12

13

14 **Abstract.** An asthenospheric window underneath much of the South American continent
15 increases the heat flow in the Southern Patagonian Andes, where glacial-interglacial cycles
16 drive the building and melting of the Patagonian Icefields since the latest Miocene. The Last
17 Glacial Maximum (LGM) was reached ~20000 years ago, and an acceleration of the
18 deglaciation rate is recorded since the Little Ice Age (LIA), ~400 years ago. Fast uplift rates
19 of up to 41 ± 3 mm/yr are measured by GNSS around the Southern Patagonian Icefield and
20 currently ascribed to post-LIA lithospheric rebound, but the possible longer-term post-LGM
21 rebound is poorly constrained. These uplift rates, in addition, are one order of magnitude
22 higher than those measured on other glaciated orogens (e.g., the European Alps), which raises
23 questions about the role of the asthenospheric window in affecting the vertical surface
24 displacement rates. Here, we perform geodynamic thermo-mechanical numerical modelling
25 to estimate the surface uplift rates induced by post-LIA and post-LGM deglaciation
26 accounting for temperature dependent rheologies and different thermal regimes in the
27 asthenosphere. Our modelled maximum postglacial rebound matches the observed uplift rate
28 budget only when both post-LIA and post-LGM deglaciation are accounted for and if a
29 standard continental mantle potential temperature is increased by 150-200 °C. The
30 asthenospheric window thus plays a key role in controlling the magnitude of presently
31 observed uplift rates in the Southern Patagonian Andes.

32 1 Introduction

33 Vertical displacements of the Earth's surface with respect to the geoid occur in
34 response to the motion of crustal and mantle rock masses due to plate tectonics and the
35 associated redistribution of sediments, water, and ice by surface processes (e.g., Molnar and
36 England, 1990; Watts, 2001; Champagnac et al., 2012; Sternai, 2023; Cloetingh et al., 2023).
37 For instance, excess of topography in orogenic regions due to convergence and crustal
38 stacking deflects the lithosphere downward, whereas unloading by erosion and ice melting
39 causes upward deflection of the lithosphere, known as "isostatic" adjustment (e.g., Peltier and
40 Andrews, 1976; Peltier, 1996, 2004; Mitrovica and Forte, 1997; Butler and Peltier, 2000;
41 Kaufman and Lambeck, 2002; Watts, 2001; Turcotte and Schubert, 2002). The magnitude of
42 surface uplift rates is set primarily by the lithosphere and asthenosphere viscosities, which
43 depend, amongst other factors, on the thermal field at depth (McKenzie and Richter, 1981;
44 McKenzie and Bickle, 1988; Gurnis, 1989; Ranalli, 1995, 1997; Kaufman et al., 1997; Watts,
45 2001; Turcotte and Schubert, 2002). Although the theory that relates surface ice load changes
46 and isostatic adjustment is well developed (e.g., Peltier and Andrews, 1976; Peltier, 1996,
47 2004; Mitrovica and Forte, 1997; Kaufman and Lambeck, 2002; Stuhne and Peltier, 2015;
48 Van der Wal et al., 2015), recognizing and quantifying expressions of such dynamics in
49 natural settings is difficult.

50 The Southern Patagonian Andes in the South American Continent are located above a
51 transition zone between the subducting Antarctic and Nazca plates and a wide asthenospheric
52 window (Fig. 1a; Cande and Leslie, 1986). The Chile Triple Junction (CTJ) at $\sim 46^\circ\text{S}$
53 delimits the surface tip of the asthenospheric window, which opened during the last ~ 16 Ma
54 from south to north (Ramos and Kay, 1992; Breitsprecher and Thorkelson, 2009). First order
55 effects of the asthenospheric flow on the surface continental geology are the inhibition of arc
56 volcanism in favour of retroarc magmatism, forward propagation of the fold-and-thrust belt,
57 and rock uplift (Ramos and Kay, 1992; Ramos, 2005; Breitsprecher and Thorkelson, 2009;
58 Guillaume et al., 2009; Lagabrielle et al., 2010; Georgieva et al., 2016). Rock uplift due to
59 asthenospheric upwelling, in particular, was estimated as < 0.15 mm/yr in the last 3 Ma over
60 an area of about 100000 km² around the CTJ latitude (Guillaume et al., 2009). The heat flow
61 was calculated as >100 mW/m² near the CTJ, ~ 70 - 90 mW/m² in the center of the
62 asthenospheric window ($\sim 50^\circ\text{S}$), and 50 - 60 mW/m² near its northern boundary ($\sim 46^\circ\text{S}$)
63 (Ávila and Dávila, 2018), suggesting that the mantle temperature beneath Southern Patagonia
64 is likely higher than in normal subduction zones (Ranalli, 1997).

