**Abstract.** Arctic warming is causing permafrost thaw and release of organic carbon (OC) to fluvial systems. Permafrost-derived OC can be transported downstream and degraded into greenhouse gases that may enhance climate warming. Susceptibility of OC to decomposition depends largely upon its source and composition which varies throughout the seasonally distinct hydrograph. Most studies on carbon dynamics to date have focused on larger Arctic rivers, yet little is known about carbon cycling in lower order rivers/streams. Here, we characterize composition and sources of OC, focusing on less studied particulate OC (POC), in smaller waterways within the Kolyma River watershed. Additionally, we examine how watershed characteristics control carbon concentrations. In lower order systems, we find rapid initiation of primary production in response to warm water temperatures during spring freshet, shown by decreasing  $\delta^{13}\text{C}$ -POC, in contrast to larger rivers. This results in  $\text{CO}_2$  uptake by primary producers and microbial degradation of mainly autochthonous OC, however, if terrestrially derived inorganic carbon is assimilated by primary producers, also  $\text{CO}_2$  emissions may occur. As Arctic warming and hydrologic changes may increase OC transfer from smaller waterways to larger river networks, understanding carbon dynamics in smaller waterways is crucial.

## 1 Introduction

The Arctic is warming up to four times the rate of the global average (Meredith et al., 2019; Rantanen et al., 2022) which affects hydrology, carbon cycling and permafrost (Turetsky et al., 2019; Walvoord and Kurylyk, 2016). Terrestrial permafrost thaw adds organic carbon (OC) to fluvial systems via active layer leaching and abrupt thaw processes (e.g., river bank erosion), the former releasing predominantly dissolved OC (DOC) and the latter particulate OC (POC) (Guo et al., 2007; Schuur et al.,

2015). Mineralization of terrestrially derived permafrost OC in fluvial systems adds greenhouse gases into the atmosphere enhancing climate warming (Meredith et al., 2019; Schuur et al., 2015).

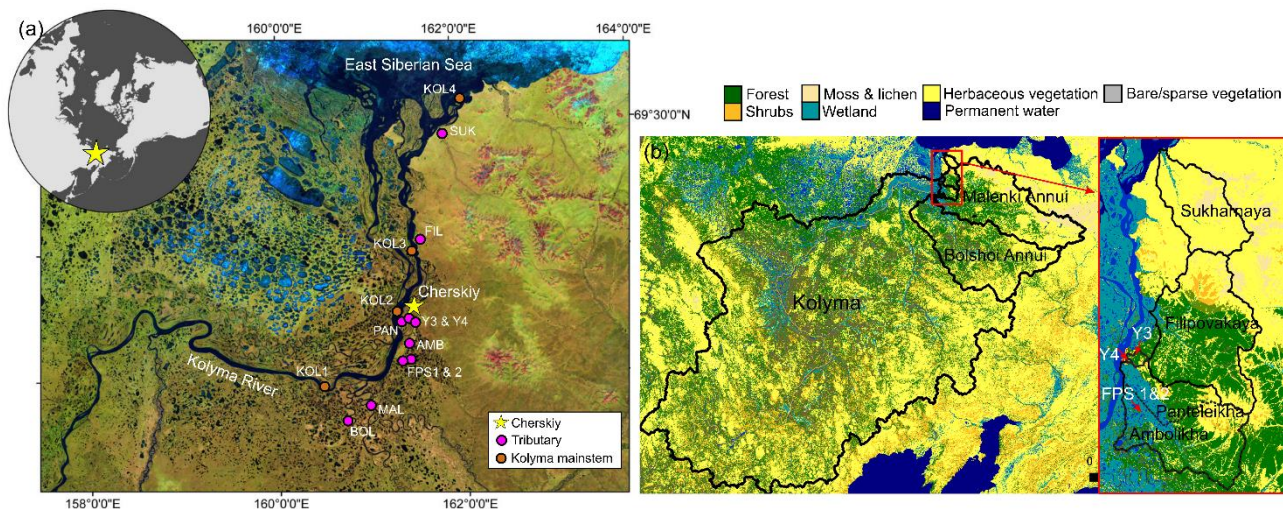

35 Mineralization dynamics of fluvial OC are largely determined by its composition. Modern-aged DOC predominantly fuels CO<sub>2</sub> emissions from Arctic waters (Dean et al., 2020), yet permafrost DOC is preferentially degraded when present (Mann et al., 2015; Vonk et al., 2013). The fluxes, composition, and degradation of mainstem-POC have been addressed in large Arctic rivers (e.g., Bröder et al., 2020; Guo and Macdonald, 2006; Keskitalo et al., 2022; McClelland et al., 2016), but our understanding of the carbon dynamics, especially regarding POC, and seasonality of smaller waterways are lacking.

40 Here, we investigate carbon characteristics (POC, DOC, dissolved inorganic carbon - DIC, stable carbon isotope  $\delta^{13}\text{C}$  of these carbon pools, and radiocarbon  $\Delta^{14}\text{C}$ -POC) and water chemistry (temperature, pH, conductivity, and water isotopes  $\delta^{18}\text{O}$  and  $\delta^2\text{H}$ ) in lower order streams/ivers within the Kolyma watershed (Fig. 1). We perform source-apportionment modelling to characterize sources of POC, and investigate how seasons and spatial characteristics (e.g., slope, soil OC content) affect carbon contributions in these streams. A future intensification of the Arctic hydrological cycle combined with longer growing season, earlier onset of spring freshet and on-going permafrost thaw is expected to shunt organic matter more rapidly from land into lower order streams/ivers and into large river systems. It is therefore necessary to understand carbon dynamics of lower order  
45 systems in order to project future changes within Arctic rivers (Collins et al., 2021; Mann et al., 2022; Raymond et al., 2016; Stadnyk et al., 2021).

## 2 Materials and Methods

### 2.1 Study area and background

50 The Kolyma River drains 100 % continuous permafrost terrain (Holmes et al., 2012) with variable landscapes including wetlands, tundra and forests (Mann et al., 2012). Here, permafrost consists partially of the OC- and ice-rich Yedoma sediments, which date to the Pleistocene (Strauss et al., 2017, 2021; Zimov et al., 2006). The continental climate encompasses cold winters (January mean -32.7 °C) and mild summers (July mean 13.2 °C) (Fedorov-Davydov et al., 2018b). River hydrology is characterized by a discharge peak ( $>30,000 \text{ m}^3 \text{ s}^{-1}$ ) during spring freshet (May–June), followed by a lower discharge (average of  $6,200 \pm 3000 \text{ m}^3 \text{ s}^{-1}$  in 2007–2017) during summer (July–August) (Shiklomanov et al., 2021). River OC concentrations  
55 follow the same pattern as discharge with higher concentrations during freshet than summer (Holmes et al., 2012; McClelland et al., 2016). All tributaries investigated in this study are partially underlain by Yedoma and located within the taiga or the tundra zone (Fig. 1) (Siewert et al., 2015; Strauss et al., 2021, 2022). Mean active layer thickness varies between catchments ranging from 154 cm in Panteleikha, 90 cm across the uplands (Y3), 65 cm at Ambolikha and 48 cm in tundra (measured at Cape Maliy Chukochiy) (Fedorov-Davydov et al., 2018a, 2018b).

60

**Figure 1.** (a) Sampling locations of the Kolyma River and tributaries (i.e., lower order streams). The tributaries are Sukharnaya (SUK), Filipovkaya (FIL), Panteleikha (PAN), Malenki Annui (MAL) and Bolshoi Annui (BOL). Ambolikha (AMB), Y3 and Y4 are tributaries of Panteleikha, and floodplain streams (FPS1 and FPS2) tributaries of Ambolikha. All the sites were sampled in both seasons: summer (July–August 2018) and freshet (June 2019). Map adapted from Mann et al. (2012) (b) Land cover of the Kolyma and its tributary watersheds. Land cover classes according to Buchhorn et al. (2020).

65

## 2.2 Field sampling

Surface water samples were collected in summer (July–August) 2018 and spring (June) 2019 (Fig. 1, Table A1) from ~20 cm depth from the middle of the tributary river/stream (one sample per river/stream per season, total n=10 tributaries per season) and additionally in the Kolyma mainstem (n=6 in spring and n=4 in summer) using pre-rinsed 1 L Nalgene bottles, which were decanted into a 10 L sterile and pre-rinsed polyethylene bag to maximize the sample size. During the spring freshet sampling campaign, all the rivers were ice-free during sampling. A few larger lakes in the area still had visible ice cover (5<sup>th</sup> of June 2019), but snow had largely melted and was only present in landscape depressions. The ice broke up in the Kolyma River mainstem 1<sup>st</sup> of June 2019 around the North East Science Station in Cherskiy. Water quality parameters were recorded using a multi-parameter sonde (Eijkelkamp Aquaread AP-800 in 2018, YSI Professional Plus in 2019).

