ABSTRACT. Highly oxygenated organic molecules (HOMs) can participate in new particle formation (NPF) and enhance growth of newly formed particles partially because of their low volatility. Previous studies have shown formation of HOMs via autoxidation reactions of RO₂ intermediates generated by OH-initiated oxidation of anthropogenic volatile organic compounds (VOCs). It was also suggested that multi-generation OH oxidation could be an important source for aromatics-derived HOMs. However, our understanding on the generation of aromatics-derived HOMs are still insufficient, especially for their formation mechanisms, which determine molar yields of HOMs and are essential to the establishment of global chemical box models related to HOMs. In this study, with a potential aerosol formation oxidation flow reactor (PAM OFR), a series of OH-initiated oxidation experiments of 1,3,5-trimethylbenzene (1,3,5-TMB) were conducted to investigate the influences of the extent of OH exposure on the formation of aromatics-derived HOMs. The evolution of oxidation products of 1,3,5-TMB in an OH exposure range of $(0.5 - 5.0) \times 10^{10}$ molecules cm⁻³ s, equivalent to an OH exposure of 0.7 – 6.9 hours at an OH concentration of 2×10^6 molecules cm⁻³, was investigated by a nitrate-based chemical ionization mass spectrometer and a Vocus proton-transfer-reaction mass spectrometer, indicating significant secondary OH chemistry

37 during the ageing of stabilized first generation oxygenated products within an intraday OH
38 exposure and formation of various HOMs with more oxygen content and thus lower volatility.
39 In addition, organonitrates, formed after the introduction of NO_x into the reaction systems,
40 further confirmed the existence of such secondary reactions. Our study suggests an important
41 role of secondary OH chemistry in the oxidation of aromatics and elucidates detailed formation
42 mechanisms of certain HOM products.

43

44 **1 Introduction**

45 OH radicals can react with volatile organic compounds (VOCs) in the atmosphere,
46 converting primary pollutants to secondary ones. Generated from oxidation of VOCs,
47 oxygenated organic molecules (OOMs) are crucial in a variety of atmospheric chemical
48 processes, contributing efficiently to the formation of secondary organic aerosols (SOAs) and
49 ground-level O₃ (Ng et al., 2010; Wang et al., 2022; Qu et al., 2021). Among the enormous
50 number of oxygenated VOCs (OVOCs), highly oxygenated organic molecules (HOMs) have
51 recently attracted significant attention (Bianchi et al., 2019). Most of HOMs are low volatile
52 organic compounds (LVOCs) or extremely low volatile organic compounds (ELVOCs), and
53 thus are able to drive the initial formation of nucleated particles under certain conditions and
54 contribute to the subsequent growth of newly-formed particles, which finally enhance SOA
55 formation (Tröstl et al., 2016; Lehtipalo et al., 2018; Stolzenburg et al., 2018; Mohr et al., 2019;
56 Qiao et al., 2021).

57 Formation of HOMs is typically triggered by oxidation of VOCs in the gas phase. Peroxy
58 radicals (RO₂) are generated at the initial step and will undergo an intramolecular hydrogen
59 atom shift forming a hydroperoxide functionality and an alkyl radical. A molecular oxygen will
60 rapidly attach to this alkyl radical and form a new and more oxidized RO₂. This reaction is
61 called as autoxidation and the newly formed RO₂ can go through another autoxidation or
62 bimolecular termination reactions to form a stabilized product (Crouse et al., 2013).
63 Autoxidation is suggested to be responsible for widely detected HOMs in the atmosphere,
64 because it can form highly oxygenated RO₂ in a short time scale. In terms of bimolecular
65 reactions, RO₂ reacts appreciable only with hydroperoxyl radical (HO₂), NO, and another RO₂.
66 The RO₂ reaction chain in polluted areas is largely terminated by NO, which prohibits
67 generation of compounds with high oxidation levels and reduces yields of HOMs (Bianchi et
68 al., 2019).

69 Nevertheless, autoxidation reactions alone are not enough to explain the large numbers of
70 oxygen atoms in HOMs observed in laboratory experiments and ambient campaigns. Take
71 alkylbenzenes as an example, previous studies suggest that the main products of OH-initiated

72 oxidation of alkylbenzenes (C_xH_{2x-6} , $x=7, 8, \text{ or } 9$), i.e., bicyclic peroxy radicals (BPR, C_xH_{2x-6}
73 O_5^\bullet , $x=7, 8, \text{ or } 9$) (Jenkin et al., 2003), can undergo an autoxidation reaction and form a new
74 peroxy radical, $C_xH_{2x-6}O_7^\bullet$ ($x=7, 8, \text{ or } 9$) (Wang et al., 2017). The autoxidation of BPR could be
75 fast if it has a favorable structure, as found in a previous study (Wang et al., 2017). On the
76 other hand, the structure of resulting $C_xH_{2x-6}O_7^\bullet$ is strongly different from that of BPR, whose
77 autoxidation reaction rate can be as low as the order of 0.001 s^{-1} , since it lacks enhancements
78 from favorable transition state geometries and substitutes or resonance structures (Bianchi et
79 al., 2019; Otkjær et al., 2018). Such a slow autoxidation reaction rate cannot explain the
80 extensive existence of HOM monomers with more than 7 oxygen atoms and HOM dimers with
81 more than 10 oxygen atoms, which are the maximum numbers of oxygen atoms in stabilized
82 monomer and dimer products, respectively, formed from $C_xH_{2x-6}O_7^\bullet$ (Molteni et al., 2018;
83 Wang et al., 2020; Mentel et al., 2015). Another possibility is the formation of a second oxygen
84 bridge after the hydrogen shift of BPR (Molteni et al., 2018), but this reaction pathway would
85 not allow a further oxygenation reaction without a breakage of the carbon ring, which is also
86 unpromising. A very recent investigation offers new insights into the formation mechanism of
87 these products, indicating the molecular rearrangement of BPR can initiate a series of
88 autoxidation (Iyer et al., 2023). However, the formation mechanism of HOMs with a large
89 hydrogen atom number is still vague, e.g., monomer products with 16 hydrogen atoms in the
90 OH-initiated oxidation of TMB and with 14 hydrogen atoms in the OH-initiated oxidation of
91 xylene.

92 Multigeneration reactions of VOCs complicate HOMs' formation. Previous studies
93 indicate that HOMs can also be formed by sequential oxidation of stabilized first-generation
94 products of benzene and toluene (Garmash et al., 2020; Cheng et al., 2021). Garmash et al.
95 (2020) conducted OH oxidation experiments of benzene and toluene with an OH exposure
96 equivalent to atmospheric oxidation times of 10 hours – 15 days at OH concentrations of $\sim 10^6$
97 molecules cm^{-3} . Cheng et al. (2021) simulated oxidation of benzene and toluene with an OH
98 exposure equivalent to 2.4 – 19.4 days of atmospheric photochemical ageing. Certainly, such
99 extremely high OH exposures favor secondary OH chemistry and help to facilitate our
100 understanding on product distributions, but such a long timescale limits atmospheric
101 implications of their results, given the complex physical and chemical processes at night.