65 The Patagonian Ice Sheet covered the Southern Patagonian Andes between ~30000
66 and ~17000 years ago, extending from latitudes 38 to 55 °S with estimated area of ~490000
67 km² and volume of ~550000 km³ (Fig. 1 a) based on preserved glacial geomorphologies,
68 stratigraphic and paleoecological records, and geochronological data (Moreno et al., 1999,
69 2005; McCulloch et al., 2000, 2005; Hulton et al., 2002; Rabassa, 2008; Glasser et al., 2005,
70 2016; Glasser and Jansson, 2008; Hein et al., 2010; Boex et al., 2013; Bourgois et al., 2016;
71 Martinod et al., 2016; Bendle et al., 2017; Thorndycraft et al., 2019; Davies et al., 2020). The
72 average and maximum ice thickness were estimated as ~1100 m and ~2500 m, respectively
73 (McCulloch et al., 2000; Hulton et al., 2002; Boex et al., 2013; Davies et al., 2020).
74 Currently, the SPI covers an area of ~13219 km² with a volume of 3632 ± 675 km³, whereas
75 the Northern Patagonian Icefield (NPI) covers an area of ~3976 km² with a volume of $1124 \pm$
76 260 km³ (Fig. 1). The present-day ice thickness reaches up to ~2000 m in deep glacial valleys
77 (Millan et al., 2019). The long term ice loss rate is uncertain, but more than 75% of ice was
78 certainly lost since the Last Glacial Maximum (LGM, approximately 20000 years ago), and
79 some models predicted more than 95% of ice loss with separation between the SPI and NPI in
80 the first 5000 to 10000 years of post-LGM deglaciation (McCulloch et al., 2000; Hulton et
81 al., 2002; Boex et al., 2013; Bourgois et al., 2016; Thorndycraft et al., 2019; Davies et al.,
82 2020).

83 GNSS and remote sensing data show ongoing vertical rock uplift rates between 30 ± 3
84 and 41 ± 3 mm/yr in the northern part of the Southern Patagonian Icefield (SPI, Fig. 1b),
85 gradually decreasing toward its peripheral parts (Aniya, 1996; Aniya et al., 1997; Rignot et
86 al., 2003; Ivins and James, 1999, 2004; Dietrich et al., 2010; Willis et al., 2012; Lange et al.,
87 2014). Such outstandingly high uplift rates are currently ascribed to lithospheric viscoelastic
88 glacial isostatic adjustment (GIA) following the Little Ice Age (LIA), with apex around 1630
89 AD (Ivins and James, 1999, 2004; Glasser et al., 2011). Deglaciation since the LIA was
90 responsible for an ice loss of 503 ± 101.1 km³ in the SPI (Glasser et al., 2011), with a
91 substantial increase of the glacial recession after the 20th century (Aniya, 1996; Aniya et al.,
92 1997; Rignot et al., 2003; Glasser et al., 2011; Davies and Glasser, 2012; Ivins et al., 2011;
93 Willis et al., 2012). To match the very high observed uplift rate budget, previous GIA studies
94 infer low asthenosphere viscosity (in the order of 10^{18} Pa s) and thin elastic lithosphere (~35
95 km thick) (Ivins and James, 1999, 2004; Klemann et al., 2007; Dietrich et al., 2010; Lange et
96 al., 2014). However, although this is consistent with abnormally high mantle temperatures,
97 viscosity estimates from previous studies are untied to the regional thermal regime, which

98 prevents a more thorough characterization of the role of the asthenospheric window
99 underneath the SPI in affecting the observed uplift rates. In addition, the contribution of post-
100 LGM deglaciation to present-day rock uplift rate was marginally addressed. Here, we
101 perform fully coupled thermo-mechanical numerical geodynamic experiments forced by
102 surface unloading scaled on post-LIA and post-LGM ice melting to evaluate their relative
103 contribution to the observed regional uplift rates. Numerical experiments account for a range
104 of positive thermal anomalies in the asthenosphere to further asses the role of the
105 asthenospheric window in setting the mantle viscosity and associated postglacial rebound.
106 Focusing on the magnitude, rather than the pattern, of the inferred surface uplift rates, we use
107 the observed budget of rock uplift rate to constrain plausible thermal and viscosity structures
108 at depth as well as the timing of postglacial rebound.
109

110 2 Methodology

111 2.1 Numerical model

112 We use a fully coupled thermo-mechanical, visco-elasto-plastic, numerical
113 geodynamic model to quantify the effect of thermal anomalies in the mantle on the magnitude
114 of surface uplift rates due to deglaciation. We provide a short overview of the governing
115 equations hereafter, while a detailed description of numerical technique can be found, for
116 instance, in Gerya and Yuen (2007), Gerya et al. (2019), Sternai (2020), and Muller et al.
117 (2022). The continuity equation allows for the conservation of mass during the displacement
118 of a geological continuum:

$$119 \quad (1) \quad \frac{\partial \rho}{\partial t} + \nabla(\rho v) = 0$$

120 where ρ is the local density, t is time, v is the velocity vector, and ∇ is the divergence
121 operator. The momentum equation describes the changes in velocity of an object in the
122 gravity field due to internal and external forces:

$$123 \quad (2) \quad \frac{\partial \sigma_{ij}}{\partial x_i} + \rho g_i = \rho \left(\frac{\partial v_i}{\partial t} + v_j \frac{\partial v_i}{\partial x_j} \right)$$

