Those of $C_9H_{13}O_7 \cdot$ were all observed
 620 clearly, including $C_9H_{12}O_6$, $C_9H_{14}O_6$, and $C_9H_{14}O_7$. Especially, $C_9H_{14}O_7$ was the most abundant
 621 one among all of the HOM monomer products (Figure 2a). As proved by a previous study, these

622 three species should be typical first-generation stabilized products derived from autoxidation
623 (Wang et al., 2020b). These HOM monomers should consist of several isomers bearing the
624 same formula, because products from the secondary reactions cannot share the same structure
625 as that of the one from the first-generation reaction. However, limited by the inherent
626 disadvantages of mass spectrometers, we could not distinguish isomers here and further
627 illustrate their different chemical behaviors.

628 In addition to these three ones, the next most prominent products to $C_9H_{14}O_7$ were $C_9H_{16}O_7$
629 and $C_9H_{16}O_8$ (Figure 3a), which are produced from multi-generation oxidation according to
630 their hydrogen content DBE (Molteni et al., 2018; Cheng et al., 2021). Based on the formulae
631 of these three HOM monomers, they ($C_9H_{14}O_7$, $C_9H_{16}O_7$, and $C_9H_{16}O_8$) could be formed from
632 the bimolecular termination reactions of $C_9H_{15}O_8^*$, which can be generated by an OH attack to
633 $C_9H_{14}O_5$ (Scheme 2), the hydroperoxyl termination product of the BPR, $C_9H_{13}O_5^*$. The other
634 HOM monomers characterized with high signals were $C_9H_{14}O_8$ and $C_9H_{16}O_9$ (Figure 3b). These
635 two HOM monomers ($C_9H_{14}O_8$ and $C_9H_{16}O_9$), together with $C_9H_{16}O_8$, correspond to the
636 monomeric termination products of $C_9H_{15}O_9^*$, which is highly likely the peroxy radical
637 generated by an OH attack to $C_9H_{14}O_6$ (Scheme 3), i.e., the hydroxyl termination product of
638 $C_9H_{13}O_7^*$. As discussed earlier, $C_9H_{13}O_7^*$ is a typical autoxidation reaction product of the BPR
639 of $C_9H_{13}O_5^*$. Therefore, detected signals of $C_9H_{16}O_8$ should be the sum of two isomers' signals
640 at least. Other HOM monomers were generally observed at much lower signals and thus were
641 not plotted individually.

642 (a)

643

644 (b)

645

646 **Figure 3.** Normalized signals of (a) $\text{C}_9\text{H}_{14}\text{O}_7$, $\text{C}_9\text{H}_{16}\text{O}_7$, and $\text{C}_9\text{H}_{16}\text{O}_8$ and (b) $\text{C}_9\text{H}_{14}\text{O}_8$, $\text{C}_9\text{H}_{16}\text{O}_8$,
 647 and $\text{C}_9\text{H}_{16}\text{O}_9$ measured at the exit of OFR in our high [OH] experiments without NO_x as a
 648 function of OH exposure. $\text{C}_9\text{H}_{16}\text{O}_8$ are shown in both plots to better illustrate the chemical
 649 profiles of different compound groups.

650

651 **Scheme 2.** Proposed formation pathways of $\text{C}_9\text{H}_{14}\text{O}_7$, $\text{C}_9\text{H}_{16}\text{O}_7$, and $\text{C}_9\text{H}_{16}\text{O}_8$ via the secondary
 652 OH oxidation of TM135BPOOH.

653

654 **Scheme 3.** Proposed formation pathways of $C_9H_{14}O_8$, $C_9H_{16}O_8$, and $C_9H_{16}O_9$ via the secondary
 655 OH oxidation of TM135BPOOH.

656 It is worth noting that HOM monomers with 18 hydrogen atoms, i.e., a DBE of 1, were
 657 never observed in our experiments, including a potential stabilized hydroperoxyl products
 658 formed from $C_9H_{17}O_m\cdot$. This is expected, since $C_9H_{17}O_m\cdot$ should be in really low concentrations,
 659 if ever existed. As indicated by its hydrogen number, a $C_9H_{17}O_m\cdot$ was formed by at least two
 660 OH additions to the C=C bond of a $C_9H_{13}O_m\cdot$, but the main BPR, $C_9H_{13}O_5\cdot$, and its autoxidation
 661 product ($C_9H_{13}O_7\cdot$), are characterized with one C=C bond on the ring, which makes this
 662 formation pathway impossible. Other ring-breakage pathways should not contribute to the
 663 formation of this radical ($C_9H_{17}O_m\cdot$) because of their low branching ratio as determined by
 664 recent studies (Zaytsev et al., 2019; Xu et al., 2020).