102 Compared to benzene and toluene, trimethylbenzene (TMB) is a precursor characterized
103 with much larger HOM molar yields when reacted with OH, and the abundance of TMB in the
104 atmosphere is unignorable (Molteni et al., 2018; Yuan et al., 2012). Previous laboratory
105 experiments on TMB-derived HOMs mainly focused on the autoxidation reactions of BPR and
106 the influences of NO_x , while the quantity of experiments was finite with a limited range of OH

107 exposure, bringing down the universality and applicability of conclusions (Tsiligiannis et al.,
108 2019; Wang et al., 2020). From the mechanism perspective, a number of HOM monomers with
109 more than 7 oxygen atoms detected in the OH-initiated oxidation of TMB were previously
110 assumed to be generated via multiple autoxidation reactions (Molteni et al., 2018). Nevertheless,
111 a subsequent OH oxidation of the first-generation oxygenated products might be more plausible
112 for the formation of HOM monomers with more than 7 oxygen atoms from the present point of
113 view. Indeed, laboratory experiments show that RO₂ formed during the second-generation OH
114 oxidation of the first-generation stabilized oxidation products can also undergo autoxidation
115 reactions, which entangles reaction mechanisms potentially involved in the formation of those
116 HOMs and justifies more investigations on the multigeneration OH oxidation of aromatics
117 (Wang et al., 2020). OH with an atmospheric concentration up to $6 \times 10^6 - 2.6 \times 10^7$ molecule
118 cm⁻³, which is several times higher than the typical average atmospheric OH concentration,
119 1.5×10^6 molecule cm⁻³ (Jacob, 1999), has been frequently observed in both urban and suburban
120 environments in China (Tan et al., 2019; Lu et al., 2012), leading to a realistic implication of
121 multigeneration OH oxidation. Therefore, it is imperative to study chemical characteristics of
122 formation reactions of HOMs at different OH exposures, especially those fewer than or
123 equivalent to one day of atmospheric oxidation.

124 In this study, a series of laboratory experiments were conducted on the OH-initiated
125 oxidation of 1,3,5-TMB, selected as an example of anthropogenic VOCs with an OH exposure
126 equivalent to atmospheric oxidation times of roughly 0.7 – 6.9 hours at an average daytime OH
127 radical concentration of 2.0×10^6 molecules cm⁻³. A nitrate-based chemical ionization mass
128 spectrometer (nitrate CIMS) and a Vocus proton-transfer-reaction mass spectrometer (Vocus
129 PTR) were deployed to measure the oxidation products and the precursor, respectively. From
130 the evolution of oxygenated products, we explored secondary OH chemistry of stabilized first-
131 generation oxygenated products generated by the oxidation of 1,3,5-TMB. Furthermore, the
132 influence of NO on the formation of HOMs was investigated by introducing N₂O into the
133 reaction system via formation of organonitrates.

134 **2 Methods**

135 OH-initiated oxidation of 1,3,5-TMB was investigated in a potential aerosol formation
136 oxidation flow reactor (PAM OFR) system at $T = 298 \pm 1$ K and a pressure of 1 atm (Lambe et
137 al., 2015). The experimental settings in this study differed slightly from what were used
138 previously (Wang et al., 2020). Forty OH experiments (Exp. 1 – 40) and twenty-eight NO_x
139 experiments (Exp. 41 – 68) were performed, the experimental conditions of which are
140 summarized in Table S1, including concentrations of the precursor, ozone, and NO and NO₂.
141 The equivalent OH exposure in the OFR for each experiment was estimated according to the

142 precursor consumption, also listed in **Table S1**. OH exposures in the OFR were in the range of
143 $(0.5 - 5.0) \times 10^{10}$ molecules cm^{-3} s, equivalent to atmospheric oxidation times of roughly 0.7 –
144 6.9 hours for 1,3,5-TMB at an average daytime OH radical concentration of 2.0×10^6 molecules
145 cm^{-3} . In contrast, the OH oxidation lifetime for 1,3,5-TMB is around 2.4 hours at the
146 aforementioned atmospheric average daytime OH concentrations.

147 A home-made 1,3,5-TMB/ N_2 cylinder was used as a stable gaseous precursor source in the
148 experiments, from which the flow rate of 1,3,5-TMB/ N_2 varied between 1 – 3 sccm (standard
149 cubic centimeter per minute, standard to 0 °C, 1 atm), leading to 28.9 – 62.7 ppb of 1,3,5-TMB
150 in the OH oxidation experiments (**Table S1**). A total flow of 15 slpm (standard liters per minute,
151 standard to 0 °C, 1 atm) zero-gas generated by a zero-gas generator (model 737-13, Aadco
152 Instruments Inc.), together with the 1,3,5-TMB/ N_2 flow, was introduced into the OFR. The
153 reaction time in this series of experiments was kept at around 53 s. The flow in the PAM OFR
154 is laminar with a very low axial mixing, as characterized with a Taylor dispersion model in a
155 previous study (Lambe et al., 2011). Among the 15 slpm zero-gas, 6 slpm was initially passed
156 through a Nafion humidifier (Perma Pure Model FC100-80-6MSS) filled with ultra-pure water
157 and finally converged with the main flow into the OFR to achieve and keep a desired RH of
158 20.0 ± 2.5 % in the OFR throughout all the experiments, and 2 slpm was initially passed through
159 a separate ozone chamber, resulting in an initial ozone concentration of around 429 – 881 ppb
160 in the OFR. The OFR was operated with only the 254 nm lights on, under which the primary
161 oxidant production reactions in the OFR were $\text{O}_3 + h\nu (254 \text{ nm}) \rightarrow \text{O}_2 + \text{O}(^1D)$ and
162 $\text{O}(^1D) + \text{H}_2\text{O} \rightarrow 2\text{OH}$. After turning on of UV lights, a certain HOM compound is believed to
163 be generated if its signal is more than 3 standard deviations of its background signal. If the
164 fluctuations in the 1-min-averaged signals of both TMB in the Vocus PTR and typical HOMs
165 (i.e., $\text{C}_9\text{H}_{14}\text{O}_7(\text{NO}_3)$) in the nitrate CIMS are within 2% during a 10-min period, we assume
166 that a steady state has been reached. It usually took around no more than 2 minutes for the
167 signals of HOMs to stabilize after the adjustment of UV lights. We typically monitored the
168 reaction products for around 20 minutes for each experiment. An ozone monitor (Model 106-
169 M, 2B technologies) and a trace-gas analyzer for NO- NO_2 - NO_x (Thermo, 42i-TL) were placed
170 at the exit of the OFR to measure concentrations of ozone and NO_x , respectively.

171 Non-tropospheric VOC photolysis is a typical issue that should be taken into account when
172 evaluating the settings of OFR laboratory experiments. Photolysis of the precursor and HOMs
173 were evaluated, showing that photolysis was not a contributor to our observation. The
174 photolysis rate of 1,3,5-TMB can be estimated based on the absorption cross-sections of 1,3,5-
175 TMB at 254 nm (Keller-Rudek et al., 2013) and UV photon fluxes estimated by a chemistry
176 model discussed in the following sections. The ratio of photolysis-to-OH reaction in our

177 experiments was merely 0.010 – 0.033. Hence, photolysis of 1,3,5-TMB was insignificant in
178 the OFR. For stabilized products such as HOMs, the cross sections of organic molecules are
179 usually $\sim 3.9 \times 10^{-18}$ - 3.9×10^{-17} cm² (Peng et al., 2016), while the reaction rate between OH and
180 the stabilized first-generation products are estimated to be around 1.28×10^{-10} molecule⁻¹ cm³ s⁻¹,
181 as suggested by MCM (Jenkin et al., 2003). Hence, the ratio of photolysis rates of HOMs to
182 their secondary OH oxidation rates is estimated to be merely around 0.020 – 0.056.