124 where σ_{ij} is the stress tensor, x_i and x_j are spatial coordinates, and g_i is the i -th component of
125 the gravity vector. The energy equation allows for the conservation of energy during
126 advective and conductive heat transfer in the continuum:

$$127 \quad (3) \quad \rho C_p \frac{dT}{dt} - \text{div}(c \nabla T) + v \nabla T = H_r + H_s + H_a + H_t$$

128 where P is pressure, T is temperature, C_p is specific heat capacity at a constant P , c is the
129 thermal conductivity, $H_r + H_s + H_a + H_l$ are the volumetric heat productions by
130 radiogenic, shear, adiabatic and latent heat, respectively. $H_a \propto \frac{DP}{Dt}$, $H_s = \sigma'_{ij} \dot{\epsilon}'_{ij(viscous)}$, and
131 H_r and H_l are the radiogenic and latent heat productions.

132 Ductile deformation is thermally activated generating viscous flow, which involves
133 diffusion and dislocation creep, calculated according to the material shear viscosity:

$$134 \quad (4) \quad \frac{1}{\eta_{ductile}} = \frac{1}{\eta_{diff}} + \frac{1}{\eta_{dist}}$$

135 with

$$136 \quad \eta_{diff} = \frac{\eta_0}{2\sigma_{cr}^{n-1}} \exp\left(\frac{E_a + PV_a}{RT}\right), \text{ and}$$

$$137 \quad \eta_{dist} = \frac{\eta_0^{\frac{1}{2}}}{2} \exp\left(\frac{E_a + PV_a}{nRT}\right) \dot{\epsilon}'_{II}{}^{\frac{1}{2}-1}$$

138 where η_{diff} and η_{dist} are the shear viscosity for diffusion and dislocation creep, respectively,
139 η_0 is the material static viscosity, σ_{cr} is the diffusion-dislocation transition critical stress, n
140 is the stress exponent, E_a is the activation energy, V_a is the activation volume, R is the gas
141 constant, and $\dot{\epsilon}'_{II}$ is the second invariant of the strain rate tensor. The viscous deviatoric strain
142 rate tensor, $\dot{\epsilon}'_{ij(viscous)}$, is defined by:

$$143 \quad (5) \quad \dot{\epsilon}'_{ij(viscous)} = \frac{1}{2\eta_{ductile}} \sigma'_{ij} + \delta_{ij} \eta_{bulk} \dot{\epsilon}_{kk} = \frac{1}{2\eta_{diff}} \sigma'_{ij} + \frac{1}{2\eta_{dist}} \sigma'_{ij} + \delta_{ij} \eta_{bulk} \dot{\epsilon}_{kk}$$

144 where σ'_{ij} is the deviatoric stress tensor, δ_{ij} is the Kronecker delta, $\dot{\epsilon}_{kk}$ is the volumetric
145 strain rate (e.g., related to phase transformations), and η_{bulk} is the bulk viscosity.
146 Recoverable deformation is defined by the elastic deviatoric strain rate tensor, $\dot{\epsilon}'_{ij(elastic)}$, as:

$$147 \quad (6) \quad \dot{\epsilon}'_{ij(elastic)} = \frac{1}{2\mu} \frac{\overset{\circ}{D}\sigma'_{ij}}{Dt}$$

148 where μ is the shear modulus and $\frac{\overset{\circ}{D}\sigma'_{ij}}{Dt}$ is the objective co-rotational time derivative of the
149 deviatoric stress tensor. The plastic deformation, brittle and localised, occurs at low
150 temperature when the absolute shear stress limit, σ_{yield} , is reached, with

$$151 \quad (7) \quad \sigma_{yield} = C + \sin(\varphi)P$$

152 where C is cohesion and φ is the effective internal friction angle. The plastic strain rate
153 tensor, $\dot{\epsilon}'_{ij(plastic)}$, is defined as:

$$154 \quad (8) \quad \dot{\epsilon}'_{ij(plastic)} = 0 \text{ for } \sigma_{II} < \sigma_{yield}, \dot{\epsilon}'_{ij(plastic)} = \mathcal{X} \frac{\partial \sigma'_{ij}}{\partial \sigma_{II}} \text{ for } \sigma_{II} \geq \sigma_{yield}$$

155 where \mathcal{X} is the plastic multiplier which satisfies the plastic yielding condition $\sigma_{II} = \sigma_{yield}$.