75

Water samples were filtered (within 12 h) using pre-combusted (350 °C, 6 h) glass-fiber filters (Whatman, 0.7 µm). Prior to filtering, samples were vigorously agitated to ensure thorough particle mixing. Filters (POC samples) were frozen to -20 °C, while the filtrate (DOC samples, ~30 ml) was acidified with 30 µl of HCl (37 %) and stored cool (+5 °C). Samples for stable water isotopes ( $\delta^{18}\text{O}$ ,  $\delta^2\text{H}$ ) were filtered and stored cool (+5 °C) without headspace.

## 2.3 Analytical methods

### 80 2.3.1 Total suspended solids, organic carbon, and carbon isotope analyses

The amount of total suspended solids (TSS, mg L<sup>-1</sup>) was calculated by the difference in filter weight before and after filtering, divided by the volume of water filtered. For POC concentrations,  $\delta^{13}\text{C}$ -POC and total particulate nitrogen (TPN) filters were freeze-dried and subsampled by punching 18 % of the 45 mm filter area and fitted into silver capsules/boats. The subsamples were treated with 1M HCl to remove inorganic carbon, and then placed into an oven at 60 °C until dry. Afterwards, the samples were wrapped in tin capsules/boats to aid combustion during analysis. The samples were analyzed with a Thermo Fisher Elemental Analyzer (FLASH 2000 CHNS/O) coupled with a Thermo Finnigan Delta plus isotope ratio mass spectrometer (IRMS) at the National Research Council, Institute of Polar Sciences in Bologna, Italy.

For the <sup>14</sup>C analysis, filters (see above for the subsampling method) were fumigated over 37 % HCl (72 h at 60 °C) to remove all inorganic carbon. After fumigation, samples were neutralized of excess acid (60 °C, a minimum of 48 h) in the presence of NaOH pellets, and subsequently wrapped in tin boats. The samples were analyzed using a coupled elemental analyzer-accelerator mass spectrometer (EA-AMS) system (vario MICRO cube, Elementar; Mini Carbon Dating System MICADAS, Ionplus, Dietikon, Switzerland) (Synal et al., 2007). The filter samples were blank corrected for constant contamination according to the method presented in Haghypour et al. (2019). The <sup>14</sup>C analysis was carried out at the Laboratory of Ion Beam Physics at the Swiss Federal Institute of Technology (ETH), Zürich, Switzerland.

95 The DOC samples from summer 2018 were analyzed for OC and  $\delta^{13}\text{C}$ -DOC with an Aurora 1030 TOC analyzer (OI Analytical) coupled to a Delta V Advantage IRMS via a custom-built cryotrapping interface at KU Leuven, Belgium. Quantification and calibration were performed with IAEA-C6 ( $\delta^{13}\text{C} = -10.4 \text{ ‰}$ ) and an in-house sucrose standard ( $\delta^{13}\text{C} = -26.9 \text{ ‰}$ ) prepared in different concentrations. All  $\delta^{13}\text{C}$  data are reported in the notation relative to VPDB (Vienna Pee Dee Belemnite). The precision in duplicate samples was <5 % for DOC, and 0.2 ‰ for  $\delta^{13}\text{C}$ -DOC in >95 % cases. The DOC samples from freshet 2019 were analyzed for OC and  $\delta^{13}\text{C}$ -DOC at the North Carolina State University, Raleigh, USA. For the method details, see Osburn and St-Jean (2007).

### 2.3.2 Dissolved inorganic carbon analyses

Samples for DIC were collected by filtering 4 ml of water into pre-evacuated 12 ml exetainer (Labco, UK) containing 100  $\mu\text{l}$  of H<sub>3</sub>PO<sub>4</sub> in 2018, while in 2019, DIC samples were filtered into exetainers containing 100  $\mu\text{L}$  of saturated KI and filled to the rim. The samples were stored cool (+5 °C) and dark until analysis. Headspace CO<sub>2</sub> of the DIC samples from 2018 was analyzed using a Gasbench interfaced to a Thermo Delta V IRMS at the Northumbria University, UK. The DIC samples from 2019 were inserted into exetainers (pre-flushed with He) containing three drops of concentrated H<sub>3</sub>PO<sub>4</sub>. Subsequently, the CO<sub>2</sub> was measured with a Finnigan GasBench II interfaced with a Thermo Finnigan Delta+ mass spectrometer at the Vrije Universiteit Amsterdam, The Netherlands. Analytical standard deviation for both instruments was <0.15 ‰.

### 110 2.3.3 Analysis of water isotopes

We measured stable isotopes of oxygen and hydrogen ( $\delta^{18}\text{O}$ ,  $\delta^2\text{H}$ ) in water to characterize the hydrological conditions in the Kolyma River and its tributaries. Samples were analyzed with a Picarro Inc L2140-i Wavelength-scanning cavity ring-down spectrometer in replicates of seven, of which the first three were discarded to avoid carry-over effects. After a sequence of 10 samples, three in-house standards, all calibrated against international IAEA standards (VSLAP and VSMOW), were analyzed.

115 The fourth in-house standard (KONA) was used to control precision and accuracy of the measurements (standard deviation  $<0.1\text{‰}$  for  $\delta^{18}\text{O}$  and  $<2\text{‰}$  for  $\delta^2\text{H}$ ). The analysis was carried out at the Vrije Universiteit Amsterdam, The Netherlands.

### 2.4 Spatial analysis and landscape characterization

We delineated catchments using a 90 m digital elevation model (DEM) (Santoro and Strozzi, 2012) and determined mean soil OC content (SOCC) (Hugelius et al., 2013), land cover (Buchhorn et al., 2020) and calculated slope for each catchment using  
120 QGIS 3.16.1 with GRASS 7.8.4 (Fig. 1B). Prior to the spatial analysis, the DEM was pre-processed by filling all data gaps and sinks using algorithm described in Wang and Liu (2006). Two of the smallest catchments, FPS1 and FPS2, were delineated manually using a satellite image as a template, as the DEM resolution was too coarse for delineating these small and flat catchments. For the Kolyma River watershed, we used a delineation from Shiklomanov et al. (2021). Based on size and land cover, we grouped catchments into floodplain (FPS1, FPS2), headwater (Y3, Y4), tundra (Sukharnaya, Malenki Annu),  
125 wetland (Panteleikha, Ambolikha), and forest (Bolshoi Annu, Filipovkaya) stream/rivers and Kolyma mainstem as its own.

### 2.5 Source apportionment

For the source apportionment of POC, we used a Markov Chain Monte Carlo model to quantify contributions between autochthonous (i.e., primary production), active layer, terrestrial vegetation and permafrost sources. The source apportionment model accounts for uncertainties in the sources (i.e., endmembers), and estimates the residual error for the model (Stock and  
130 Semmens, 2016). We used a trophic discrimination factor (TDF) of zero assuming no discrimination (Stock and Semmens, 2016), and sampling year/season and river classes (e.g., tundra, headwater) as fixed effects for the model. The  $\delta^{13}\text{C}$  and  $\Delta^{14}\text{C}$  endmembers used were: autochthonous ( $\delta^{13}\text{C} -32.6 \pm 5.2\text{‰}$ ,  $n=157$ ;  $\Delta^{14}\text{C} -43.2 \pm 79\text{‰}$ ,  $n=79$ ), active layer ( $\delta^{13}\text{C} -26.4 \pm 0.8\text{‰}$ ,  $n=56$ ;  $\Delta^{14}\text{C} -198 \pm 148\text{‰}$ ,  $n=60$ ), terrestrial vegetation ( $\delta^{13}\text{C} -27.7 \pm 1.3\text{‰}$ ,  $n=94$ ;  $\Delta^{14}\text{C} 97 \pm 125\text{‰}$ ,  $n=58$ ) and permafrost ( $\delta^{13}\text{C} -26.3 \pm 0.7\text{‰}$ ,  $n=414$ ;  $\Delta^{14}\text{C} -777 \pm 106\text{‰}$ ,  $n=527$ ) according to Behnke et al. (2023), Levin et al. (2013), Vonk et al.  
135 (2012), Wild et al. (2019) and Winterfeld et al. (2015). See further details about the endmembers in Text A2.

For the model prior, we used a Dirichlet distribution as an uninformative (on the simplex) prior. We used the model with a chain length of 300,000, burn-in period of 200,000 and thinning of 100. The model was run in R (R Core Team, 2020) with a package *MixSiar* (Stock and Semmens, 2016). To evaluate the model convergence, we used the Gelman-Rubin and Geweke diagnostics, as well as the deviance information criteria. We report results as a mean  $\pm$  standard deviation.

## 140 2.6 Statistical analyses

We used linear regression to test how water temperature affects  $\delta^{13}\text{C}$ -POC, and how carbon isotopes depict POC-% to better understand river carbon dynamics. Additionally, we used linear regression to relate spatial catchment characteristics to organic carbon concentrations in rivers. For the linear regression model of water temperature and  $\delta^{13}\text{C}$ -POC;  $\delta^{13}\text{C}$ -POC and POC-%; and  $\Delta^{14}\text{C}$ -POC and POC-%, we used a function *lm*. The same function was used for linear regression of spatial parameters  
145 (slope and SOCC) and OC concentrations.