183 For experiments with NO_x, 350 sccm N₂O (99.999%, Air Liquid) was added into the OFR
184 to produce and sustain NO_x mixing ratios at levels that were sufficiently high to be a competitive
185 sink for RO₂ radicals. NO and NO₂ were produced via the reaction $N_2O + O(^1D) \rightarrow 2NO$,
186 followed by the reaction $NO + O_3 \rightarrow NO_2 + O_2$. Two sets of irradiance intensities were chosen
187 for NO_x experiments, generally resulting in two NO_x levels, 1.8 ppb NO + 70 ppb NO₂ (Exp.
188 41 – 54) and 4.8 ppb NO + 120 ppb NO₂ (Exp. 55 – 68) at the exit of the OFR. With the aim to
189 slightly modify OH exposure but keep NO_x concentrations constant among each set of
190 experiments, the initial concentrations of 1,3,5-TMB were adjusted in a large range (16.7 – 84.1
191 ppb), as an increase in the precursor concentration corresponds to a larger sink for OH, while
192 RH and irradiances were not changed.

193 A nitrate CIMS (Ehn et al., 2014; Eisele and Tanner, 1993) and a Vocus PTR (Krechmer
194 et al., 2018) were deployed at the exit of the OFR to measure the oxidation products of 1,3,5-
195 TMB. These two mass spectrometers have been well characterized in a previous study (Wang
196 et al., 2020).

197 In this study, the sample flow rate for the nitrate CIMS was 8 slpm through a Teflon tube
198 with an outer diameter (OD) of 1/4 in. and a length of 70 cm. The sheath flow for the nitrate
199 CIMS was supplied by a zero-gas generator at a flow rate of 15 slpm. Mass resolution was
200 approximately 8000 for ions with m/z larger than 200 Th. HOMs generated from TMB
201 oxidation were charged in the ambient pressure interface region by collisions with nitrate
202 clusters, (HNO₃)_x·NO₃⁻ (x = 0 – 2), and detected by nitrate CIMS as clusters with NO₃⁻, i.e.,
203 HOM·NO₃⁻ (Hyytinen et al., 2015). In addition, HOMs' signals were corrected with relative
204 transmission efficiencies of our nitrate CIMS obtained via a method reported previously
205 (Heinritzi et al., 2016). We followed the same sampling method of PAM OFR as those in
206 previous studies, in order to obtain a similar flow tube residence time distributions (RTDs) and
207 thus validate usage of a modified PAM_chem_v8 model to estimate concentrations of radicals
208 in the OFR as discussed below. We acknowledge that this is not a perfect sampling setting for
209 nitrate CIMS. However, the reduction in the sampling efficiencies of various HOMs is likely
210 to be close, if not identical, which keeps the distributions of HOMs.

211 Vocus PTR was applied to quantify precursor concentrations and measure volatile and
212 intermediate volatility oxidation products. The focusing ion-molecule reactor (FIMR) was
213 heated up and its temperature was maintained at 100 °C during the experiments. The FIMR can
214 be operated under 2.0 mbar without a strong interference from corresponding water clusters
215 when ionizing the neutral compounds. The Vocus front and back voltages were 650 V and 15
216 V, respectively, forming an axial voltage of 635V and a reduced electrical field (E/N , where E
217 is the electric field strength and N is the number density of the buffer gas in FIMR) of 180 Td.
218 The radio frequency (RF) voltages and frequency were set to be 450 V and 1.3 MHz,
219 respectively. The sample flow was introduced to the Vocus PTR through a Teflon tube with an
220 OD of 1/4 in. and a length of 120 cm from the OFR. A total sample flow of 1.4 slpm was
221 maintained by a pump with an orifice to minimize the delay time of sampling, from which
222 approximately 125 sccm was sampled into the FIMR through a capillary tube.

223 We did not quantify HOMs' concentrations. Since the inner diameters of PAM OFR,
224 sampling tube, and the nitrate CIMS inlet were different, and two reducing unions were used
225 during sampling, the estimation of the penetration efficiency and sampling efficiency of HOMs
226 are of a significant uncertainty. The initial concentrations of TMB utilized in the experiments
227 fluctuated slightly, which resulted from sample preparation processes, but generally were
228 around 50 ppbv. We tried to minimize potential influences of the differences in the initial TMB
229 concentrations on the signals of HOMs by normalizing the HOMs signals with the initial TMB
230 signal. To precisely illustrate changes in the abundance of HOMs at different OH exposures, a
231 normalized signal was chosen to present the abundance of detected HOMs, which is defined as
232 the ratio of the signals of HOMs in the nitrate CIMS normalized by the reagent ions and the
233 initial signal of 1,3,5-TMB, i.e., $S(HOMs)/S(TMB)$. $S(HOMs)$ is the signal of HOM detected
234 by the nitrate CIMS normalized with the signal of reagent ions, whereas $S(TMB)$ is the initial
235 signal of 1,3,5-TMB detected by the Vocus PTR.

236

237 To validate our settings, a PAM chemistry model (PAM_chem_v8), utilized widely in
238 previous studies, were chosen with the latest updates to calculate radical profiles in our OFR
239 (Li et al., 2015; Cheng et al., 2021; Wang et al., 2020; Mehra et al., 2020; Lambe et al., 2015,
240 2018; Peng and Jimenez, 2020; Lambe et al., 2017). This model is based on a photochemical
241 box model that includes chemistry of photolysis of oxygen, water vapor, and other trace gases
242 by the primary wavelengths of mercury lamps, and simplified VOC and RO₂ chemistry (Table
243 S2), but further reactions of the first-generation stabilized products and the second-generation
244 organic radicals are not considered. The detailed reactions involved with RO₂ include:

255 R1, R2, and R3 are reactions of $RO_2 + RO_2$, forming alkoxy radicals, carbonyl termination
 256 products, and hydroxyl termination products, respectively. R4 is the accretion reaction,
 257 forming dimers via combination of two monomeric RO_2 . R5 is the reaction between RO_2 and
 258 HO_2 , forming hydroperoxyl radicals. R6 is the reaction between OH and RO_2 , whose reaction
 259 channels/products are proposed according to previous studies (Table S3). R7 is the
 260 unimolecular reactions of RO_2 in the PAM OFR, among which the autoxidation reaction rate is
 261 the most significant. R8 and R9 are the reactions between NO and RO_2 , generating alkoxy
 262 radicals and organonitrates, respectively. R10 is the physical loss of RO_2 .