156 The bulk strain rate tensor, $\dot{\epsilon}'_{ij(bulk)}$, integrates the viscous, elastic and plastic deformation:

157 (9) $\dot{\epsilon}'_{ij(bulk)} = \dot{\epsilon}'_{ij(viscous)} + \dot{\epsilon}'_{ij(elastic)} + \dot{\epsilon}'_{ij(plastic)}$

158 **2.2 Reference model setup and modeling approach**

159 The model domain, scaled on the study region, is 700 km wide and 120 km thick.
 160 From top to bottom, the model accounts for 10 km of ‘sticky’ air, 30 km of continental crust
 161 (with rheology of quartzite, Ranalli, 1995), 30 km of lithospheric mantle, and 50 km of
 162 asthenospheric mantle (with rheology of dry dunite, Ranalli, 1995), in agreement with
 163 literature data (e.g., Klemann et al., 2007). The initial geotherm is piece-wise linear resulting
 164 from an adiabatic temperature gradient of 0.5 °C/km in the asthenosphere (Turcotte and
 165 Schubert, 2002) and thermal boundary conditions equal to 0 °C at the surface and 1327 °C at
 166 the bottom of the lithosphere, with nil horizontal heat flux across the vertical boundaries. The
 167 rheologic and thermal structure of the reference model give a lithospheric elastic thickness,
 168 *Te* (*sensu* Burov and Diament, 1995), of ~30 km, comparable to previous estimates
 169 underneath the SPI based on GIA models (Ivins and James, 1999; Dietrich et al., 2010; Lange
 170 et al., 2014), heat flow data (Ávila and Dávila, 2018), and waveform inversion (Robertson
 171 Maurice et al., 2003). Rocks rheological properties are listed in Table 1.

172 The numerical model uses the finite differences with marker-in-cell technique,
 173 resolved by 51 × 61 nodes in x and y directions, respectively, distributed on a Eulerian grid
 174 that accounts for a maximum resolution of 1 km along the y direction in the upper part of the
 175 model domain, and ~13 km in the x direction. 400 × 400 Lagrangian markers are randomly
 176 distributed along the x and y dimensions and used for advecting the material properties
 177 (Gerya and Yuen, 2007; Gerya et al., 2019). The material properties carried by Lagrangian
 178 markers are then interpolated onto the Eulerian grid via a 4th order Runge-Kutta interpolation
 179 scheme. An internal free surface is simulated through the 10 km thick layer of sticky air. The
 180 velocity boundary conditions are free slip at all boundaries (x = 0 and x = 700 km; y = 0 and
 181 y = 120 km).

182 On the top of the crust and in the middle of the model domain we impose a 2 km thick
 183 pseudo-icecap to simulate lithospheric unloading during deglaciation. The pseudo-icecap is
 184 70 km wide for the post-LIA model set and 200 km wide for the post-LGM model sets (Fig. 2
 185 a). We compute the surface load, *L*, as

186 (10) $L = \rho_{ice} g h_{ice}$,

187 where ρ_{ice} is the pseudo-icecap density, *g* is the gravity acceleration, and *h_{ice}* is the pseudo-
 188 icecap thickness, and deglaciation occurs by gradually reducing *h_{ice}* in time (Fig. 2 b, c). We
 189 run two sets of experiments for the post-LGM deglaciation. In *Model set 1*, 75% of ice loss

190 occurs in 20000 years (i.e., 1500 m drop of ice thickness, Fig. 2 b), thus assuming a
191 conservative estimate of ice loss since the beginning of the LGM until the present-day. In
192 *Model set 2*, 95% of ice loss occurs in 10000 years (i.e., 1900 m drop of ice thickness, Fig. 2
193 b), assuming faster deglaciation rates of the Patagonian Ice Sheet in the first half of post-
194 LGM deglaciation (McCulloch et al., 2000; Hulton et al., 2002; Boex et al., 2013; Bendle et
195 al., 2017; Thorndycraft et al., 2019; Davies et al., 2020). For the post-LIA deglaciation, we
196 simulate 10% of ice loss in 400 years (i.e., 200 m drop of ice thickness, Fig. 2 c) (Aniya,
197 1996; Aniya et al., 1997; Rignot et al., 2003; Ivins and James, 1999, 2004; Dietrich et al.,
198 2010; Willis et al., 2012; Lange et al., 2014).

199 In the models the initial lateral extent of the pseudo-icecap does not change
200 throughout the deglaciation. Although this simplification may affect the inferred pattern of
201 postglacial rebound, it greatly facilitates the simulation of deglacial lithospheric unloading
202 without significantly affecting the magnitude of postglacial rebound, which is the main focus
203 here. All simulations account for some spin up time before the deglaciation begins, so that the
204 lithosphere-asthenosphere system adjusts to the pseudo-icecap initial load. The surface uplift
205 rate during the deglaciation is calculated through time as the surface elevation change
206 resulting from the modelled strain field divided by the viscoelastic timestep. Given the
207 geologically short time window investigated here, we neglect deformation related to longer
208 term tectonic forces. The parametric study focuses on the mantle potential temperature (*sensu*
209 McKenzie and Bickle, 1988) which accounts for positive thermal anomalies, TA, of up to
210 200 °C in steps of 50 °C, added to the reference mantle potential temperature of 1265 °C
211 (McKenzie and Bickle, 1988; Currie and Hyndman, 2006; Ávila and Dávila, 2018; Sternai,
212 2020) to mimic the presence of a slab window at depth.