To test the difference in means in water chemistry parameters (water temperature, electrical conductivity – EC, pH and  $\delta^{18}\text{O}$ ) and carbon data (POC, DOC, DIC,  $\delta^{13}\text{C}$ -OC,  $\delta^{13}\text{C}$ -DIC and  $\Delta^{14}\text{C}$ -POC) between seasons (freshet vs summer) in the tributaries and the Kolyma mainstem, we used a paired t-test. For the tributaries, n=10 for each season for each parameter (except n=8 for DIC and  $\delta^{13}\text{C}$ -DIC for summer), and for the Kolyma mainstem, n=6 during freshet and n=4 during summer  
150 for each parameter.

Additionally, we tested differences in above mentioned carbon parameters between differently sized streams/ivers separately during freshet and summer using analysis of variance (ANOVA). We grouped the rivers in small (FPS1, FPS2, Y3, Y4), midsized (Panteleikha, Ambolikha, Sukharnaya, Filipovkaya) and large rivers (Malenki Annui, Bolshoi Annui, Kolyma mainstem). In the freshet, we analyzed small rivers n=4, midsized rivers n=4 and larger rivers n=6 for each parameter, and for  
155 summer, n=4 in small and midsized rivers and n=6 in large rivers (except for DIC and  $\delta^{13}\text{C}$ -DIC n=3 for small and midsized rivers and n=5 for large rivers). The significance level of all the statistical testing was 0.05. Testing was conducted in R (R Core Team, 2020). For further details on statistical methods, see Text A3.

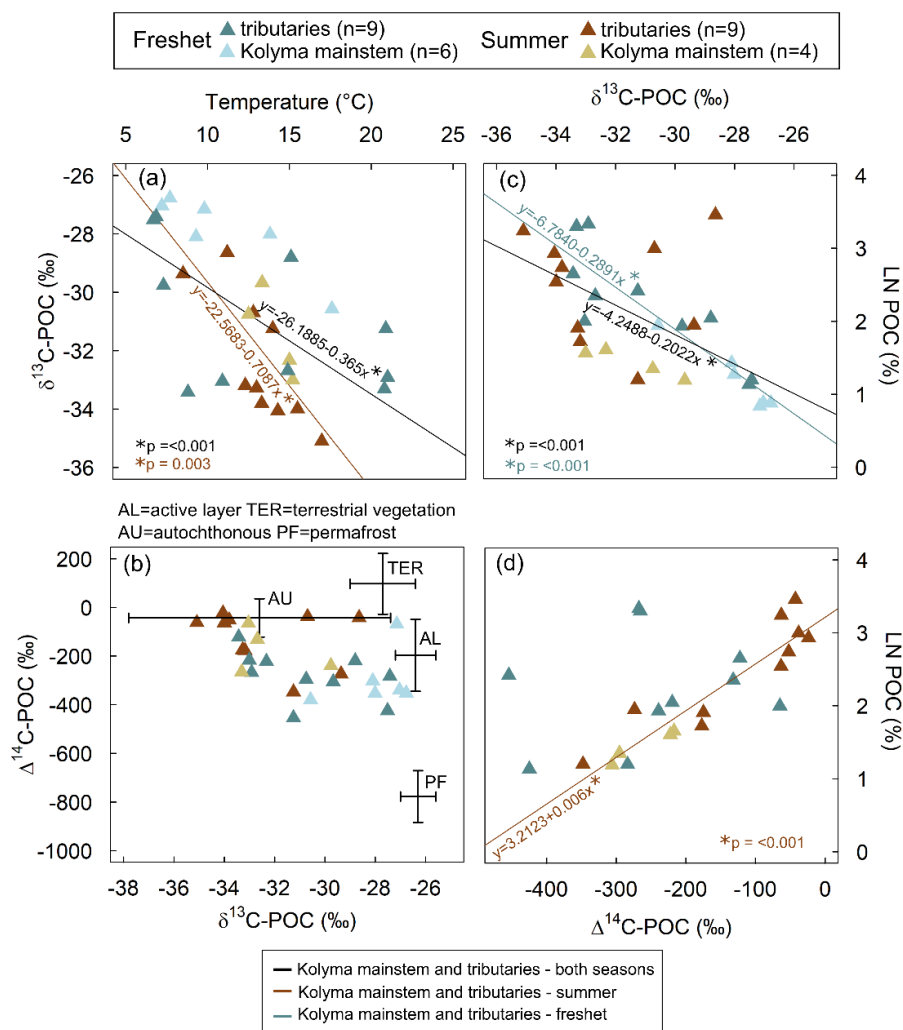

## 3 Results

Part of the Kolyma River mainstem data that we present here has already been reported in Keskitalo et al. (2022), including  
160 water chemistry, OC concentrations, and isotopes for organic and inorganic carbon (Tables A1, A2, A3).

### 3.1 Catchment characteristics and water chemistry

Tributary catchments ranged in size from  $<1 \text{ km}^2$  to nearly  $60,000 \text{ km}^2$  (Table A1). Mean SOCC varied between 269 and  $414 \text{ hg C/m}^2$  with the highest SOCC in the floodplain streams (FPS1, FPS2) and lowest in the tundra river Sukharnaya (Table A1). Mean catchment slope ranged from 0.01 to  $7^\circ$  with lowest slope in the floodplain streams and highest in the tundra river  
165 Malenki Annui (Table A1). Bolshoi Annui, Filipovkaya, Y3 and Y4 were largely covered by forest (55–74 %), while Sukharnaya and Malenki Annui showed highest coverage of herbaceous vegetation (53–84 %; Fig. 1B, Table A2). The floodplain streams had the highest fraction of wetland coverage (76–80 %).

Surface water temperatures did not significantly differ between freshet and summer in the tributaries ( $p=0.946$ ) or in the Kolyma mainstem ( $p=0.167$ ), but showed a larger spatial variability during freshet ( $6.7$  to  $21^\circ\text{C}$  in tributaries;  $7.2$  and  $18.0^\circ\text{C}$   
170 in mainstem) compared to summer ( $8.5$  to  $17^\circ\text{C}$  in tributaries;  $12.5$  to  $15.0^\circ\text{C}$  in mainstem, Fig. 2A, Table A6). The EC and

**Figure 2.** (a) Surface water temperature and  $\delta^{13}\text{C}$  of particulate organic carbon (POC). The linear regression for tributaries and Kolyma mainstem during both freshet and summer ( $R^2=0.33$ ,  $F(1,28)=15.07$ ,  $p<0.001$ ; black line) and only during summer ( $R^2=0.49$ ,  $F(1,12)=13.58$ ,  $p=0.003$ ; brown line) was statistically significant while for freshet, or Kolyma mainstem and the tributaries separately, it was not (not shown). (b) The  $\Delta^{14}\text{C-POC}$  and  $\delta^{13}\text{C-POC}$ . Endmembers are indicated with arrows: OC from active layer (AL), terrestrial vegetation (TER), autochthonous (AU) and permafrost (PF) sources. Endmembers are according to Behnke et al. (2023), Levin et al. (2013), Vonk et al. (2012), Wild et al. (2019) and Winterfeld et al. (2015). See Appendix A for more details about endmembers. (c) The  $\delta^{13}\text{C-POC}$  and natural logarithm (LN) of POC-% (amount of POC of total suspended solids). The linear regression for the Kolyma mainstem and tributaries (both freshet and summer,  $R^2=0.39$ ,  $F(1,28)=19.36$ ,  $p<0.001$ ; black line) and separately for freshet was statistically significant ( $R^2=0.82$ ,  $F(1,14)=67.57$ ,  $p<0.001$ ; blue line). Linear regression for summer only was not significant, or for tributaries and Kolyma mainstem separately (not shown). (d) The  $\Delta^{14}\text{C-POC}$  as a function of LN POC-%. Linear regression for summer (both Kolyma mainstem and tributaries) was significant ( $R^2=0.85$ ,  $F(1,12)=75.4$ ,  $p<0.001$ ; brown line). Linear regression for the Kolyma mainstem or tributaries separately was not significant (not shown). All panels include data from freshet (June 2019) and summer (July–Aug 2018) in the Kolyma River mainstem and its tributaries. Part of the Kolyma data has been previously reported in Keskitalo et al. (2022).

water isotope ( $\delta^{18}\text{O}$ ) signature were lower during freshet than summer both in the tributaries ( $p < 0.001$  and  $p < 0.001$ , respectively) and the Kolyma mainstem ( $p < 0.001$  and  $p = 0.006$ , respectively; Tables 1, A2 and A6).

### 3.2 Total suspended solids, carbon concentrations and isotopes of carbon

#### 3.2.1 Seasonal carbon patterns across the catchment

190 Concentrations of TSS were higher during freshet than summer at most sites, except at FPS1, FPS2 and Y3, but was not statistically significant ( $p = 0.1309$ ; Tables 1, A6). Concentrations of POC and TPN largely followed the same trend (not statistically significant,  $p = 0.391$  and  $p = 0.599$ , respectively; Table A6). In the Kolyma mainstem, POC concentrations were higher during freshet than summer ( $p = 0.049$ ; Table A6), while TSS and TPN showed a similar pattern (not statistically significant,  $p = 0.09$  and  $p = 0.06$ , respectively). In the tributaries, DOC concentrations did not differ between seasons ( $p = 0.153$ ),  
195 while DIC concentrations were lower during freshet than summer ( $p < 0.003$ ; Table A6). In the Kolyma mainstem, DOC concentrations were higher during freshet than summer ( $p = 0.001$ ) while DIC showed the opposite pattern (not statistically significant  $p = 0.08$ ; Table A6). Of the total carbon pool (POC, DOC and DIC), POC was the smallest carbon fraction both during freshet and summer (Fig. 3, Table A7).