263 Kinetic data in the modified PAM_chem_v8 are obtained from the IUPAC (International
 264 Union of Pure and Applied Chemistry) dataset (<https://iupac-aeris.ipsl.fr>, last access: 26
 265 October 2023) and the MCM dataset (MCM v3.3.1, <https://mcm.york.ac.uk/MCM/>, last access:
 266 9 October 2023), except those that are specifically discussed in details in the supplement. Note
 267 that the total RO_2 concentration is simplified to be the sum of concentrations of BPR and
 268 $C_9H_{13}O_7\cdot$. In this work, the autoxidation reaction and the accretion reaction of 1,3,5-TMB-
 269 derived BPR, as well as the subsequent reactions of the autoxidation product of BPR, i.e.,
 270 $C_9H_{13}O_7\cdot$, are newly implemented or modified in this model (Reaction No. 41 – 57 in Table
 271 S2). The newly implemented or modified reactions in this model are discussed in
 272 Supplementary Text S1. NO_x -related reactions are also included in the model. When we
 273 simulate experiments without NO_x , these reactions do not contribute to the simulation results.

274 The input parameters of temperature, mean residence time, water vapor concentration, O_3
 275 concentration, and the initial 1,3,5-TMB concentration are 25 °C, 53 s, 0.8%, 500 ppbv, and 50
 276 ppbv, respectively, as measured directly in the experiments. The actinic flux at 254 nm, I_{254} , is
 277 constrained by comparing OH exposures by model output and OH exposures estimated by the
 278 consumption of 1,3,5-TMB as measured by a Vocus PTR. Consumption of O_3 estimated by the
 279 model agrees well with the measured results, with discrepancies being always within 10% at
 280 different OH exposures.

281

282 3 Results and discussion

283 3.1 Validation of experiment settings

284 Concentration profiles of OH, RO₂, and HO₂ as a function of OH exposures in our
285 experiments without NO_x are illustrated in **Figure S1a**. According to the modified
286 PAM_chem_v8, when OH increased from 1.09×10⁸ to 1.57×10⁹ molecule cm⁻³, HO₂
287 concentrations increased from 7.72×10⁸ to 3.18×10⁹ molecule cm⁻³, whereas RO₂
288 concentrations increased from 4.83×10⁹ to 8.48×10⁹ molecule cm⁻³. The radical concentrations
289 in experiments with NO_x (**Figure S1b**) varied in a similar range, with RO₂ ranging from
290 3.89×10⁹ to 9.34×10⁹ molecule cm⁻³, HO₂ ranging from 3.66×10⁹ to 6.82×10⁹ molecule cm⁻³,
291 and OH ranging from 4.83×10⁸ to 9.05×10⁸ molecule cm⁻³, respectively. The ratios between
292 HO₂/OH and RO₂/OH in our experiments are displayed in **Figure S1c**. The HO₂/OH ratio
293 ranged between 1.9 and 7.1 in our PAM OFR experiments without NO_x, and the RO₂/OH ratio
294 ranged between 4.9 and 47.9. In experiments with NO_x, the HO₂/OH ratio ranged between 3.7
295 and 17.9, whilst the RO₂/OH ratio ranged between 4.0 and 13.2. A recent comprehensive
296 ambient campaign conducted in the wintertime central Beijing reported mean daytime peak
297 concentrations of 8.8×10⁷, 3.9×10⁷, and 2.7×10⁶ molecule cm⁻³ for total RO₂, HO₂, and OH,
298 respectively (Slater et al., 2020), which corresponds to ambient RO₂/OH and HO₂/OH ratios of
299 32.6 and 14.4 (**Figure S1c**), respectively. Therefore, radical ratios in our flow tube were
300 generally in the same order of magnitude with the ambient conditions.

301

302 **Figure 1.** Fates of RO₂ generated in the low NO_x experiment (Exp. 44), urban Beijing (Slater
303 et al., 2020), low OH and zero NO_x experiment (Exp. 19), and high OH and zero NO_x
304 experiment (Exp. 12). Note that RO₂ fates of RO₂, OH, HO₂, and accretion channels are blown

305 up for a better comparison for urban Beijing and the high OH and zero NO_x experiment.
306 Reactions and kinetic rate coefficients used in the calculations are provided in **Table S2**.

307

308 We take Exp. 12, 19 and 44 as representative examples and compare simulation results
309 with those from the ambient environment (Slater et al., 2020). The RO₂ lifetime in urban Beijing
310 (Slater et al., 2020), low NO_x experiment, low OH and zero NO_x experiment, and high OH and
311 zero NO_x concentration experiment was 1.0, 0.7, 1.2, and 0.6 s, respectively. As shown in
312 **Figure 1**, In the low NO_x experiment (Exp. 44), the fractions of RO₂ + RO₂ (*R1* – *R3*), accretion
313 reaction (*R4*), RO₂ + HO₂ (*R5*), RO₂ + OH (*R6*), autooxidation (*R7*), and RO₂ + NO (*R8* – *R9*)
314 were 0.06%, 12.1%, 0.9%, 0.07%, 82.9%, and 4.0%, respectively. Calculated based on the
315 mean daytime peak concentrations of radicals in Beijing (Slater et al., 2020), the fractions of
316 *R1* – *R3*, *R4*, *R5*, *R6*, *R7*, and *R8* – *R9* were 0.0005%, 0.09%, 0.007%, 0.003%, 87.4%, and
317 12.5%, respectively. For the experiment with low OH and zero NO_x (Exp. 19), the fractions of
318 *R1* – *R3*, *R4*, *R5*, *R6*, and *R7* were 0.05%, 10.0%, 0.15%, 0.14%, and 89.7%, respectively. For
319 the one with high OH and zero NO_x (Exp. 12), the fractions of *R1* – *R3*, *R4*, *R5*, *R6*, and *R7*
320 were 0.08%, 16.6%, 0.54%, 1.8%, and 81.0%, respectively. The overall lifetimes of RO₂ and
321 the fractions of autooxidation together determine the significant and similar roles of
322 autooxidation in both laboratory experiments and the ambient. Therefore, the autooxidation chain
323 will run to a similar oxidation level between the laboratory and the ambient.

324 In experiments with NO_x (e.g., Exp. 44), though the yields of organonitrates were lower in
325 the laboratory experiments, the formation pathways of these compounds were the same as those
326 in the ambient. Based on the formulae of organonitrates, the detailed formulae for monomer
327 RO₂ could be probed, which helps to investigate the existence of multi-generation OH oxidation.
328 Alkoxy radicals generated in the NO termination channel will unlikely influence the
329 distributions of C₉ stabilized products since they tend to get decomposed in the subsequent
330 reactions, as discussed in the Supplementary **Text S1**.

331 In experiments in absence of NO_x (e.g., Exp. 12 and 19), the proportions of *R8* - *R9* , i.e.,
332 the NO channel in urban environment were reassigned to termination reactions of *R1* - *R6*, i.e.,
333 RO₂ + RO₂, accretion reaction, RO₂ + HO₂, and RO₂ + OH. Comparison of relative fractions of
334 RO₂ fates of RO₂, OH, HO₂, and accretion channels (**Figure 1**) shows similarities between
335 laboratory and ambient results. By expanding proportions of these termination reactions,
336 laboratory investigations on distributions of products can be facilitated, as the detection of
337 certain HOM products became more precise and the mass spectra became simplified. As
338 discussed in the “results” session, products of *R2*, *R3*, and *R5* channels of the main BPR were
339 not detected in our experiments due to their low oxygen contents, while secondary products

340 between products of *R2*, *R3*, and *R5* channels of the main BPR and OH were observed.
341 Together with stabilized products and secondary products from $C_9H_{13}O_7\cdot$ (the peroxy radical
342 formed from autooxidation of BPR), secondary products between products of *R2*, *R3*, and *R5*
343 channels of the main BPR and OH help to elucidate the first- and multi-generation reaction
344 pathways in the 1,3,5-TMB+OH system, according to their molecular formulae.