213 3 Results

214 Results are shown in Table 2 and Figs. 4-7. In agreement with the theory of
215 lithospheric flexure (e.g., Turcotte and Schubert, 2002) the deglaciation triggers uplift in the
216 region covered by the melting pseudo-icecap and subsidence in the neighbouring regions
217 (Figs. 4-6). Overall, increasing the mantle potential temperature decreases the asthenospheric
218 viscosity, with significant effects on the magnitude of the modelled surface velocity field.
219 The asthenosphere viscosity ranges between 10^{22} - 10^{19} Pa s in simulations with TA equal to 0
220 (reference model), 50 and 100 °C, and between 10^{19} - 10^{16} Pa s in simulations with TA equal
221 to 150 and 200 °C (Fig. 3 a-d). Lithospheric warming due to increasing mantle potential
222 temperature also leads to a reduction of the lower lithosphere viscosity (from 10^{22} to 10^{20} Pa
223 s), thereby decreasing the integrated lithospheric strength.

224 In *Model set 1* for Post-LGM deglaciation, when TA is 0 (reference model) the
225 maximum uplift rates is < 1 mm/yr during the first 5000 years of the deglaciation, increasing
226 gradually up to 9.5 mm/yr in the later stages of the deglaciation (i.e., 20000 years, Fig. 4).
227 When TA equals 50, 100, 150 and 200 °C, the maximum uplift rates can reach up to ~2, ~5,
228 ~12, and ~15 mm/yr, respectively, already in the first 1000 years of the deglaciation (Fig. 4
229 a). When TA is 50 and 100 °C the maximum uplift rate is subject to a protracted increase in
230 time, reaching up to ~12 and ~14 mm/yr after 20000 years of deglaciation (Figs. 4 b-d and 7
231 a). For TA equal to 150 and 200 °C, the maximum uplift rate reach a plateau between 11 and
232 17 mm/yr during the 20000 years of deglaciation (Figs. 4 and 7 a, Table 2). After the end of
233 the deglaciation, the maximum uplift rate takes longer than about 5000 years to re-equilibrate
234 to 0 mm/yr when $TA \leq 100$ °C, whereas it drops to 0 mm/yr almost immediately when TA is
235 150 or 200 °C (Fig. 7 a).

236 In the *Model set 2* for Post-LGM deglaciation, the maximum uplift rate is less than 2
237 mm/yr during the first 1000 years of deglaciation when TA is 0, 50 and 100 °C, whereas it
238 reaches up to ~22 and ~30 mm/yr during in the first 1000 years of deglaciation when TA is
239 150 and 200 °C (Fig. 5 a, 7 b, and Table 2). Between 5000 and 10000 years of deglaciation,
240 the maximum uplift rate increases to ~19, ~25 and ~36 mm/yr, respectively when TA is 0, 50
241 and 100 °C, whereas it reach up to between 36 and 41 mm/yr between 50000 and 1000 years
242 of deglaciation when TA equal to 150 and 200 °C. The maximum uplift rate decreases slower
243 if TA is 0, 50 and 100 °C, taking longer than 5000 year after the deglaciation to drop to
244 values <5 mm/yr (Fig. 7 b and Table 2), whereas it quickly drops to < 2 mm/yr when the
245 deglaciation is over and TA is 150 and 200°C (Figs. 5 b-d and 7b). Overall, a warmer and

246 less viscous asthenosphere generates a higher magnitude and fast changing postglacial
247 rebound than a cooler and more viscous asthenosphere.

248 In the post-LIA model set, the maximum uplift rate is ~ 1.4 , ~ 2.3 and ~ 2.2 mm/yr
249 during the first 100 years of deglaciation when TA is respectively 0, 50, and 100 °C, whereas
250 it reaches ~ 8.3 and ~ 23 mm/yr during the same interval when TA is respectively 150 and 200
251 °C (Figs. 6 a, 7 c, and Table 2). Between 200 and 400 years of deglaciation, the maximum
252 uplift rate reaches ~ 1.9 , ~ 2.5 and ~ 3 mm/yr when TA equal to 0, 50 and 100 °C, and ~ 14 and
253 ~ 25.5 mm/yr when TA is 150 and 200 °C, respectively (Figs. 6 c-d, 7 c, and Table 2). When
254 the deglaciation ends, the maximum uplift rate drops to ~ 0 mm/yr in ~ 100 years when TA \leq
255 100 °C, whereas it takes longer than 1000 years when TA equals 150 °C or 200 °C (Fig. 7 c).
256 Overall, a warmer and less viscous asthenosphere generates a higher magnitude postglacial
257 rebound which, however, takes much longer to re-equilibrate to 0 mm/yr after the end of the
258 deglaciation than a cooler and more viscous asthenosphere.