665 Proposed according to MCM and Molteni et al. (2018), Scheme-scheme 4 shows the NO
 666 termination pathways of the main BPR $C_9H_{13}O_5\cdot$ and its autoxidation product, $C_9H_{13}O_7\cdot$. After
 667 introducing N_2O into PAM OFR, quantities of organonitrates were generated, including both
 668 C9 and C18 organonitrates. The averaged mass spectrometry of nitrate CIMS in the 1.8 ppb
 669 NO experiment and 4.8 ppb NO experiment is shown in Figure S3. Organonitrates were formed
 670 via the $NO + RO_2$ reaction, called as NO termination reactions. The distribution of oxidation
 671 products under these two NO settings were similar.

672
 673 **Scheme 4.** NO termination reactions of the bicyclic peroxy radical $C_9H_{13}O_5\cdot$ (MCM name:
 674 TM135BPRO2) and its autoxidation reaction products. Green, blue, and black formulae denote
 675 alkyl peroxy radicals, alkoxy radicals and stabilized products, respectively. Black arrows
 676 denote the autoxidation pathway. MCM names of NO-termination products of TM135BPRO2
 677 are present.

678 As discussed above, most of the first-generation HOMs should contain a C=C bond in the
 679 carbon backbone. The ubiquitous existence of organonitrates that contain two nitrogen atoms
 680 exactly confirms the extensive secondary OH oxidation in the systems, because the NO
 681 termination reaction of RO_2 is the only pathway that can generate organonitrates in our
 682 experiments and this pathway can only introduce one nitrogen atom at a time, as indicated in
 683 **Scheme 4**. RO_2 can react with NO_2 to form peroxy nitrates ($ROONO_2$) but these species are

684 thermally unstable except at very low temperatures or when the RO₂ is an acylperoxy radical
685 (Orlando and Tyndall, 2012), neither of which were not met in our experiments. The
686 concentrations of NO₃ were estimated to be lower than 1 pptv by our modified PAM_chem_v8
687 because of the existence of decent concentrations of NO, which would consume NO₃ at a rapid
688 reaction rate, i.e., 2.7×10^{-11} molecule⁻¹ cm³ s⁻¹ (IUPAC dataset, <https://iupac-aeris.ipsl.fr>, last
689 access: 26 October 2023). Therefore, NO₂ and NO₃ were not likely to react with RO₂ to form
690 large amounts of organonitrates in our experiments. Taking the most abundant organonitrate,
691 C₉H₁₄N₂O₁₀, as an example, it was exactly the NO termination product of C₉H₁₄NO₉[•], which
692 was generated from an OH attack and a subsequent O₂ addition to C₉H₁₃NO₆, the NO
693 termination product of C₉H₁₃O₅[•]. For other organonitrates, C₉H₁₃NO₈, the second most
694 abundant organonitrate, could be either a NO termination product of C₉H₁₃O₇[•] or, together with
695 other most abundant organonitrates, C₉H₁₅NO₇ and C₉H₁₅NO₈, classical termination products
696 of C₉H₁₄NO₉[•]. C₉H₁₄N₂O₁₀, C₉H₁₅NO₇, and C₉H₁₅NO₈ all have a DBE of 2 lower than the
697 precursor and thus are the typical multi-generation OH oxidation products.

698 The NO:RO₂ ratio in the PAM OFR in this series of experiments is lower than typical
699 values in the ambient atmosphere, which is due to the existence of O₃ that was utilized to
700 generate O(¹D) in the OFR and its rapid reaction rate with NO. However, due to rapid reaction
701 rate constants between NO and RO₂, i.e., around 8.5×10^{-12} molecule⁻¹ cm³ s⁻¹, the reaction rate
702 for the NO termination channel of RO₂ was as fast as around 0.3 – 1.0 s⁻¹. Large amounts of
703 organonitrates would still be formed, as discussed in Section 3.1. Our conclusion is also valid
704 because of detection of compounds with multiple nitrogen atoms.