345 On the other hand, the much-expanded proportion of HOM dimers through accretion
346 reactions makes it inadequate to compare yields of HOM dimers and HOM monomers.
347 However, identification of HOM dimers can help us identify the exact RO_2 in the OFR and
348 confirm the conditions of secondary OH oxidation according to the number of hydrogen atoms
349 in the molecules.

350 3.2 Oxidation products

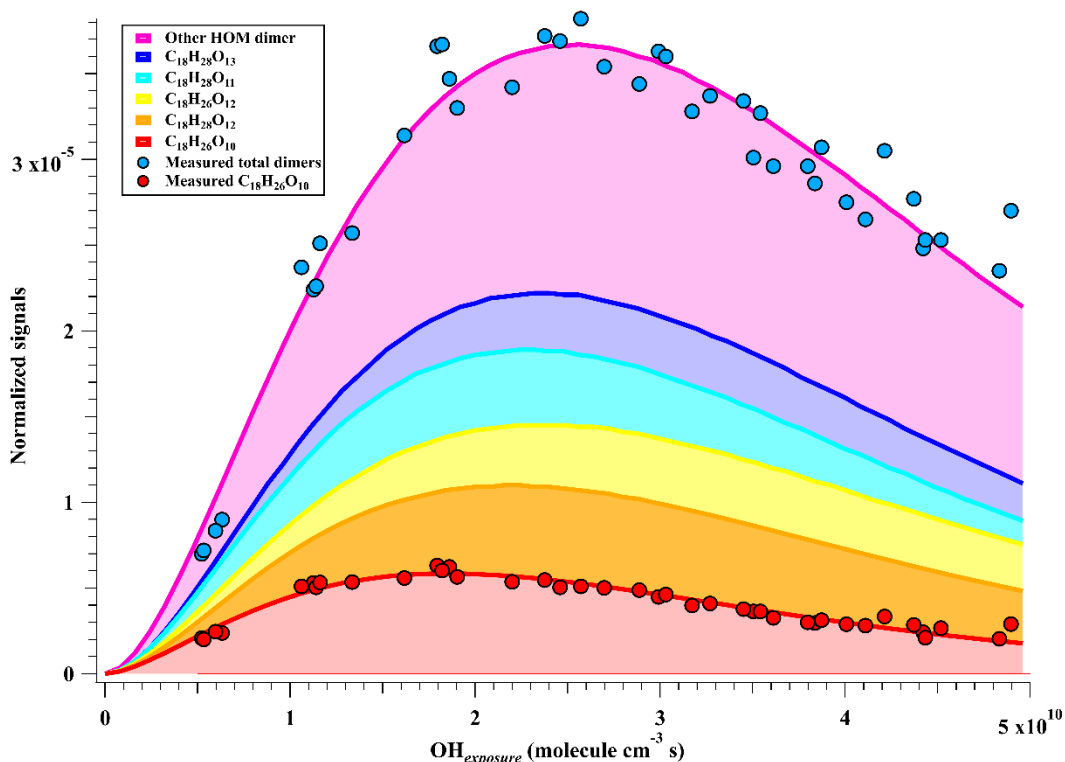

351 A total of 33 HOM monomers with formulae of $C_{7-9}H_{8-16}O_{6-11}$ and 22 HOM dimers with
352 formulae of $C_{17-18}H_{24-30}O_{8-14}$ were observed in the gas phase OH-initiated oxidation of 1,3,5-
353 TMB in the OFR, as listed in [Table S4](#). The relative signal contributions of HOMs to the total
354 signals of all HOMs at an OH exposure of 2.38×10^{10} molecules cm^{-3} s are listed as an example
355 in [Table S4](#). The most abundant HOM products were also shown in [Figure 2](#), whose
356 relationships with OH exposures are superimposed by a gamma function ($f(x) = ax^m e^{-x}$)
357 simulation line to guide the eyes. The sum of normalized HOM monomers' abundance
358 increased monotonically up to the highest OH exposure of 5×10^{10} molecule cm^{-3} s, whereas
359 those of HOM dimers showed a non-monotonic dependence on OH exposure. The observed
360 faster increase of accretion products than that of HOM monomers can be explained jointly by
361 the fast second-order kinetics for accretion reactions of RO_2 (Berndt et al., 2018b) and the high
362 concentrations of relevant radicals in this work. On the other hand, most of the first-generation
363 HOM dimers formed from accretion reactions contain at least one C=C bond and have more
364 functionalities than HOM monomers, and thus should be more reactive to OH radicals, which,
365 together with a faster deposition loss of dimers, results in a faster consumption of HOM dimers
366 than monomers in the OFR. The faster production and consumption of HOM dimers allowed
367 their concentrations to summit at middle levels of OH exposures. Because of the inherent
368 disadvantage of laboratory experiments, RO_2 concentrations are always too high in the OFR,
369 which has been pointed out in a previous study (Bianchi et al., 2019). The accretion reactions
370 in the OFR are relatively more significant than it should be in the ambient atmosphere. We do
371 not mean to compare HOM monomer and HOM dimer signals crossly here, but to pay attention
372 to their formulae.

373 (a)

374

375 (b)

376

377 **Figure 2.** Normalized signals of (a) HOM monomers and (b) HOM dimers versus OH exposure

378 that are fitted via a gamma function and shown in stacked.

379

380 Theoretically, at a given RH and UV (i.e., a given OH), an increase in the initial TMB
381 would lead to formation of more RO₂, which corresponds to a larger RO₂/OH. However, under
382 our experimental conditions, the RO₂/OH/HO₂ channels of RO₂ radicals are always minor, and
383 thus an increase in RO₂/OH would not have a significant impact on the relative distribution of
384 products formed from these channels. We compared product MS for experiments with a similar
385 OH exposure but different initial concentrations of TMB (e.g., Exp. 3 v.s. Exp. 19, and Exp. 12
386 v.s. Exp. 22). The OH exposures of Exp. 3 and Exp. 19 were estimated by the modified
387 PAM_chem_v8 model to be 5.2×10^9 and 5.3×10^9 molecule cm⁻³ s, respectively, but the initial
388 concentration of TMB of Exp. 3 was 25% more than that in Exp. 19. Meanwhile, the OH
389 exposures of Exp. 12 and Exp. 22 were 4.5×10^{10} and 4.4×10^{10} molecule cm⁻³ s, respectively,
390 but the initial concentration of TMB of Exp. 12 was 48% more than that in Exp. 22.
391 Comparisons between the product MS of Exp. 3 and Exp. 19 (Figure S2), as well as of Exp. 12
392 and Exp. 22, show that increase in the initial concentration of precursors generally resulted in
393 a minor increment in the absolute signals of HOMs. Clearly, the relative distributions of
394 products in these experiments are quite similar, indicating a minor difference in the relative
395 distributions of products caused by fluctuations of initial concentrations of TMB.