In the tributaries, the  $\delta^{13}\text{C}$ -POC did not differ between seasons ( $p = 0.281$ ) while  $\delta^{13}\text{C}$ -DOC were higher during freshet than  
200 in summer ( $p < 0.001$ ; Table A6). In the Kolyma mainstem, both  $\delta^{13}\text{C}$ -POC (not statistically significant  $p = 0.05$ ) and  $\delta^{13}\text{C}$ -DOC ( $p = 0.002$ ; Table A6) showed higher values during freshet than summer. The  $\Delta^{14}\text{C}$ -POC were lower (i.e., older) during freshet than summer in the tributaries ( $p = 0.026$ ) while in the Kolyma mainstem the trend was similar, but not statistically significant ( $p = 0.95$ ; Fig. 2B, Table A6). While we did not measure  $\Delta^{14}\text{C}$ -DOC, we report previously unpublished data (May–October 2006–2011) at FPS, Y3, Y4 and Pantheleikha (Table A10) showing that all DOC is modern. The  $\delta^{13}\text{C}$ -DIC was lower  
205 during freshet than summer both in the tributaries ( $p < 0.001$ ) and in the Kolyma mainstem ( $p = 0.002$ ; Table A6).

#### 3.2.2 Carbon patterns between different sized rivers during freshet and summer

During freshet, large rivers showed higher TSS, POC and lower DOC concentrations than small ones ( $p = 0.001$ ,  $p = 0.048$  and  $p = 0.029$ , respectively), while TPN and DIC did not differ between different sized rivers (Table A8). The POC-% (amount of OC of TSS) was higher in small and midsized rivers than large ones during freshet ( $p = 0.034$  and  $0.016$ , respectively) and  
210 summer ( $p = 0.016$  and  $0.048$ , respectively; Fig. 4, Table A8). In summer, DOC concentrations were higher in small rivers than in large ones ( $p = 0.029$ ) while TSS and POC were lower ( $p = 0.001$  and  $0.048$ , respectively). TPN and DIC did not differ between different sized rivers during summer (Table A8).

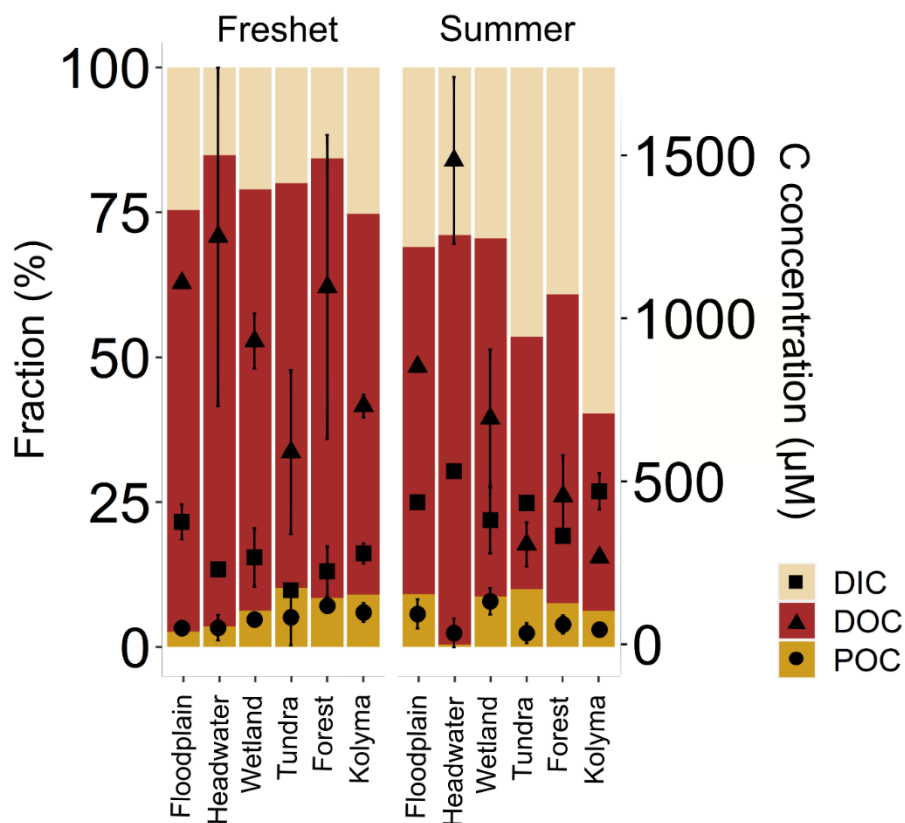

During freshet, small and midsized rivers showed lower  $\delta^{13}\text{C}$ -POC than large rivers ( $p = 0.03$ ) while only midsized rivers showed also lower  $\delta^{13}\text{C}$ -DOC ( $p = 0.026$ ; Table A8). During summer, the  $\Delta^{14}\text{C}$ -POC was higher (i.e., younger) in the small and  
215 midsized rivers than in the large ones (only significant for the small ones  $p = 0.044$ ; Fig. 4). In summer, there was no significant difference in  $\delta^{13}\text{C}$ -OC and  $\delta^{13}\text{C}$ -DIC between differently sized rivers (Table A8).

**Table 1.** Concentrations of total suspended solids (TSS), particulate and dissolved organic carbon (POC and DOC, respectively), dissolved inorganic carbon (DIC) in the tributary streams and the Kolyma River during freshet (June 2019) and summer (July–Aug 2018). Watershed types (WST) are abbreviated as headwaters (H), floodplain (FP), wetland (W), tundra (T) and forest (F). Tributary streams are abbreviated as AMB=Ambolikha, SUK=Sukhamaya, PAN=Panteleikha, FIL=Filipovkaya, MAL=Malenki Annui and BOL=Bolshoi Annui. The Kolyma mainstem is abbreviated as KOL. Also shown are stable and radioisotopes of carbon:  $\delta^{13}\text{C}$  of POC, DOC and DIC, and  $\Delta^{14}\text{C}$ -POC, and concentrations of total particulate nitrogen (TPN), molar ratio of POC/TPN and water isotopes ( $\delta^{18}\text{O}$ ). For DIC,  $\delta^{13}\text{C}$ -DIC,  $\Delta^{14}\text{C}$ -POC and water isotopes, mean  $\pm$  analytical standard deviation is shown. For the Kolyma River, mean  $\pm$  standard deviation between different sampling locations (freshet n=6, summer n=4) is indicated, including standard deviation between replicate samples (Table A2) and analytical uncertainties when applicable. Additionally, we show mean (Avg)  $\pm$  standard deviation of all tributaries. Further information regarding the watersheds (e.g., size, land cover) is available in Appendix A.

\*average of a tributary of Y3 and Y3 mainstem upstream of the sampling site in 2018 as  $\delta^{13}\text{C}$  analysis at the sampling location was not successful.

229 **Figure 3.** Fraction (%) of different carbon pools: particulate and dissolved organic carbon (POC and DOC, respectively) and  
 230 dissolved inorganic carbon (DIC) in the Kolyma River and its tributary rivers/streams during freshet (2019) and summer (2018).  
 231 On the right-side y-axis, concentrations of respective carbon pools are shown with square (DIC), triangle (DOC) and circle  
 232 (POC) symbols with mean  $\pm$  standard deviation between samples. The tributaries are grouped based on their land cover and  
 233 size as follows (n=2 per group per season except for the Kolyma mainstem n=6 during freshet and n=4 during summer): tundra  
 234 = Sukharnaya and Malenki Annui; headwater (small, forested watersheds) = Y3, Y4; floodplain = FPS1 and FPS2; wetland  
 235 (influenced) = Ambolikha and Panteleikha; forest (larger forested watersheds) = Filipovkaya and Bolshoi Annui; Kolyma =  
 236 Kolyma mainstem. The DIC concentrations were not measured for Sukharnaya and Y3 during summer.

### 238 **3.3 Source apportionment**

239 Both during freshet and summer, POC was largely autochthonous in the tributaries (34–82 % and 56–92 %,  
240 respectively; Fig. 5, Table A11) and in the Kolyma mainstem (35 and 59 %, respectively). Permafrost-derived  
241 POC was higher during freshet than summer at all sites (tributaries 8–33 % during freshet and 3–22 % during  
242 summer; mainstem 34 % during freshet and 22 % during summer). Contributions from active layer and terrestrial  
243 vegetation were lowest to tributary-POC (8–24 % and 4–10% during freshet, respectively; 3–16 % and 2–7 %  
244 during summer, respectively; Fig. 5). Similarly, active layer and terrestrial vegetation contributed least to the  
245 Kolyma-POC during freshet (9–22 %) and summer (6–13 %; Table A11).