705 3.2.2 HOM dimers

706 Accretion reaction $RO_2 + RO'_2 \rightarrow ROOR' + O_2$ is a source of gas-phase dimer
707 compounds from highly oxidized, functional RO₂ radicals (Ehn et al., 2014; Berndt et al., 2018b;
708 Zhao et al., 2018; Berndt et al., 2018a). C₁₈H₂₆O₈ and C₁₈H₂₆O₁₀ are two typical accretion
709 reaction products in the 1,3,5-TMB + OH system, whose formation pathways have been
710 elucidated (Berndt et al., 2018b). C₁₈H₂₆O₈ can only be formed via the accretion reaction of two
711 C₉H₁₃O₅[•]. C₉H₁₃O₃[•] is not likely to react with C₉H₁₃O₇[•] to form large amounts of C₁₈H₂₆O₈.
712 C₉H₁₃O₃[•] can only be formed after addition of a hydroxyl radical to the aromatic ring of 1,3,5-
713 TMB and a subsequent O₂ addition to the newly formed hydroxyl-substituted cyclohexadienyl
714 radical (Vereecken, 2019). However, the lifetime of this radical is extremely short, as C₉H₁₃O₃[•]
715 will undertake a ring-closure reaction and get attached by a O₂ very rapidly, forming BPR,
716 C₉H₁₃O₅[•]. Its short lifetime and low concentration, as indicated by Berndt et al. (2018), lead to
717 its insignificant role in the accretion reactions. In contrast, C₁₈H₂₆O₁₀ can be formed either by
718 the accretion reaction between C₉H₁₃O₅[•] and C₉H₁₃O₇[•] or via a second OH attack to C₁₈H₂₆O₈.

719 These two HOM dimers are so far the only ones that are confirmed to be formed via the
 720 accretion reactions (Berndt et al., 2018b; Bianchi et al., 2019). ~~There are currently no evidences~~
 721 ~~supporting that $C_9H_{15}O_m$ radicals can participate in the formation of HOM dimers with 28~~
 722 ~~hydrogens. Therefore, it hints that one could attribute the formation of $C_{18}H_{28}O_m$ to multi-~~
 723 ~~generation OH oxidation of $C_{18}H_{26}O_m$.~~

724 $C_{18}H_{26}O_{10}$ was characterized with the highest dimer signals for experiments with OH
 725 exposures under 3.5×10^{10} molecule cm^{-3} s. Nevertheless, $C_{18}H_{26}O_{10}$, together with $C_{18}H_{28}O_{12}$,
 726 $C_{18}H_{26}O_{12}$, $C_{18}H_{28}O_{11}$, $C_{18}H_{28}O_{13}$, and $C_{18}H_{28}O_{10}$ contributed more than 50% of total HOM
 727 dimer signals at any OH exposure levels (Figure 2b). These six most abundant HOM dimers
 728 correspond exactly to the hydroperoxyl, hydroxyl, and carbonyl termination products of
 729 $C_{18}H_{27}O_{11}^{\bullet}$ and $C_{18}H_{27}O_{13}^{\bullet}$, respectively. These two RO_2 ($C_{18}H_{27}O_{11}^{\bullet}$ and $C_{18}H_{27}O_{13}^{\bullet}$), on the
 730 other hand, could be generated by OH attacks to $C_{18}H_{26}O_8$ and $C_{18}H_{26}O_{10}$, respectively, which
 731 strongly suggests the significant role of secondary OH chemistry in the formation of HOMs in
 732 our experiments. In addition, $C_{18}H_{28}O_x$ can also be formed through accretion of a $C_9H_{13}O_m^{\bullet}$
 733 radical and a $C_9H_{15}O_m^{\bullet}$ radical, as suggested by previous studies (Molteni et al., 2018;
 734 Tsiligiannis et al., 2019). However, since a $C_9H_{15}O_m^{\bullet}$ radical, as suggested by its hydrogen atom
 735 number, can only be formed via an OH addition to the stabilized $C_9H_{14}O_m$ products through
 736 multi-generation OH reactions, our conclusion that $C_{18}H_{28}O_x$ are multi-generation OH
 737 oxidation products still holds. Figure 4 shows the normalized signals of these abundant HOM
 738 dimers at different OH exposures.

739 (a)

740

741 (b)

742

743 **Figure 4.** Normalized signals of (a) $\text{C}_{18}\text{H}_{26}\text{O}_{12}$, $\text{C}_{18}\text{H}_{28}\text{O}_{12}$, and $\text{C}_{18}\text{H}_{28}\text{O}_{13}$, and (b) $\text{C}_{18}\text{H}_{26}\text{O}_{10}$,
744 $\text{C}_{18}\text{H}_{28}\text{O}_{10}$, and $\text{C}_{18}\text{H}_{28}\text{O}_{11}$ measured at the exit of OFR in our high [OH] experiments without
745 NO_x as a function of OH exposure.