396 3.2.1 HOM monomers

397 Previous studies indicate that oxidation products derived from the peroxide-bicyclic
398 pathway represent a main fraction of HOMs (Wang et al., 2017; Zaytsev et al., 2019). For 1,3,5-
399 TMB, this pathway, as recommended by Master Chemical Mechanism (MCM), starts from a
400 BPR, C₉H₁₃O₅• (MCM name: TM135BPRO2) (Molteni et al., 2018). Scheme 1 has been
401 proposed to provide a good understanding of this reaction system and the structures of oxidation
402 products. Molteni et al. (2018) suggested that C₉H₁₃O₇•, i.e., peroxy radical formed from
403 autooxidation of C₉H₁₃O₅• has two isomers. A second-step of endo-cyclization is required in
404 the formation of one of the isomer, which is extremely slow and not competitive as shown in
405 several previous studies using both experimental and theoretical approaches (Wang et al., 2017;
406 Xu et al., 2020). Even if such a second O₂ bridging to a double bond is assumed to be possible,
407 the abundance of this isomer should be significantly smaller than the other one, because of the
408 much faster reaction rate of H-shift reaction. Therefore, we do not take the C₉H₁₃O₇• isomer
409 containing a double endo-cyclization into consideration in this work. The majority of HOM
410 monomers is generated from subsequent reactions of C₉H₁₃O₅• and newly formed C₉H₁₃O₇•,
411 both of which contain one C=C bond in the carbon backbone and thus have a feasible site for
412 OH addition. Meanwhile, the autooxidation reaction rate for newly formed C₉H₁₃O₇• should be
413 significantly smaller than C₉H₁₃O₅•, as there is no hydrogen atom in C₉H₁₃O₇• that is able to
414 undergo a hydrogen atom shift at an appreciable rate based on our current understanding.

430 products derived from autoxidation (Wang et al., 2020). These HOM monomers should consist
431 of several isomers bearing the same formula, because products from the secondary reactions
432 cannot share the same structure as that of the one from the first-generation reaction. However,
433 limited by the inherent disadvantages of mass spectrometers, we could not distinguish isomers
434 here and further illustrate their different chemical behaviors.

435 In addition to these three ones, the next most prominent products to $C_9H_{14}O_7$ were $C_9H_{16}O_7$
436 and $C_9H_{16}O_8$ (Figure 3a), which are produced from multi-generation oxidation according to
437 their hydrogen content (Molteni et al., 2018; Cheng et al., 2021). Based on the formulae of
438 these three HOM monomers, they ($C_9H_{14}O_7$, $C_9H_{16}O_7$, and $C_9H_{16}O_8$) could be formed from the
439 bimolecular termination reactions of $C_9H_{15}O_8^*$, which can be generated by an OH attack to
440 $C_9H_{14}O_5$ (Scheme 2), the hydroperoxyl termination product of the BPR $C_9H_{13}O_5^*$. The other
441 HOM monomers characterized with high signals were $C_9H_{14}O_8$ and $C_9H_{16}O_9$ (Figure 3b). These
442 two HOM monomers ($C_9H_{14}O_8$ and $C_9H_{16}O_9$), together with $C_9H_{16}O_8$, correspond to the
443 monomeric termination products of $C_9H_{15}O_9^*$, which is highly likely the peroxy radical
444 generated by an OH attack to $C_9H_{14}O_6$ (Scheme 3), i.e., the hydroxyl termination product of
445 $C_9H_{13}O_7^*$. As discussed earlier, $C_9H_{13}O_7^*$ is a typical autoxidation reaction product of the BPR
446 of $C_9H_{13}O_5^*$. Therefore, detected signals of $C_9H_{16}O_8$ should be the sum of two isomers' signals
447 at least. Other HOM monomers were generally observed at much lower signals and thus were
448 not plotted individually.

450

451 (b)

452

453 **Figure 3.** Normalized signals of (a) C₉H₁₄O₇, C₉H₁₆O₇, and C₉H₁₆O₈ and (b) C₉H₁₄O₈, C₉H₁₆O₈,
 454 and C₉H₁₆O₉ measured at the exit of OFR in experiments without NO_x as a function of OH
 455 exposure. C₉H₁₆O₈ are shown in both plots to better illustrate the chemical profiles of different
 456 compound groups.

457

458 **Scheme 2.** Proposed formation pathways of C₉H₁₄O₇, C₉H₁₆O₇, and C₉H₁₆O₈ via the secondary
 459 OH oxidation of TM135BPOOH.

460

461 **Scheme 3.** Proposed formation pathways of C₉H₁₄O₈, C₉H₁₆O₈, and C₉H₁₆O₉ via the secondary
 462 OH oxidation of TM135BPOOH.

463 It is worth noting that HOM monomers with 18 hydrogen atoms were never observed in
 464 our experiments, including a potential stabilized hydroperoxyl products formed from C₉H₁₇O_m·.
 465 This is expected, since C₉H₁₇O_m· should be in really low concentrations, if ever existed. As
 466 indicated by its hydrogen number, a C₉H₁₇O_m· was formed by at least two OH additions to the
 467 C=C bond of a C₉H₁₃O_m·, but the main BPR, C₉H₁₃O₅·, and its autoxidation product (C₉H₁₃O₇·),
 468 are characterized with one C=C bond on the ring, which makes this formation pathway
 469 impossible. Other ring-breakage pathways should not contribute to the formation of this radical
 470 (C₉H₁₇O_m·) because of their low branching ratio as determined by recent studies (Zaytsev et al.,
 471 2019; Xu et al., 2020).

472 **Scheme 4** shows the NO termination pathways of the main BPR C₉H₁₃O₅· and its
 473 autoxidation product, C₉H₁₃O₇·. After introducing N₂O into PAM OFR, quantities of
 474 organonitrates were generated, including both C9 and C18 organonitrates. The averaged mass
 475 spectrometry of nitrate CIMS in the 1.8 ppb NO experiment and 4.8 ppb NO experiment is
 476 shown in **Figure S3**. Organonitrates were formed via the NO + RO₂ reaction, called as NO
 477 termination reactions. The distribution of oxidation products under these two NO settings were
 478 similar.

479

480 **Scheme 4.** NO termination reactions of the bicyclic peroxy radical $C_9H_{13}O_5\cdot$ (MCM name:
 481 TM135BPRO2) and its autoxidation reaction products. Green, blue, and black formulae denote
 482 alkyl peroxy radicals, alkoxy radicals and stabilized products, respectively. Black arrows
 483 denote the autoxidation pathway. MCM names of NO-termination products of TM135BPRO2
 484 are present.