259

260 **4 Discussion and conclusions**

261 Our modelling is simplistic in that we impose a linear and uniform ice loss instead of
262 a more realistic ice-sheet melting pattern in space and time. This choice is motivated by the
263 limited data reporting on the SPI melting velocities and associated redistribution of the
264 surface masses, which cover time spans much shorter than the post-LIA and post-LGM time
265 windows investigated here (Aniya, 1996; Aniya et al., 1997; Rignot et al., 2003; Ivins and
266 James, 1999, 2004; Willis et al., 2012; Dietrich et al., 2010; Lange et al., 2014). As
267 previously highlighted (Hulton et al., 2002; Rabassa, 2008; Glasser et al., 2011; Davis and
268 Glasser, 2012; Martinod et al., 2016; Bendle et al., 2017; Davies et al., 2020), constraints
269 regarding the ice-sheet mass balance and melting velocities throughout the time windows of
270 interest are difficult to obtain from the preserved geomorphological, stratigraphic and
271 geochronological records. We also assume a homogeneous lithosphere and neglect lateral
272 viscosity variations in the asthenosphere (Klemann et al., 2007) despite the long-term
273 southern Andean orogenic history (Cande and Leslie, 1986; Ramos, 2005; Muller et al.,
274 2021). Notwithstanding these limitations, however, our fully coupled numerical thermo-
275 mechanical geodynamic models provide realistic uplift rates that one can compare to current
276 geodetic observations. Following the example of previous studies (Ivins and James, 1999,
277 2004; Klemann et al., 2007; Dietrich et al., 2010; Lange et al., 2014), we discuss our results
278 assuming that GNSS-measured rock uplift rates are mostly related to the deglaciation history

279 and only marginally controlled by the longer term geodynamics (e.g., Ramos, 2005; Muller et
280 al., 2021).

281 We first remark that inferred maximum post-LIA uplift rate of up to a few mm/yr
282 from experiments without or with a low asthenospheric thermal anomaly ($TA \leq 100$ °C) are
283 within the same order of magnitude of maximum uplift rates measured in collisional orogens
284 such as the European Alps (Sue et al., 2007; Serpelloni et al., 2013; Walpersdorf et al., 2015;
285 Sternai et al., 2019) and the Himalayas (Larson et al., 1999). Since these collisional orogens
286 are characterized by a thicker lithosphere (Geissler et al., 2010; Ravikumar et al., 2020), they
287 are likely less sensitive to mantle dynamics than the Southern Patagonian Andes. When we
288 consider lithospheric unloading due to post-LGM deglaciation of a wider ice sheet, however,
289 the inferred maximum uplift rate via *Model set 1* and *Model set 2* reaches up to 10 mm/yr for
290 and 20 mm/yr, respectively, even without asthenospheric thermal anomaly. This suggests a
291 that a contribution from long-term postglacial rebound to the present-day uplift rates
292 measured in the SPI is likely.

293 In the Southern Patagonian Andes, the regional asthenosphere viscosity was estimated
294 between 1.6 and 8×10^{18} Pa s from GIA models based on GNSS and satellite observations
295 (Ivins and James, 1999, 2004; Klemann et al., 2007; Dietrich et al., 2010; Willis et al., 2012;
296 Lange et al., 2014). Similarly, the asthenosphere viscosity from our models when $TA > 100$
297 °C is $< 10^{19}$ Pa s, with the lowest viscosity value of 10^{16} Pa s imposed where partial melting,
298 supported by the regional Holocene volcanism (Stern and Kilian, 1996), occurs. Under these
299 conditions, however, our experiments provide uplift rates between 14 and 26 mm/yr for post-
300 LIA deglaciation indicating that, even with a very low viscosity asthenosphere, the rebound
301 due to the short-term post-LIA deglaciation does not reach the presently observed maximum
302 uplift rates of 41 ± 3 mm/yr. Experiments that account for a low viscosity asthenosphere and
303 long-term post-LGM deglaciation lasting for 20000 years and 10000 years reach up to ~ 25
304 and ~ 42 mm/yr of uplift rate, respectively, comparable to present-day values. Results,
305 therefore, indicate that the outstanding observational budget of rock uplift in the SPI is
306 matched only when accounting for higher-than-normal mantle temperatures, thereby
307 highlighting the relevance of the regional asthenospheric window.

308 Because of the limited knowledge regarding the timing and amount of ice loss since
309 the LGM (e.g., Davies et al., 2020), it is difficult to position in time present-day uplift rate
310 measurements within the investigated deglaciation scenarios to assess the contribution of
311 post-LGM and post-LIA deglaciation to the maximum uplift rate budget. In the faster post-
312 LGM deglaciation scenario (*Model set 2*) the observed maximum uplift rate budget is

313 attained in about 10000 years of deglaciation, but only minor residual rebound could be
314 observed today regardless of the amount of ice loss (Fig. 7 b). If post-LGM deglaciation
315 occurred slower (*Model set 1*), this event may contribute to up to 40% to the present-day
316 uplift rate budget. Although it is difficult to reconcile this scenario with the geomorphological
317 and geochronological evidences (Hulton et al., 2002; Boex et al., 2013; Davis and Glasser,
318 2012; Martinod et al., 2016; Bendle et al., 2017; Thorndycraft et al., 2019; Davies et al.,
319 2020), it appears that post-LIA rebound alone cannot cover the entire budget of the observed
320 uplift rates even with the highest tested TA, which points to a non-negligible contribution
321 from post-LGM deglaciation. This latter conclusion is reinforced by estimates of the mantle
322 relaxation time, τ_r , as (Turcotte and Schubert, 2002):