746 This decrease of dimer at relatively high OH exposures are likely due to the accelerated
747 accretion reactions in the OFR, resulted by the high RO_2 concentrations. The HOM dimers are
748 formed earlier compared to under ambient conditions and then can go through the further
749 oxidation reactions. Note that this does not mean the maximum concentrations of HOM dimers
750 will also accurately occur at the same OH exposures in the atmosphere, because the detailed
751 appearance time of the maximum concentrations of HOM dimers is dependent on their
752 formation rate and loss rate. In our experiments, the formation rate and loss rate were not
753 accelerated equally. On the other hand, the loss pathways of HOM dimers were not exactly the
754 same as the ambient due to the lack of aerosols in the OFR. With the decrease of particulate
755 pollution and thus condensation sinks in the polluted areas, the physical loss of HOMs might
756 be lower and the chemical process can be more important. This series of experiments are not
757 meant to specifically find out the detailed OH exposures when the maximum concentrations of
758 HOM dimers will occur, but try to indicate how HOM dimers evolve with the increase of OH
759 exposures. This work can be regarded as an indicator for the potential chemical fates of HOM
760 dimers in the atmosphere if their survival time permitted. It should be noted that the gas-phase
761 chemistry in the PAM OFR cannot be exactly the same as that in the ambient. Reactions of OH
762 with OVOCs often lead to HO_2 formation, resulting in a $\text{HO}_2:\text{RO}_2$ ratio larger than 1 in the real

763 atmosphere (Bianchi et al., 2019). A recent campaign conducted at a rural site in the Yangtze
764 River Delta estimated that the local ratio of HO₂:RO₂, the latter of which was presumably
765 derived from longer chain alkanes (> C₃), alkenes, and aromatic compounds, was around 1.66
766 (Ma et al., 2022). Such a high HO₂:RO₂ ratio condition is typically difficult to be simulated in
767 the laboratory experiments, as the precursors are usually hydrocarbons without any OVOCs
768 (Peng and Jimenez, 2020). This is exactly the case for our experiments, but its influences on
769 our conclusion were tiny, as have been discussed in the Section 3.1. Therefore, the difference
770 in the distribution of products will not change our conclusion.

771 Such an active secondary OH chemistry is consistent with the fast OH reaction rates of
772 HOMs. We take C₁₈H₂₆O₈ whose plausible structure is shown in **Figure S4** as an example,
773 which is the accretion product of two C₉H₁₃O₅[•]. Its OH reaction rate constant is estimated to be
774 around $2.07 \times 10^{-10} \text{ cm}^3 \text{ molecule}^{-1} \text{ s}^{-1}$ according to the structure-activity relationship (Jenkin et
775 al., 2018b, a), whose details are provided in Supplementary **Text S2**. This rate is several times
776 larger than that of 1,3,5-TMB, which enables a very active secondary OH chemistry in the
777 system. MCM recommended an OH reaction rate of $1.28 \times 10^{-10} \text{ cm}^3 \text{ molecule}^{-1} \text{ s}^{-1}$ for
778 TM135BPOOH (C₉H₁₄O₅) and $1.00 \times 10^{-10} \text{ cm}^3 \text{ molecule}^{-1} \text{ s}^{-1}$ for TM135OBPOH (C₉H₁₂O₄)
779 (Jenkin et al., 2003). The OH reaction rate for C₁₈H₂₆O₈ should also be fast due to the C=C
780 bonds in its structure, which is activated by the adjacent functionalities. Our calculation result
781 is consistent with this estimation.

782 The distributions of C18 organonitrates also verified the extensive secondary reactions.
783 The most abundant C18 organonitrate, C₁₈H₂₇NO₁₂ was a NO termination product of radical
784 C₁₈H₂₇O₁₁[•], which, as mentioned above, was the radical generated from the OH reaction with
785 C₁₈H₂₆O₈. C₁₈H₂₇NO₁₂ can also be formed either by accretion between a C₉H₁₅O_m[•] radical and
786 a C₉H₁₂NO_m[•] radical or accretion between a C₉H₁₃O_m[•] radical and a C₉H₁₄NO_m[•] radical. Both
787 C₉H₁₅O_m[•] and C₉H₁₄NO_m[•] radicals are a typical multi-generation RO₂ and thus prove
788 C₁₈H₂₇NO₁₂ is a multi-generation OH oxidation product. Other C18 organonitrates are believed
789 to be formed in a similar pathway. Hence, plenty of organonitrates have been formed via the
790 multi-generation OH reactions of first-generation stabilized products.