485

486 As discussed above, most of the first-generation HOMs should contain a C=C bond in the
 487 carbon backbone. The ubiquitous existence of organonitrates that contain two nitrogen atoms
 488 exactly confirms the extensive secondary OH oxidation in the systems, because the NO
 489 termination reaction of RO_2 is the only pathway that can generate organonitrates in our
 490 experiments and this pathway can only introduce one nitrogen atom at a time, as indicated in

491 Scheme 4. RO₂ can react with NO₂ to form peroxy nitrates (ROONO₂) but these species are
492 thermally unstable except at very low temperatures or when the RO₂ is an acylperoxy radical
493 (Orlando and Tyndall, 2012), neither of which were not met in our experiments. The
494 concentrations of NO₃ were estimated to be lower than 1 pptv by our modified PAM_chem_v8
495 because of the existence of decent concentrations of NO, which would consume NO₃ at a rapid
496 reaction rate, i.e., 2.7×10^{-11} molecule⁻¹ cm³ s⁻¹ (IUPAC dataset, <https://iupac-aeris.ipsl.fr>, last
497 access: 26 October 2023). Therefore, NO₂ and NO₃ were not likely to react with RO₂ to form
498 large amounts of organonitrates in our experiments. Taking the most abundant organonitrate,
499 C₉H₁₄N₂O₁₀, as an example, it was exactly the NO termination product of C₉H₁₄NO₉[•], which
500 was generated from an OH attack and a subsequent O₂ addition to C₉H₁₃NO₆, the NO
501 termination product of C₉H₁₃O₅[•]. For other organonitrates, C₉H₁₃NO₈, the second most
502 abundant organonitrate, could be either a NO termination product of C₉H₁₃O₇[•] or, together with
503 other most abundant organonitrates, C₉H₁₅NO₇ and C₉H₁₅NO₈, classical termination products
504 of C₉H₁₄NO₉[•].

505 The NO:RO₂ ratio in the PAM OFR is lower than typical values in the ambient atmosphere,
506 which is due to the existence of O₃ that was utilized to generate O(¹D) in the OFR and its rapid
507 reaction rate with NO. However, due to rapid reaction rate constants between NO and RO₂, i.e.,
508 around 8.5×10^{-12} molecule⁻¹ cm³ s⁻¹, the reaction rate for the NO termination channel of RO₂
509 was as fast as around 0.3 – 1.0 s⁻¹. Large amounts of organonitrates would still be formed. Our
510 conclusion is also valid because of detection of compounds with multiple nitrogen atoms.

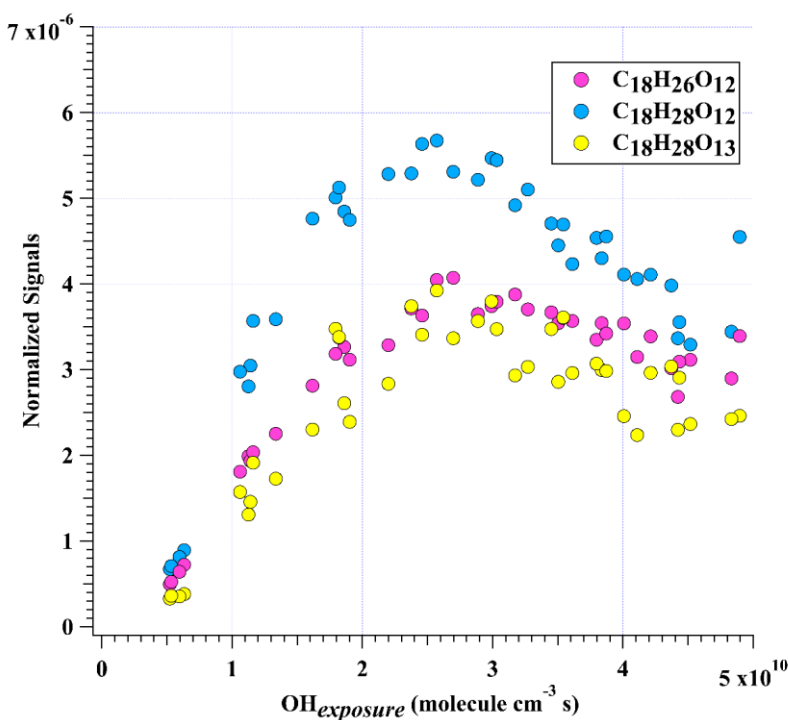

511 HOM dimers

512 Accretion reaction $RO_2 + RO'_2 \rightarrow ROOR' + O_2$ is a source of gas-phase dimer
513 compounds from highly oxidized, functional RO₂ radicals. (Ehn et al., 2014; Berndt et al., 2018b;
514 Zhao et al., 2018; Berndt et al., 2018a) C₁₈H₂₆O₈ and C₁₈H₂₆O₁₀ are two typical accretion
515 reaction products in the 1,3,5-TMB + OH system, whose formation pathways have been
516 elucidated. (Berndt et al., 2018b) C₁₈H₂₆O₈ can only be formed via the accretion reaction of two
517 C₉H₁₃O₅[•]. C₉H₁₃O₃[•] is not likely to react with C₉H₁₃O₇[•] to form large amounts of C₁₈H₂₆O₈.
518 C₉H₁₃O₃[•] can only be formed after addition of a hydroxyl radical to the aromatic ring of 1,3,5-
519 TMB and a subsequent O₂ addition to the newly formed hydroxyl-substituted cyclohexadienyl
520 radical (Vereecken, 2019). However, the lifetime of this radical is extremely short, as C₉H₁₃O₃[•]
521 will undertake a ring-closure reaction and get attached by a O₂ very rapidly, forming BPR,
522 C₉H₁₃O₅[•]. Its short lifetime and low concentration, as indicated by Berndt et al. (2018), lead to
523 its insignificant role in the accretion reactions. In contrast, C₁₈H₂₆O₁₀ can be formed either by
524 the accretion reaction between C₉H₁₃O₅[•] and C₉H₁₃O₇[•] or via a second OH attack to C₁₈H₂₆O₈.
525 These two HOM dimers are so far the only ones that are confirmed to be formed via the

526 accretion reactions (Berndt et al., 2018b; Bianchi et al., 2019). There are currently no evidences
527 supporting that $C_9H_{15}O_m\cdot$ radicals can participate in the formation of HOM dimers with 28
528 hydrogens. Therefore, it hints that one could attribute the formation of $C_{18}H_{28}O_m$ to multi-
529 generation OH oxidation of $C_{18}H_{26}O_m$.

530 $C_{18}H_{26}O_{10}$ was characterized with the highest dimer signals for experiments with OH
531 exposures under 3.5×10^{10} molecule cm^{-3} s. Nevertheless, $C_{18}H_{26}O_{10}$, together with $C_{18}H_{28}O_{12}$,
532 $C_{18}H_{26}O_{12}$, $C_{18}H_{28}O_{11}$, $C_{18}H_{28}O_{13}$, and $C_{18}H_{28}O_{10}$ contributed more than 50% of total HOM
533 dimer signals at any OH exposure levels (Figure 2b). These six most abundant HOM dimers
534 correspond exactly to the hydroperoxyl, hydroxyl, and carbonyl termination products of
535 $C_{18}H_{27}O_{11}\cdot$ and $C_{18}H_{27}O_{13}\cdot$, respectively. These two RO_2 ($C_{18}H_{27}O_{11}\cdot$ and $C_{18}H_{27}O_{13}\cdot$), on the
536 other hand, could be generated by OH attacks to $C_{18}H_{26}O_8$ and $C_{18}H_{26}O_{10}$, respectively, which
537 strongly suggests the significant role of secondary OH chemistry in the formation of HOMs in
538 our experiments. In addition, $C_{18}H_{28}O_x$ can also be formed through accretion of a $C_9H_{13}O_m\cdot$
539 radical and a $C_9H_{15}O_m\cdot$ radical, as suggested by previous studies (Molteni et al., 2018; Wang et
540 al., 2020; Tsiligiannis et al., 2019). However, since a $C_9H_{15}O_m\cdot$ radical, as suggested by its
541 hydrogen atom number, can only be formed via an OH addition to the stabilized $C_9H_{14}O_m$
542 products through multi-generation OH reactions, our conclusion that $C_{18}H_{28}O_x$ are multi-
543 generation OH oxidation products still holds. Figure 4 shows the normalized signals of these
544 abundant HOM dimers at different OH exposures.