$$323 \quad (11) \quad \tau_r = \frac{4\pi\nu}{g\lambda},$$

324 where ν is the asthenosphere viscosity, λ is the width of the ice sheet, and g is the
325 gravity acceleration. Using $10^{16} < \nu < 10^{18}$ Pa s and $\lambda = 200$ km leads to $\sim 2000 < \tau_r < \sim 200000$
326 years, a time range considerably longer than the post-LIA deglaciation and including full
327 Pleistocene glacial-interglacial cycles (Ruddiman et al., 1986). We therefore propose that
328 currently observed uplift rates in the Southern Andes are driven by both post-LGM and post
329 LIA lithospheric rebound enhanced by a thermal anomaly of at least 150 °C due to the
330 regional asthenospheric window which lowers mantle viscosities.

331 As a final consideration, our models suggest that we shall measure regional uplift
332 rates in the order of the tens of cm/yr in the next century if the currently observed ice loss rate
333 of at least -20 Gt/yr in the SPI (Willis et al., 2012) will continue until the total meltdown of
334 the ice sheet in ~ 200 years.

560 **Fig. 1. Regional context and uplift rate data.** a) Map of southern Patagonia with the Southern Patagonian Icefield (SPI), Northern
 Patagonian Icefield (NPI), and the Cordillera Darwin Icefield (CDI) in light blue, the approximate extension of the icefields at the Last
 Glacial Maximum (LGM limit), and the approximate extension of the present-day asthenospheric window (dashed region) beneath the
 South American Continent (SAM). In the Pacific Ocean, the spreading ridges (s.r., thick black lines) and transform faults (t.f., thin black
 lines) separate the Nazca (NZ) and the Antarctic (AT) plates. The subduction trench is also highlighted in black. The arrows show the
 565 approximate rate and direction of subduction of the oceanic plates. b) Zoom on the SPI with GPS stations (circles) used to estimate the
 viscoelastic uplift rates, from Lange et al. (2014).

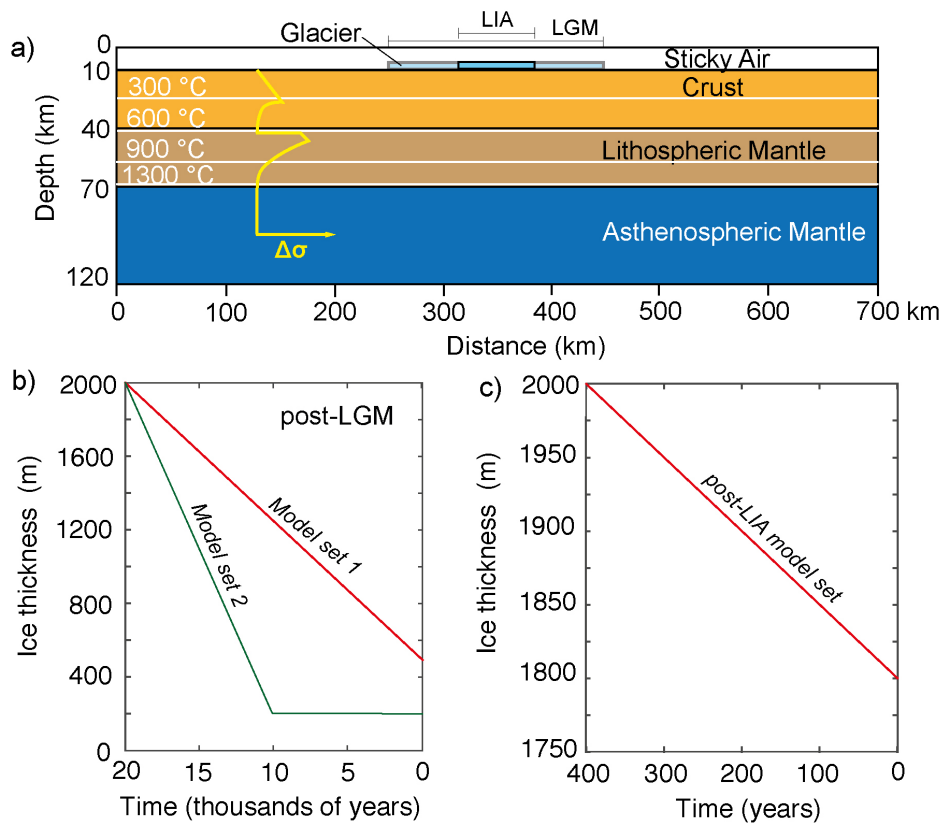

Fig. 2. Reference numerical model setup. a) Thermo-mechanical numerical model domain with rheological layers (Table 1), isotherms (white lines), and yield strength ($\Delta\sigma$) profile (yellow line). (b, c) Ice thickness vs. time used in the numerical models to simulate the post-LGM deglaciation in two model sets (b), and the post-LIA deglaciation (c).