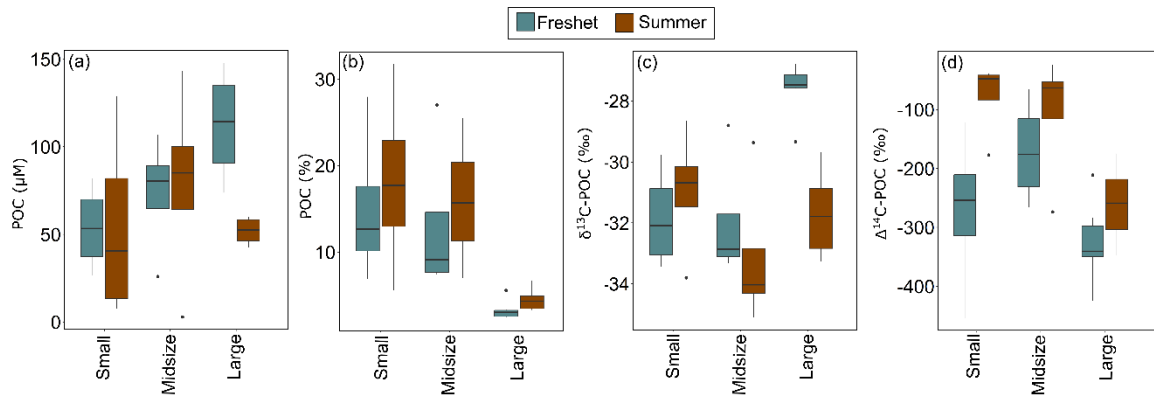

## 246 **4 Discussion**

247 Our results show contrasting water chemistry and carbon dynamics between spring freshet and summer in the  
248 Kolyma River tributaries and mainstem, while POC pool is mostly autochthonous both in the tributaries and the  
249 Kolyma mainstem during both seasons. Small and mid-sized rivers differ in their POC composition from large  
250 rivers with higher POC-% (freshet and summer), lower  $\delta^{13}\text{C}$ -POC (freshet) and higher  $\Delta^{14}\text{C}$  (summer).

### 251 **4.1 Smaller tributary streams may start primary production earlier than larger rivers in the spring**

252 In all tributaries and the Kolyma mainstem, the water isotope  $\delta^{18}\text{O}$  signature significantly differed between seasons  
253 (Table A6). Lower  $\delta^{18}\text{O}$  signal during freshet suggests that snowmelt was the dominant water source (Welp et al.,  
254 2005), supported by lower EC values (Table A6). However, water temperatures varied more within a season than  
255 between seasons both in the tributaries and in the Kolyma (Table A6). Air temperatures were particularly warm  
256 during freshet 2019 (see Fig. A2 for average air temperatures in 2007–2017) that was reflected as warm water  
257 temperatures especially in Filipovkaya and the floodplain streams ( $>20\text{ }^\circ\text{C}$ ). These high temperatures likely  
258 promoted a rapid onset of autochthonous production as suggested by relatively low  $\delta^{13}\text{C}$ -POC (up to  $-33.43\text{ ‰}$ )  
259 for the season, combined with high POC-% (11–28 %, Fig. 2C). However, in tributaries Y4, Panteleikha and  
260 Ambolikha low  $\delta^{13}\text{C}$ -POC occurred already prior to the high air temperatures (Table A3), suggesting that other  
261 factors such as higher nutrient fluxes during freshet likely also play a role in inducing primary production (Harrison  
262 and Cota, 1991; Holmes et al., 2012; Mann et al., 2012). While the POC pool is dominated by autochthonous OC,  
263 it is likely that allochthonous OC is also present, as suggested by POC/TPN ratios (e.g., Meyers, 1994) and our  
264 source apportionment results (see Section 4.3 and Fig. 5). Water temperature explained 33 % of the variability in  
265  $\delta^{13}\text{C}$ -POC overall (higher temperature indicating lower  $\delta^{13}\text{C}$ -POC), while during summer it explained  $\sim 50\%$  of  
266 its variability (Fig. 2A), confirming that other factors affect  $\delta^{13}\text{C}$ -POC. Overall, freshet  $\delta^{13}\text{C}$ -POC was lower and  
267 POC-% higher in small and mid-sized rivers compared to the large ones (Fig. 4; Table A8), suggesting that river  
268 size may play a role in the timing for primary production onset during freshet. Higher input of (terrestrial) DOC  
269 (via degradation to inorganic carbon to be taken up by primary producers) and/or nutrients combined with shorter  
270 transport times may enhance primary production in smaller streams during freshet. In contrast, large rivers have  
271 longer transport times, and nutrients may already have been utilized (in headwaters), and terrestrially derived DOC  
272 degraded (Denfeld et al., 2013). Our POC data suggest that autochthonous production may start sooner in small  
273 and mid-sized tributaries than in large rivers during freshet.

274

275

276 **Figure 4.** Concentrations of particulate organic carbon (POC) in (a)  $\mu\text{M}$  (no statistically significant differences between  
 277 different size groups) and (b) in percent POC in small, midsized, and large rivers during freshet and summer (small and  
 278 midsized rivers were significantly different from the large rivers both during summer and freshet). The (c)  $\delta^{13}\text{C-POC}$  (small  
 279 and midsized rivers were significantly different from large rivers during freshet) and (d)  $\Delta^{14}\text{C-POC}$  in small, midsized, and  
 280 large rivers during freshet and summer (small rivers were significantly different from large ones during summer). Boxplots  
 281 show median (line), interquartile range (the box) and minimum and maximum (whiskers). For small rivers  $n=4$ , for midsized  
 282 rivers  $n=4$  and for large rivers  $n=6$  per season. See Table A8 for analysis of variance (ANOVA) results regarding statistically  
 283 significant differences between different sized rivers.

284 **4.2 Organic and inorganic carbon dynamics differ between the tributaries and the Kolyma River mainstem**

285 **4.2.1 Suspended matter dynamics**

286 During freshet, mean TSS and POC concentrations were higher in the large rivers than in the small tributary rivers  
 287 (statistically significant only for TSS; Table A8) likely due to higher river power causing greater bank erosion  
 288 (delivering sediment and POC) as well as higher turbulence promoting particle suspension (Striegl et al., 2007).  
 289 Spatial characteristics such as catchment slope or SOCC did not show a linear relationship with summer-POC,  
 290 indicating that other factors, such as abrupt permafrost thaw, primary production, and water temperature, likely  
 291 play a more important role in driving POC concentrations (Fig. A3, Sect. 4.3). In the Kolyma, POC and  $\delta^{13}\text{C-POC}$   
 292 differed between seasons (significant only for POC), while in the tributaries there was no significant difference  
 293 (Table A6). This likely suggests both local variability and stronger fluctuations in the tributaries that react faster  
 294 to environmental changes such as high air temperatures.

295

296

297 **Figure 5.** Fraction of different particulate organic carbon (POC) sources (active layer, terrestrial vegetation, autochthonous and  
 298 permafrost) according to Markov Chain Monte Carlo source apportionment modelling using  $\delta^{13}\text{C}$  and  $\Delta^{14}\text{C}$  during (a) freshet  
 299 and (b) summer. The dashed lines separate the Kolyma mainstem from the tributaries. For each catchment type (floodplain,  
 300 headwater, wetland, tundra and forest)  $n=2$  for the number of tributaries per season while for the Kolyma mainstem  $n=6$  during  
 301 freshet and  $n=4$  during summer. The endmembers were according to Behnke et al. (2023), Levin et al. (2013), Vonk et al.  
 302 (2012), Wild et al. (2019) and Winterfeld et al. (2015), see more information in the Appendix A.

#### 303 4.2.2 Dissolved matter dynamics

304 Previous studies have shown that lower order streams differ from the Kolyma River in their dissolved carbon  
 305 concentrations and composition (Drake et al., 2018a; Mann et al., 2012; Rogers et al., 2021). Similarly, our results  
 306 show that DOC concentrations were higher in the small tributaries than in the large ones both during freshet and  
 307 summer, while  $\delta^{13}\text{C}$ -DOC differed only between midsized and large rivers during freshet (lower for midsized  
 308 rivers; Table A8). In the tributaries, SOCC predicted nearly half of the variability in DOC concentrations during  
 309 summer (Fig. A3). It has been shown that the majority of DOC in the Kolyma mainstem originates from modern  
 310 vegetation rather than permafrost sources (Rogers et al., 2021), potentially due to rapid degradation of permafrost-  
 311 derived DOC during transit from the headwaters (Mann et al., 2015). Similarly, the  $\Delta^{14}\text{C}$ -DOC shows a modern  
 312 signal for FPS, Y4, Y3 and Panteleikha (Table A10), implying that small and midsized stream DOC is also  
 313 predominantly modern.