545 (a)

546

547 (b)

548

549 **Figure 4.** Normalized signals of (a) $\text{C}_{18}\text{H}_{26}\text{O}_{12}$, $\text{C}_{18}\text{H}_{28}\text{O}_{12}$, and $\text{C}_{18}\text{H}_{28}\text{O}_{13}$, and (b) $\text{C}_{18}\text{H}_{26}\text{O}_{10}$,
 550 $\text{C}_{18}\text{H}_{28}\text{O}_{10}$, and $\text{C}_{18}\text{H}_{28}\text{O}_{11}$ measured at the exit of OFR in experiments without NO_x as a function
 551 of OH exposure.

552

553 This decrease of dimer at relatively high OH exposures are likely due to the accelerated
 554 accretion reactions in the OFR, resulted by the high RO_2 concentrations. The HOM dimers are
 555 formed earlier compared to under ambient conditions and then can go through the further
 556 oxidation reactions. Note that this does not mean the maximum concentrations of HOM dimers
 557 will also accurately occur at the same OH exposures in the atmosphere, because the detailed
 558 appearance time of the maximum concentrations of HOM dimers is dependent on their
 559 formation rate and loss rate. In our experiments, the formation rate and loss rate were not
 560 accelerated equally. On the other hand, the loss pathways of HOM dimers were not exactly the
 561 same as the ambient due to the lack of aerosols in the OFR. With the decrease of particulate
 562 pollution and thus condensation sinks in the polluted areas, the physical loss of HOMs might
 563 be lower and the chemical process can be more important. This series of experiments are not
 564 meant to specifically find out the detailed OH exposures when the maximum concentrations of
 565 HOM dimers will occur, but try to indicate how HOM dimers evolve with the increase of OH
 566 exposures. This work can be regarded as an indicator for the potential chemical fates of HOM
 567 dimers in the atmosphere. It should be noted that the gas-phase chemistry in the PAM OFR
 568 cannot be exactly the same as that in the ambient. Reactions of OH with OVOCs often lead to
 569 HO_2 formation, resulting in a $\text{HO}_2:\text{RO}_2$ ratio larger than 1 in the real atmosphere (Bianchi et al.,

2019). A recent campaign conducted at a rural site in the Yangtze River Delta estimated that the local ratio of HO₂:RO₂, the latter of which was presumably derived from longer chain alkanes (> C₃), alkenes, and aromatic compounds, was around 1.66 (Ma et al., 2022). Such a high HO₂:RO₂ ratio condition is typically difficult to be simulated in the laboratory experiments, as the precursors are usually hydrocarbons without any OVOCs (Peng and Jimenez, 2020). This is exactly the case for our experiments, but its influences on our conclusion were tiny, as have been discussed in the Section 3.1. Therefore, the difference in the distribution of products will not change our conclusion.

Such an active secondary OH chemistry is consistent with the fast OH reaction rates of HOMs. We take C₁₈H₂₆O₈ whose plausible structure is shown in Figure S4 as an example, which is the accretion product of two C₉H₁₃O₅·. Its OH reaction rate constant is estimated to be around 2.07 × 10⁻¹⁰ cm³ molecule⁻¹ s⁻¹ according to the structure-activity relationship (Jenkin et al., 2018b, a), whose details are provided in Supplementary Text S2. This rate is several times larger than that of 1,3,5-TMB, which enables a very active secondary OH chemistry in the system. MCM recommended an OH reaction rate of 1.28 × 10⁻¹⁰ cm³ molecule⁻¹ s⁻¹ for TM135BPOOH (C₉H₁₄O₅) and 1.00 × 10⁻¹⁰ cm³ molecule⁻¹ s⁻¹ for TM135OBPOH (C₉H₁₂O₄) (Jenkin et al., 2003). The OH reaction rate for C₁₈H₂₆O₈ should also be fast due to the C=C bonds in its structure, which is activated by the adjacent functionalities. Our calculation result is consistent with this estimation.

The distributions of C18 organonitrates also verified the extensive secondary reactions. The most abundant C18 organonitrate, C₁₈H₂₇NO₁₂ was a NO termination product of radical C₁₈H₂₇O₁₁·, which, as mentioned above, was the radical generated from the OH reaction with C₁₈H₂₆O₈. C₁₈H₂₇NO₁₂ can also be formed either by accretion between a C₉H₁₅O_m· radical and a C₉H₁₂NO_m· radical or accretion between a C₉H₁₃O_m· radical and a C₉H₁₄NO_m· radical. Both C₉H₁₅O_m· and C₉H₁₄NO_m· radicals are a typical multi-generation RO₂ and thus prove C₁₈H₂₇NO₁₂ is a multi-generation OH oxidation product. Other C18 organonitrates are believed to be formed in a similar pathway. Hence, plenty of organonitrates have been formed via the multi-generation OH reactions of first-generation stabilized products.

598

599

600 **4 Atmospheric Implications**

This study highlights the influences of OH exposure on the distribution and evolution of 1,3,5-TMB-derived HOMs. Secondary OH reactions can influence HOMs' composition by directly reacting with the stabilized first-generation oxidation products, leading to enhanced formation of HOMs. Organonitrates generated in the NO experiments further confirmed this.

605 Due to the elevated abundance and the reduced volatility of HOMs, growth rates of newly
606 formed nanoparticles in the presence of HOMs should be raised, especially in high-OH
607 environments, which prevails in the summer noon. Substantially high concentrations of OH
608 have been frequently observed in polluted environments during summer, e.g., megacities in
609 China (Tan et al., 2019), and thus more active secondary OH reactions are expected compared
610 to wintertime. As a plausible consequence, seasonal differences of HOMs and new particle
611 formation (NPF) are resulted (Qiao et al., 2021; Yao et al., 2018; Guo et al., 2022). Furthermore,
612 previous studies suggest that high concentrations of NO can suppress the formation of HOMs
613 via the suppression of autoxidation (Pye et al., 2019), but the influences of such a suppression
614 could have been overestimated, since secondary OH reactions can continue to oxidize the
615 stabilized organonitrates. Our conclusions help to explain the existing gap between model
616 prediction and ambient measurement on the HOMs concentrations (Qi et al., 2018), and to build
617 a global HOMs simulation model.

618

619 *Data availability.* Data used in this work are available upon request from the corresponding
620 authors.

621

622 *Supplement.* The supplement related to this article is available online.

623

624 *Author contributions.* LW and Yuwei Wang designed the experiments. Yuwei Wang conducted
625 the laboratory experiments. Yuwei Wang analyzed the data. Yuwei Wang and LW wrote the
626 paper. All co-authors discussed the results and commented on the manuscript.

627

628 *Competing interests.* The authors declare that they have no conflict of interest.

629

630 *Acknowledgments.* This work was financially supported by the National Natural Science
631 Foundation of China (21925601, 22127811). The authors declare no competing interests.