791 **3.3 Oxidation products in low [OH] experiments**

792 Given the larger sampling port, lower initial ozone concentrations, lower UV light
793 intensities, and a better performance of mass spectrometer in this series of low [OH]
794 experiments, a number of new species were detected in the 2nd-round experiments, including
795 three typical termination reaction products of BPR, i.e., C₉H₁₄O₄, C₉H₁₄O₅, and C₉H₁₃NO₆, and
796 a number of low volatile compounds, e.g., C₉H_xO₁₁ (x = 12 - 15). The distributions of oxidation
797 products detected by nitrate CI-TOF in Exp. 2-3, 2-4, and 2-7, representative low [OH]

798 experiments, are displayed in [Figure 5](#). The detailed molecular formula and their contributions
799 to total HOMs signals are provided in [Tables S6 and S7](#).

800 In addition, certain C9 and C18 HOMs with lower DBE than typical first-generation
801 products predicted by MCM (Saunders et al., 2003) or reported by previous studies (Berndt et
802 al., 2018b), were detected in Exp. 2-3, 2-4, and 2-7, although [OH] in these experiments are
803 much lower than those in the 1st-round experiments.

804 Observation of compounds with lower DBE in Exp. 2-3, 2-4, and 2-7 including HOM
805 monomers with DBE lower than 3 and HOM dimers with DBE lower than 6, as well as
806 monomer radicals with DBE lower than 3 including $C_9H_{15}O_m\cdot$ ($m = 7 - 11$) and $C_9H_{14}NO_9\cdot$,
807 proves the re-initiation of OH oxidation of the stabilized products in experiments with
808 atmospheric relevant [OH]. All the stabilized products and radicals depicted in the proposed
809 mechanisms ([Scheme 2 and Scheme 3](#)) were detected in both Exp. 2-3 and Exp. 2-4, except for
810 $C_9H_{15}O_9\cdot$ that was only detected in Exp. 2-3. This means that the proposed reaction pathways
811 have already happened under atmospheric [OH] conditions with limited OH exposures.
812 However, as we do not know the exact structures of these OOMs and radicals, the proposed
813 reaction pathways are merely based on the chemical formulae detected by nitrate CIMS and
814 nitrate CI-TOF and proposed according to the general mechanisms of OH addition reactions to
815 the C=C bond. Other reaction pathways to generate these compounds or other isomers
816 generated in these pathways are undoubtedly feasible.

817 A lot of compounds detected in the experiments without NO_x were not observed in
818 counterpart experiments with NO_x . We also did not detect decent signals of HOM dimers in the
819 NO_x -present experiments in the 2nd-round experiments. This might come from the dominant
820 significance of $NO + RO_2$ reactions (*R8 - R9*) after the introduction of NO_x into system, making
821 signals of certain HOMs from other channels lower than the detection limit of the instrument.
822 The proportions of other reaction channels decreased, and were reassigned to the NO channel,
823 as evidenced by the fact that most of observed oxidation products were organonitrates, which
824 is in an excellent agreement with the modeled channel proportions in Section 3.1.

825 Many organonitrates were observed in both series of experiments. In the low [OH]
826 experiments, the most significant compound was $C_9H_{13}NO_8$, whose formula matches the NO
827 termination product of $C_9H_{13}O_7\cdot$, i.e., autoxidation product of BPR. The second most important
828 compound, $C_9H_{14}N_2O_{10}$ in our low [OH] experiments, was the most significant product in the
829 high [OH] experiments in presence of NO_x , whose formula matches the NO termination product
830 of $C_9H_{14}NO_9\cdot$, i.e., the RO_2 formed via an OH addition to $C_9H_{13}NO_6$, the NO termination
831 product of BPR. All of the products and radicals mentioned above were observed in Exp. 2-7,
832 as shown in [Figure 5c](#). From the perspective of molecular formula, $C_9H_{14}N_2O_{10}$ is also one of

833 the most frequently observed multi-nitrogen-containing compound in polluted atmospheres,
834 whose seasonal variations show a good correlation with [OH] (Guo et al., 2022; Yang et al.,
835 2023).