314 In the tributaries, DIC and  $\delta^{13}\text{C}$ -DIC differed significantly between seasons (Table A6) and followed a  
 315 previously-reported trend in fluvial systems of lower concentrations and  $\delta^{13}\text{C}$ -DIC during freshet than summer  
 316 (Campeau et al., 2017; Waldron et al., 2007). In the Kolyma, only  $\delta^{13}\text{C}$ -DIC was significantly lower during freshet  
 317 than summer. Our Kolyma DIC concentrations were close to a previously reported concentration (Drake et al.,  
 318 2018b), while  $\delta^{13}\text{C}$ -DIC values were  $\sim 2\text{‰}$  higher in our study. The higher DIC concentrations during summer  
 319 may reflect an increase in leaching from the active layer and/or re-mineralization of DOC, while the higher  $\delta^{13}\text{C}$ -  
 320 DIC suggests primary production and/or partial  $\text{CO}_2$  evasion, where part of the  $\text{CO}_2$  is likely sourced from degraded  
 321 permafrost (Campeau et al., 2017; Drake et al., 2018b; Powers et al., 2017; Waldron et al., 2007). During freshet,

322 DIC concentrations were higher in watersheds with higher water temperatures, a trend not observed during summer  
323 (Table 1, Table A3). While higher temperatures may increase CO<sub>2</sub> evasion and thus lower DIC concentrations  
324 (and increase δ<sup>13</sup>C-DIC) (Campeau et al., 2017), on-going OC degradation and/or leaching of terrestrially-derived  
325 DIC potentially keeps the concentrations high. The higher δ<sup>13</sup>C-DIC of the Kolyma mainstem, Sukharnaya and  
326 Filipovkaya, suggests that they may be affected by CO<sub>2</sub> evasion during turbulent freshet conditions. At  
327 Filipovkaya, these high ratios may be partially due to primary production (i.e., biological consumption of DIC) as  
328 the δ<sup>13</sup>C-POC is relatively low (Table 1). In headwater streams, contribution of OC mineralization to the DIC pool  
329 has been suggested to be negligible relative to terrestrial input (Winterdahl et al., 2016). Smaller streams have been  
330 shown to evade more CO<sub>2</sub> to the atmosphere than larger rivers during summer, thus suggesting that CO<sub>2</sub> evasion  
331 from smaller streams is mainly driven by hydrological flow paths and terrestrial OC, while in the larger rivers  
332 autochthonous production dominates as a CO<sub>2</sub> sink (Denfeld et al., 2013). Finally, weathering, dominated by  
333 carbonates and silicates in the Kolyma watershed, may add to the DIC concentrations (Tank et al., 2012).

#### 334 **4.3 The importance of autochthonous production: riverine POC dominates in the tributaries**

335 Tributary-POC is mostly autochthonous both during freshet (58 ± 33 %) and summer (76 ± 27 %) indicating high  
336 primary production, especially in summer (Fig. 5), supported by higher OC-% in small and mid-sized tributaries  
337 (6.9–20 % and 5.6–32 %, respectively) than in the large rivers (~3 % and 3–7 %, respectively; Tables A8). The  
338 Δ<sup>14</sup>C-POC was significantly higher (i.e., younger) in tributaries during summer than freshet, likely due to higher  
339 primary production, while in the Kolyma Δ<sup>14</sup>C-POC did not significantly differ between seasons as shown  
340 previously (Bröder et al., 2020; McClelland et al., 2016). Filipovkaya and the floodplain streams (FPS1, FPS2)  
341 showed relatively low Δ<sup>14</sup>C-POC combined with high POC-% and low δ<sup>13</sup>C-POC (Fig. 2C–D), suggesting  
342 incorporation of old CO<sub>2</sub> into biomass, likely originating from rapid degradation of permafrost-derived DOC  
343 (Drake et al., 2018b). The permafrost fraction was relatively low during summer due to dominance of primary  
344 production (Behnke et al., 2023), which was particularly pronounced in the smaller waterways (Fig. 5).

345 In an earlier incubation study, we showed that riverine-produced POC (with low δ<sup>13</sup>C-POC) in Kolyma  
346 summer waters degrades rapidly (degradation constant  $k = -0.026 \text{ day}^{-1}$ ), while terrestrially-produced POC in  
347 freshet waters did not show OC loss (Keskitalo et al., 2022). Furthermore, we showed that a lower initial δ<sup>13</sup>C-  
348 POC corresponded to a higher POC loss. Therefore, the low δ<sup>13</sup>C-POC of small and mid-sized streams during  
349 freshet suggests that POC may be prone to degradation, while POC degradation in the Kolyma likely lags behind  
350 as it is still dominated by terrestrially derived POC. While warmer water temperatures have been shown to increase  
351 microbial degradation at a similar rate as primary production, additional supply of terrestrial OC may increase  
352 degradation rates resulting in higher CO<sub>2</sub> emissions (Demars et al., 2016). Furthermore, Denfeld et al., 2013 have  
353 shown that leaching of terrestrial DOC and permafrost carbon may fuel stronger degradation of OC in the smaller  
354 streams than in the larger ones (Denfeld et al., 2013).

355 While larger rivers may be able to emit more greenhouse gases than smaller ones given their size, smaller  
356 rivers/streams play an important role in CO<sub>2</sub> evasion (Denfeld et al., 2013). Smaller waterways have been shown  
357 to convey more allochthonous OC-derived CO<sub>2</sub> emissions than larger rivers (Hotchkiss et al., 2015). With the  
358 predicted earlier onset of freshet and warmer temperatures occurring earlier in the season in the future (Meredith  
359 et al., 2019; Stadnyk et al., 2021) (i.e., creating more favorable conditions both for primary production and OC  
360 degradation) lower order streams will largely fix CO<sub>2</sub> (by primary producers), but could also potentially increase

361 CO<sub>2</sub> evasion via degradation of autochthonous POC that likely comprises a fraction of old permafrost OC taken  
362 up by primary producers (Drake et al., 2018b). Furthermore, degradation of autochthonous POC may enhance  
363 degradation of allochthonous OC via priming effects (Hotchkiss et al., 2014). This may be particularly relevant in  
364 the Arctic, where the high proportion of allochthonous permafrost OC present during freshet could be susceptible  
365 to decomposition (Fig. 5). However, further studies are needed to decipher whether this has implications on CO<sub>2</sub>  
366 emissions in the whole system level. Furthermore, smaller rivers may transport permafrost carbon, in the form of  
367 aquatic biomass, downstream, where its signal is mixed with modern OC sources and is not detectable anymore  
368 (Drake et al., 2018b). Understanding dynamics of smaller rivers/streams is important given that river size may  
369 affect their response to environmental drivers (Battin et al., 2023). On the whole, the intensification of hydrological  
370 cycling could mean that in the future processes currently happening in lower order streams may shift towards  
371 larger fluvial systems.

## 372 **5 Conclusions and implications**

373 Here, we present seasonal contrasts, including the hydrologically important spring freshet period, in water  
374 chemistry and carbon characteristics of lower order streams and the Kolyma mainstem. However, during freshet  
375 small and mid-sized streams/rivers are more dynamic and seem to respond faster to environmental changes such as  
376 air temperature increases. While POC concentrations did not significantly differ between large and small/mid-sized  
377 rivers during freshet, composition of POC showed clear differences: the  $\delta^{13}\text{C}$ -POC was lower and POC-% higher  
378 in small and mid-sized streams/rivers than in large ones, indicating an early onset of primary production in these  
379 lower order streams. This will result in uptake of CO<sub>2</sub> by primary producers, however, it may also fuel CO<sub>2</sub> evasion  
380 via degradation of autochthonous POC if partly comprised of allochthonous/permafrost OC (when terrestrially  
381 derived CO<sub>2</sub> is fixed by primary producers) and/or prime degradation of allochthonous OC. Further studies are  
382 needed to discern implications on CO<sub>2</sub> uptake/emission balance on a system level. Furthermore, hydrological  
383 intensification may increase shunting and decomposition of organic matter from smaller to larger river systems,  
384 and transport permafrost-derived OC downstream in the form of autochthonous POC. An increased understanding  
385 of carbon and water chemistry of lower order streams and their linkages to hydrology is therefore crucial to  
386 understand catchment-wide OC dynamics.  
387

## 388 **Appendix A**

### 389 **Text A1. Representativeness of surface water samples**

390 As all our samples were of surface water, we compared our Kolyma River  $\delta^{13}\text{C}$ -POC data to Arctic Great Rivers  
391 Observatory (Arctic-GRO) to assess how our surface water samples would compare to depth-integrated sampling  
392 (data and sampling protocol are available in [www.arcticgreatrivers.com/data](http://www.arcticgreatrivers.com/data), water quality) carried out since 2003  
393 in the Kolyma River mainstem. All the water samples collected during 2003–2011 (programs PARTNERS,  
394 ARCTIC-GRO I) were depth-integrated, while samples collected between 2012 and 2021 (programs ARCTIC-  
395 GRO II-IV; data from 2020–2021 is provisional) are a combination of samples collected from the surface and at  
396 depth (sampled at depths of 4–15 m). The Arctic-GRO average  $\pm$  std  $\delta^{13}\text{C}$ -POC for freshet (sampled in June 2004–  
397 2021) was  $-28.2 \pm 1.4$  ‰ (n=19) and for summer (sampled in July–August 2003–2021) was  $-29.8 \pm 2.1$  ‰ (n=19).  
398 In comparison, our Kolyma River mainstem  $\delta^{13}\text{C}$ -POC sampled during freshet (June 2019) was  $-27.94 \pm 1.4$  ‰  
399 (n=6) and in summer (July–August 2018) was  $-31.44 \pm 1.5$  ‰ (n=4; table A2). Given that our  $\delta^{13}\text{C}$ -POC signature  
400 falls within the standard deviation of the depth-integrated samples we consider our samples to be sufficiently  
401 representative for the entire water column.