570

575 **Fig. 3. Distribution of viscosity and velocity vectors in the numerical models.** a) Reference model without an asthenospheric thermal anomaly, TA = 0 °C, and b) model with the higher simulated asthenospheric thermal anomaly, TA = 200 °C, in the last timestep of post-LIA deglaciation. c) Reference model with TA = 0 °C, and d) model with TA = 200 °C, in the last timestep of *Model set 1* of post-LGM deglaciation. Velocity vectors do not have the same scaling and are only meant for visualization purpose.

580 **Fig. 4. Surface uplift rates vs. distance for Model set 1 of post-LGM deglaciation.** a) $t = 1000$ years of deglaciation, b) $t = 5000$ years of deglaciation, c) $t = 10000$ of deglaciation, d) 20000 years of deglaciation. Different line colours correspond to different TA.

Fig. 5. Surface uplift rates vs. distance for *Model set 2* of post-LGM deglaciation. a) $t = 1000$ years of deglaciation, b) $t = 5000$ years of deglaciation, c) $t = 10000$ of deglaciation, d) 20000 years of deglaciation. Different line colours correspond to different TA.

585

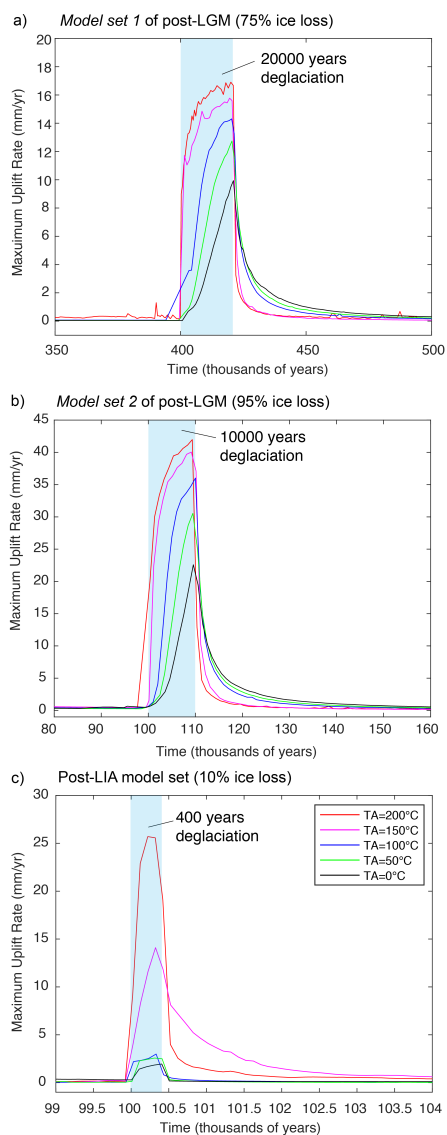

Fig. 6. Surface uplift rates vs. distance for post-LIA deglaciation model set. a) $t = 100$ years of deglaciation, b) $t = 200$ years of deglaciation, c) $t = 300$ years of deglaciation, d) 400 years of deglaciation. Different line colours correspond to different TA.

590 **Fig. 7. Maximum uplift rates vs. time for model sets of deglaciation with different TA.** a) *Model set 1* of post-LGM deglaciation accounting of 75% of ice loss in 20000 years, b) *Model set 2* of post-LGM deglaciation accounting of 95% of ice loss in 10000 years, and c) Post-LIA deglaciation model set accounting 10% of ice loss in 400 years (blue-shaded region). Blue-shaded regions highlight the modeled deglaciation intervals.

Table 1 – Material properties used in the numerical experiments.

	ρ_0^s (km/ m ³)	E_a (kJ/mo l)	V_a (m ³ / mol)	n	C (M pa)	Visc. flow law	Sin (ϕ_{eff})	c (W/m/K)	μ (Gp a)	C_p (J/kg/ K)	H_r (μ W/ m ³)	H_l (kJ/k g)	α (1/ k)	β (1/P a)

595 ρ_0^s is the standard densities of solid rocks; E_a is the activation energy; V_a is the activation volume; n is the stress exponent; C is cohesion; ϕ_{eff} is the effective internal friction angle; c is thermal conductivity; μ is the shear modulus; C_p is the specific heat capacity; H_r and H_l are the radiogenic and latent heat productions, respectively; α is thermal expansion; β is compressibility. Qz and Ol are quartzite and olivine, respectively. All rheological and partial melting laws/parameters are based on experimental rock mechanics and petrology (Ranalli, 1995; Hirschmann, 2000; Johannes, 1985; Turcotte and Schubert, 2002).

600

Table 2 – Maximum uplift rates derived from the numerical models with a thermal anomaly (TA) of 0, 50, 100, 150 and 200 °C for the Model set 1 (a) and Model set 2 (b) of post-LGM deglaciation, and the post-LIA deglaciation model set (c). The $t = 0$ is the timestep immediately before the beginning of deglaciation. Fig. 7 is a plot of the maximum uplift rate vs. time calculated for each timestep in all numerical models.

a) Model set 1 of post-LGM deglaciation (20000 years)							
TA (°C)	Maximum uplift rate (mm/yr)						
0	0.0425	0.0412	0.9781	3.2849	6.4337	9.5049	4.9781