836 A comparison of relative abundances of C9 and C18 products under different [OH] levels
837 is helpful for the elucidation of their formation pathways. The difference in product
838 distributions between Exp. 2-3 ([OH] = $\sim 1.69 \times 10^7$ molecule cm^{-3}) and Exp. 2-1 ([OH] =
839 $\sim 1.03 \times 10^8$ molecule cm^{-3}), as well as between Exp. 2-3 and Exp. 1-12 ([OH] = $\sim 8.47 \times 10^8$
840 molecule cm^{-3}) is shown in **Figure 6**. The normalized abundance was obtained by normalizing
841 all the products to the most abundant one in each experiment, i.e., $\text{C}_{18}\text{H}_{26}\text{O}_{10}$ in Exp. 2-1 and
842 Exp. 2-3, and $\text{C}_9\text{H}_{14}\text{O}_7$ in Exp. 1-12. The changes in the normalized abundance were obtained
843 by subtracting the normalized abundance in Exp. 2-1 from that in Exp. 2-3, and Exp. 1-12 from
844 Exp. 2-3. As the [OH] and OH exposure increased, there was a noticeable rise in the relative
845 abundance of more oxygenated compounds, which can be attributed to the more intensive
846 proportion of multi-generation OH oxidation in high OH exposure experiments. This
847 comparison demonstrates the capacity and potential of multi-generation OH oxidation to reduce
848 DBE and elevate the oxygenated levels of oxidation products.

849 In conclusion, observation of the same low DBE compounds, i.e., DBE = 2, in both low
850 [OH] and high [OH] experiments confirms the feasibility of the generation of HOMs under
851 atmospheric relevant conditions. The detection of $\text{C}_9\text{H}_{14}\text{O}_5$, $\text{C}_9\text{H}_{15}\text{O}_8^*$, $\text{C}_9\text{H}_{14}\text{O}_7$, $\text{C}_9\text{H}_{14}\text{O}_8$,
852 $\text{C}_9\text{H}_{15}\text{O}_7^*$, and $\text{C}_9\text{H}_{16}\text{O}_8$, and $\text{C}_9\text{H}_{14}\text{O}_6$, $\text{C}_9\text{H}_{15}\text{O}_9^*$, $\text{C}_9\text{H}_{14}\text{O}_8$, $\text{C}_9\text{H}_{14}\text{O}_9$, $\text{C}_9\text{H}_{15}\text{O}_8^*$, and $\text{C}_9\text{H}_{16}\text{O}_9$, in
853 low [OH] experiments also confirms the potential existence of the proposed mechanisms, i.e.,
854 Scheme 2 and Scheme 3, respectively. Certainly, other potential formation pathways for these
855 products are possible.

 873 relative to Exp.1-12. The reagent ion, NO_3^- , is omitted in the label. The normalized abundance was obtained by normalizing all the products to the most
 874 abundant one in each experiment, i.e., $\text{C}_{18}\text{H}_{26}\text{O}_{10}$ in Exp.2-1 and Exp.2-3, and $\text{C}_9\text{H}_{14}\text{O}_7$ in Exp.1-12.

875 **4 Atmospheric Implications**

876 This study highlights the influences of OH exposure on the distribution and evolution of
877 1,3,5-TMB-derived HOMs. Secondary OH reactions can influence HOMs' composition by
878 directly reacting with the stabilized first-generation oxidation products, leading to enhanced
879 formation of HOMs, if the stabilized, first-generation oxidation products could survive from
880 condensation loss onto pre-existing particles. Observation of organonitrates generated in the
881 NO experiments further confirmed ~~this~~the secondary OH oxidation. Due to the elevated
882 abundance and the reduced volatility of HOMs, growth rates of newly formed nanoparticles in
883 the presence of HOMs ~~should~~could be raised, especially in high-OH environments, which
884 prevails in the summer noon. Substantially high concentrations of OH have been frequently
885 observed in polluted environments during summer, e.g., megacities in China (Tan et al., 2019),
886 and thus more active secondary OH reactions are expected compared to wintertime. As a
887 plausible consequence, seasonal differences of HOMs and new particle formation (NPF) are
888 resulted (Qiao et al., 2021; Yao et al., 2018; Guo et al., 2022). Furthermore, previous studies
889 suggest that high concentrations of NO can suppress the formation of HOMs via the suppression
890 of autoxidation (Pye et al., 2019), but the influences of such a suppression could have been
891 overestimated, since secondary OH reactions can continue to oxidize the stabilized
892 organonitrates. Our conclusions help to explain the existing gap between model prediction and
893 ambient measurement on the HOMs concentrations (Qi et al., 2018), and to build a global
894 HOMs simulation model.