402

### 403 **Text A2. Endmembers for the source apportionment**

404 The endmember for autochthonous POC was according to Wild et al. (2019;  $\delta^{13}\text{C}$   $-30.6 \pm 3$  ‰, n=24), Winterfeld  
405 et al. (2015;  $\delta^{13}\text{C}$   $-30.5 \pm 2.5$  ‰, n=n/a), Levin et al. (2013;  $\Delta^{14}\text{C}$   $-39.6 \pm 5.5$  ‰, n=73) and Behnke et al. (2023;  
406  $\delta^{13}\text{C}$   $-33.1 \pm 4.7$  ‰,  $\Delta^{14}\text{C}$   $106 \pm 164$  ‰) combined with our own POC sample collected at the Panteleikha River  
407 during an algal bloom in 2019 ( $\Delta^{14}\text{C}$   $-26$  ‰;  $\delta^{13}\text{C}$   $-33.5$  ‰, n=1). The  $\delta^{13}\text{C}$  endmember values from Wild et al.,  
408 (2019) and Winterfeld et al., (2015) are of riverine phytoplankton from Ob and Yenisei rivers, and from Lena  
409 River, respectively, while the values from Levin et al. (2013) are of atmospheric  $\text{CO}_2$  (May–August 2009–2012).  
410 Endmember values from Behnke et al. (2023) are (mostly benthic) of biofilms, algae and invertebrates from  
411 Alaska, Canada, and Svalbard. As our samples were of surface water, we combined the  $\Delta^{14}\text{C}$  of atmospheric  $\text{CO}_2$   
412 from Levin et al. (2013) (following the approach used by Winterfeld et al., 2015 and Wild et al., 2019) with the  
413  $\Delta^{14}\text{C}$  of biofilms, algae, and invertebrates (following Behnke et al., 2023) as the autochthonous endmember. The  
414 autochthonous  $\delta^{13}\text{C}$  endmember was a compilation of phytoplankton (Winterfeld et al. 2015 and Wild et al. 2019)  
415 and biofilms, algae, and invertebrates (Behnke et al., 2023). For the active layer and terrestrial vegetation  
416 endmember, we used the endmembers compiled in Wild et al., (2019): endmember for active layer ( $\Delta^{14}\text{C}$   $-197.5 \pm$   
417  $148.4$  ‰, n=60;  $\delta^{13}\text{C}$   $-26.4 \pm 0.8$  ‰, n=56) and modern vegetation ( $\Delta^{14}\text{C}$   $97 \pm 124.8$  ‰, n=58;  $\delta^{13}\text{C}$   $-27.7 \pm 1.3$   
418 ‰, n=94) The active layer and terrestrial vegetation endmembers include data from Siberia, Alaska, northern  
419 Canada, and Scandinavia. For the permafrost endmember, we combined the Ice Complex Deposit ( $\Delta^{14}\text{C}$   $-954.8 \pm$   
420  $65.8$  ‰, n=329) and Holocene permafrost ( $\Delta^{14}\text{C}$   $-567.5 \pm 156.7$  ‰, n=138) endmember from Wild et al. (2019)  
421 with the Holocene permafrost endmember from Winterfeld et al. (2015;  $\Delta^{14}\text{C}$   $282 \pm 133$  ‰, n=60;  $\delta^{13}\text{C}$   $-26.6 \pm 1$   
422 ‰, n=40) and Vonk et al. (2012;  $\delta^{13}\text{C}$   $-26.3 \pm 0.7$  ‰, n=374). All endmembers were weighed with the number of  
423 observations. We recognize that having robust endmember values is important for the best modelling results, and  
424 ideally these values would come from within or close to the studied system. While the permafrost, active layer and  
425 terrestrial vegetation endmembers are relatively well defined, scientific literature lacks well-constrained  
426 autochthonous endmembers, especially for phytoplankton. Endmembers were recently discussed in Behnke et al.  
427 (2023).

428

429 **Text A3. Statistical analyses: assumptions and hypotheses**

430 For the linear regression model of water temperature and  $\delta^{13}\text{C-POC}$ ;  $\delta^{13}\text{C-POC}$  and  $\text{POC-}\%$ ; and  $\Delta^{14}\text{C-POC}$  and  
431  $\text{POC-}\%$ , we used a function *lm*. The same function was used for linear regression of spatial parameters (slope and  
432 soil organic carbon concentration - SOCC) and OC concentrations. The POC concentrations did not show a linear  
433 relationship with the spatial parameters, thus they were not modelled. We log transformed the DOC data prior to  
434 executing the model as well as the  $\text{POC-}\%$ . For all the linear regression models, we checked the assumptions of  
435 normality and homoskedasticity of the model residuals visually and using a Shapiro-Wilk test and a Breusch-  
436 Pagan test, respectively. The significance level of the test was 0.05.

437 To test the difference in means in water chemistry parameters (water temperature, electrical conductivity - EC,  
438 pH and  $\delta^{18}\text{O}$ ) and carbon data (POC, DOC, DIC,  $\delta^{13}\text{C-OC}$ ,  $\delta^{13}\text{C-DIC}$  and  $\Delta^{14}\text{C-POC}$ ) between seasons (i.e., freshet  
439 and summer) in the tributaries and the Kolyma River, we used a paired t-test (or Wilcoxon rank sum test if the  
440 assumptions for a paired t-test were not met). For the tributaries,  $n=10$  for each season for each parameter except  
441 for DIC and  $\delta^{13}\text{C-DIC}$   $n=8$ . For the Kolyma River mainstem,  $n=4$  for each season (for freshet an average of the  
442 replicate samples at sites K3 and K4 were used) except for DIC and  $\delta^{13}\text{C-DIC}$   $n=3$ . Our H0 hypothesis was that  
443 the means are equal between seasons and the H1 hypothesis that the means are not equal. The test significance  
444 level was 0.05. We checked the normality of the differences by using the Shapiro-Wilk test. .

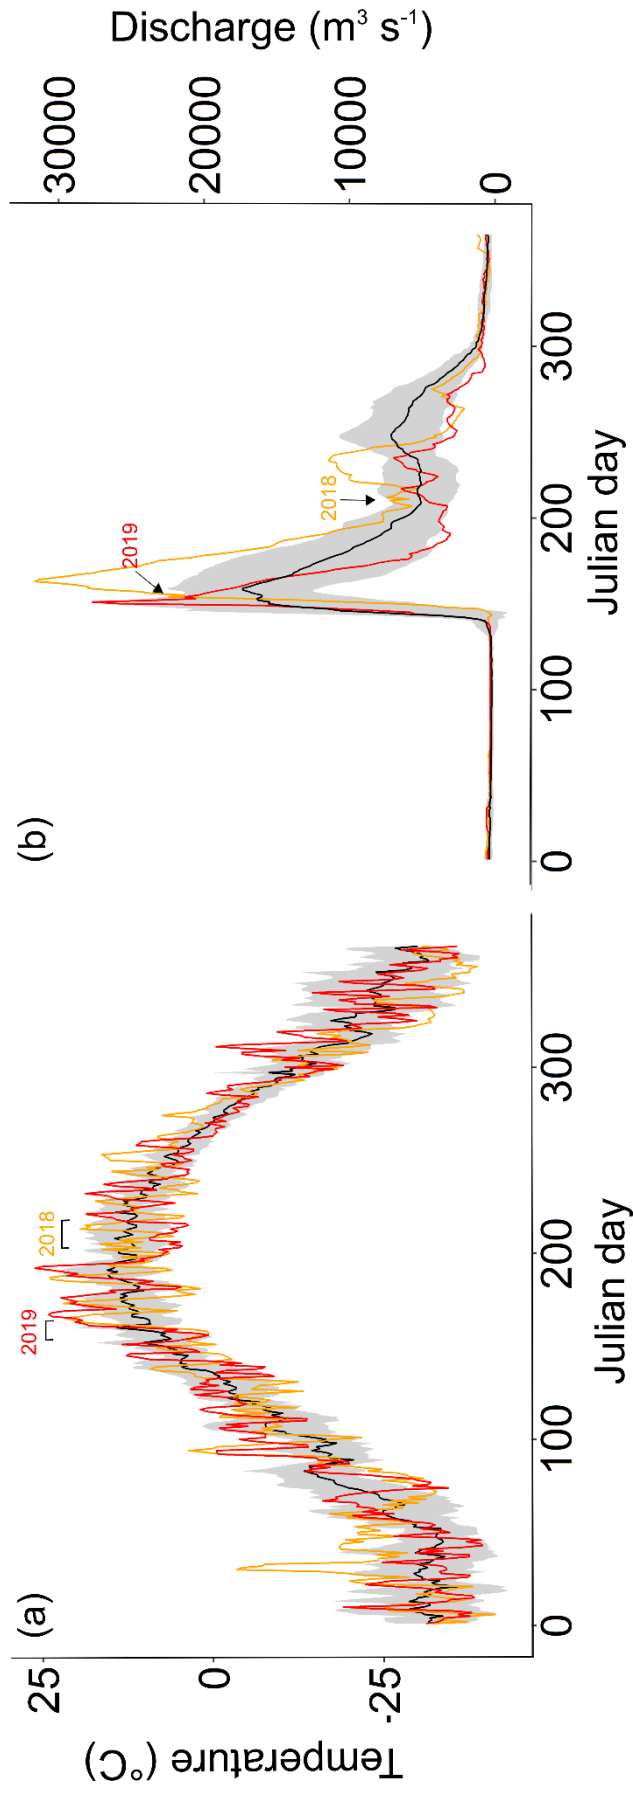

445 To test whether there was a significant difference between small streams, midsized rivers, and large rivers  
446 regarding carbon parameters (POC, DOC, DIC,  $\delta^{13}\text{C-OC}$ ,  $\delta^{13}\text{C-DIC}$  and  $\Delta^{14}\text{C-POC}$ ), we used (one-way) analysis  
447 of variance (ANOVA) or a Kruskal-Wallis test (when assumptions for ANOVA were not met) for each season  
448 separately. The floodplain streams (FPS1 and FPS2), Y3 and Y4 were classed as small streams; Panteleikha,  
449 Ambolikha, Filipovkaya and Sukarnaya as midsized rivers; and Malenki Annui, Bolshoi Annui and Kolyma  
450 mainstem as large rivers. For the small and midsized rivers during freshet,  $n=4$  while for large rivers  $n=6$  for each  
451 parameter. For the summer,  $n=4$  for each parameter in small and midsized rivers, and  $n=6$  in large rivers except  
452 for DIC and  $\delta^{13}\text{C-DIC}$   $n=3$  in small and midsized rivers and  $n=5$  in large rivers. We checked the assumptions of  
453 normality and equal variances visually and further with Shapiro-Wilk test and Breusch-Pagan test, respectively.  
454 Our H0 hypothesis was that the means are equal between different sized rivers/streams and the H1 hypothesis that  
455 the means are not all equal. With significant results, we used a Tukey's test as a *post hoc* test for ANOVA and a  
456 Dunn's test for the Kruskal-Wallis test. The significance level of all the tests was 0.05. All the statistical testing  
457 was executed in R (R Core Team, 2020).

458

459

460 **Figure A1.** Land cover of the tributary watersheds. The watersheds are organized by their size starting from the smallest (FPS1)  
 461 on the left. The land cover types with < 1 % contribution are not included in the figure, see Table A5 for full land cover data.  
 462  
 463

464  
 465 **Figure A2.** (a) average air temperature  $\pm$  standard deviation (black line  $\pm$  grey background) 2007–2017 in Cherskiy with air temperatures during the sampling years 2018 (orange line) and 2019  
 466 (red line). The weather data was retrieved from the Cherskiy weather station. Timing of the sampling campaigns is marked above the plot. See Table S3 for air temperatures on sampling days. (b)  
 467 The average  $\pm$  standard deviation of discharge measured at Kolymenskoye 2007–2017 (Shiklomanov et al., 2021). Red line shows the discharge of the year 2019 and orange line the year 2018. The  
 468 timing of the sampling campaigns is marked with arrows above the plot.  
 469

**Figure A3.** (a) Particulate and dissolved organic carbon (POC and DOC, respectively) concentration (log) and soil organic carbon content (SOCC). Linear regression for DOC was statistically significant ( $R^2 = 0.49$ ,  $F(1,8) = 9.59$ ,  $p = 0.001$ ). (b) Concentrations (log) of POC and DOC against median slope. The regression model did not show statistically significant results. All the organic carbon data are from the Kolyma River tributaries sampled during summer 2018.

470

471

472

473

474 **Table A1.** Sampling coordinates and dates of the Kolyma tributaries and Kolyma mainstem during spring freshet (2019) and  
 475 summer (2018) sampling campaigns. Data from sites KOL1–KOL4 during freshet and KOL1–KOL3 during summer were  
 476 previously reported in Keskitalo et al. (2022).

**Table A2.** Concentrations of total suspended solids (TSS), particulate and dissolved organic carbon (POC and DOC, respectively), dissolved inorganic carbon (DIC) in the Kolyma River during freshet (June 2019) and summer (July–Aug 2018). Also shown are stable isotopes of carbon:  $\delta^{13}\text{C}$  of POC, DOC and DIC, and concentrations of total particulate nitrogen (TPN) and molar ratio of POC/TPN. For  $\Delta^{14}\text{C}$ -POC, see Table A7. Mean and standard deviation between replicate samples (n=4) is shown for freshet sites KOL1-KOL4 and for summer KOL1-KOL3 (n=3, KOL3 n=4) including analytical uncertainty for DIC and  $\delta^{13}\text{C}$ -DIC. For KOL3re and KOL4re n=1. For water isotopes ( $\delta^{18}\text{O}$ ,  $\delta\text{H}$ ) and summer DIC and  $\delta^{13}\text{C}$ -DIC only analytical error (no replicates) is shown. All data from KOL1–KOL4 during freshet and KOL1–KOL3 during summer (except DIC concentrations) were previously published in Keskitalo et al. (2022).

**Table A6.** Paired t-test results for difference in means in electrical conductivity (EC), water temperature (Temp), pH, water isotope  $\delta^{18}\text{O}$ , total suspended solids (TSS), particulate and dissolved organic carbon (POC and DOC), dissolved inorganic carbon (DIC),  $\delta^{13}\text{C}$  of POC, DOC and DIC and  $\Delta^{14}\text{C}$ -POC between seasons (freshet and summer) in the Kolyma mainstem and its tributaries. The significantly different results are highlighted in bold. The significance level was 0.05. For TSS, Wilcoxon signed rank test was used. For tributaries, n=10 for all parameters except for DIC and  $\delta^{13}\text{C}$ -DIC n=8 for each season. For the Kolyma mainstem n=4 for all parameters except for DIC and  $\delta^{13}\text{C}$ -DIC n=3 for each season. See more details in Text A3.

513

**Table A8.** Analysis of variance (ANOVA) and Kruskal-Wallis test results for difference in means in total suspended solids (TSS), particulate and dissolved organic carbon (POC and DOC), total particulate nitrogen (TPN), dissolved inorganic carbon (DIC),  $\delta^{13}\text{C}$  of POC, DOC and DIC and  $\Delta^{14}\text{C}$ -POC between small rivers (FPS1, FPS2, Y3, Y4), mid-sized (mid) rivers (Panteleikha, Ambolikha, Sukharnaya, Filipovkaya) and large rivers (Malenki Annui, Bolshoi Annui and Kolyma mainstem) during freshet and summer separately with F statistics (from ANOVA) or H statistics (from Kruskal-Wallis test), degrees of freedom and p-values. The statistically significant ( $p < 0.05$ ) results are highlighted in bold. When ANOVA or Kruskal-Wallis test results were significant, post hoc test (Tukey's test for ANOVA and Dunn's test for the Kruskal-Wallis test) was conducted and their results (p-values) are listed below to indicate whether the difference was between small and midsize rivers, small and large rivers and/or midsize and large rivers (n/a indicates not applicable when post hoc test was not executed due to ANOVA or Kruskal-Wallis test not showing significant results). See more details in TextA3.

544

545 **Data availability**

546 Data will be available within the article or in the Appendix A.

547 **Author contribution**

548 JEV and KHK lead the design of the study with contribution from LB. KHK, LB, DJJ, AD, SD and NZ conducted all the field  
549 work. KHK, LB and DJJ executed all preparatory laboratory work. NH and TIE conducted the AMS analyses, and TT and  
550 PJM analytical laboratory work regarding carbon concentrations and stable isotope analysis. KHK carried out the statistical  
551 analyses. KHK and SBG conducted the spatial analysis. KHK lead the manuscript writing with contribution from all the co-  
552 authors.

553 **Competing interests**

554 The authors declare that they have no conflict of interest.

555 **Acknowledgements**

556 We thank the staff of the Northeast Science Station (NESS) for their support during fieldwork and for providing laboratory  
557 facilities. We want to thank Karel Castro Morales and her team (Friedrich-Schiller University, Jena) and Juri Palmtag  
558 (Northumbria University) for their support in the field. Equally, we want to thank both Suzanne Verdegaal-Warmerdam and  
559 Richard Logtestijn (Vrije Universiteit Amsterdam) for their help with fieldwork preparations. Finally, we thank Niek Speetjens  
560 (Vrije Universiteit Amsterdam) for his advice with the spatial analysis. This study was funded with a starting grant from the  
561 European Research Council to Jorien E. Vonk (THAWSOME #676982), UKRI NERC to Paul J. Mann (CACOON  
562 NE/R012806/1) and NWO Rubicon to Kirsi H. Keskitalo (019.212EN.033). The study of Sergei Davydov, Anna Davydova  
563 and Nikita Zimov was partly carried out within the framework of state assignment number 122020900184-5 of the Pacific  
564 Geographical Institute of RAS.
