Abstract. The young water fraction represents the fractionportion of water molecules in a stream that have entered the catchment relatively recently, typically within 2-3 months. It can be reliably estimated in spatially heterogeneous and nonstationary catchments from the amplitude ratio of seasonal isotope ( $\delta^{18}O$  or  $\delta^{2}H$ ) cycles of streamwater and precipitation, respectively. It has been Past studies found that young water fractions increase with discharge; (Q), thus reflecting increased the higher direct runoff with wetter catchment conditions. This so-ealled The rate of increase in young water fraction with increasing Q, defined as the discharge sensitivity of the young water fraction ( $S^*_{d}$ )), can be useful for describing and comparing catchments' hydrological behaviour; however. However, the estimation of existing method for estimating  $S^*_{ds}$  that only uses biweekly isotope data, can be return highly uncertain and unreliable  $S^*_{ds}$  when the streamwater isotope data are sparse and don't capture the entire flow regime. Indeed, the information provided by isotope data depends on when the respective sample was taken. Accordingly, the low sampling frequency results in information gaps that could potentially be filled by using additional tracers sampled at higher temporal resolution.

HereBy utilizing high-temporal-resolution and cost-effective electrical conductivity (EC) measurements, along with information obtainable from seasonal isotope cycles in streamwater and precipitation, we presentdevelop a new method that can increase the temporal resolution of the estimate the young water fraction at the same resolution as EC and Q measurements. These high-resolution estimates, and thus better constrain allow for improvements in the estimation estimates of the  $S_d^*$ . Our so-called EXPECT method is built upon three key assumptions: 1) the

- A mixing relationship consisting in an exponential decay of streamwater EC with increasing young water fraction. It
  has been constructed based on the relationship between flow-specific young water fractions and EC.
- The two-component <u>EC-based</u> hydrograph separation technique, by using the above-mentioned exponential mixing model, can be used to obtain the portion or a time-source partitioning of young waterstreamwater in young (transit

1

times < 2-3 months) and old water in a stream by considering EC as a proxy of the (transit times > 2-3 months) water age, 2) the,

The EC value of the young water endmember  $(EC_{yw})$  is lower than that of the old water endmember  $(EC_{ww})$ , and 3) the mixing of young water and old water fractions.).

Selecting from measurements reliable values of  $EC_{yw}$  and  $EC_{ow}$  to perform this unconventional EC-based hydrograph separation is described assuming an exponential decay of electrical conductivity with increasing young water fraction. We ealibratechallenging, but the combination of information derived from the two tracers allows estimating the endmembers,  $EC_{yw}$  and  $EC_{ow}$ , values. The two endmembers have been calibrated by constraining the time-weighted unweighted and flow-weighted average young water fraction achieved fractions obtained with the EC-based hydrograph separation to be equal to the same-corresponding quantities obtained from the seasonal isotope cycles.

We test the *EXPECT* method with data fromin three small experimental catchments in the Swiss Alptal valley by using two different temporal resolutions of Q and EC data: sampling-resolution (i.e., we only consider Q and EC measurements during dates of isotope sampling) and daily-resolution. By leveraging high resolution and low cost EC measurements and bi-weekly isotope data, the The EXPECT method has provided reliable young water fraction estimates at bi-weekly and daily resolution both temporal resolutions, from which  $S^a_{al}$  more accurate discharge sensitivity of young water fraction ( $S^{EXP}_d$ ) could be determined with higher accuracy compared to the existing approach. Also, the method provided new information on  $EC_{VW}$  and  $EC_{OW}$ , yielding calibrated values that uses only bi-weekly isotope data. For proper use of fall outside the EXPECT range of measured EC. This suggests that streamwater is always a mixture of young and old water also during very high or very low wetness conditions. The calibrated endmembers revealed a good agreement with both endmembers obtained from an independent method, we further highlight its main limitations that may vary in their relevance depending on the characteristics of the catchments under study and EC measurements from groundwater wells.

4-For proper use of the *EXPECT* method, we have highlighted the limitations of EC as a tracer, identified certain catchment characteristics that may constrain the reliability of the current method and provided recommendation about its adaptation for future applications in other catchments than those investigated in this study.

#### 1 Introduction

35

Environmental tracers in catchment studies are used for understanding the age, the origin, and pathways of water in natural environments (Kendall and McDonnell, 1998). Among tracers, hydrologists use the stable water isotopes (<sup>18</sup>O and <sup>2</sup>H) because they are constituent part of the water molecules and hence they are naturally present in precipitation (Kendall and McDonnell, 1998). The isotopic composition in precipitation (*CP*) generally shows a pronounced seasonal cycle (Dansgaard, 1964). Catchment storage acts as a filter on this input seasonal cycle, so that the isotope cycle in streamwater (*Cs*) is damped and lagged compared to that in precipitation (McGuire and McDonnell, 2006). The delay and damping we observe in the streamwater cycle is caused by the advection and dispersion of stable water isotopes that reach the catchment

65 with precipitation, thus reflecting the water mixing, diversity of flow paths and their velocities (Kirchner, 2016a; McGuire and McDonnell, 2006).

Kirchner (2016a, b) proposed the young water fraction, i.e., the fraction of water in a stream younger than roughly 2-3 months. This young water fraction can be reliably estimated from the ratio between the amplitudes of the seasonal isotope eycles in streamwater and precipitation, respectively (Kirchner, 2016a). The precipitation isotope eycle amplitude  $(A_P)$  is a new water age metric directly related to the amplitudes ratio of the seasonal isotope eycles in streamwater and precipitation: the young water fraction, i.e., the portion of runoff younger than roughly 2-3 months. The precipitation isotope cycle amplitude  $(A_P)$  is generally estimated through a robust fit of a sine function on the isotopic composition of precipitation samples by using the precipitation amount associated to each sample as weight for reducing the influence of low-precipitation events (von Freyberg et al., 2018a; Kirchner, 2016a). Concurrently, The streamwater isotope cycle amplitude is estimated through a robust fit of a sine function on the isotopic composition of streamwater samples with or without using dischargedischarges (Q) at the sampling timetimes as weights (von Freyberg et al., 2018a). Please note that hereafter the symbol "\*\*" indicates a streamflow-weighted variable. Therefore, it is necessary to distinguish between the unweighted and the flow-weighted streamwater amplitude ( $A_S$  and  $A_S$ , respectively; see supplementary material for further details) and, accordingly, between the time-weighted unweighted and the flow-weighted variable.

Recently, Gallart et al. (2020b) proposed a <u>new approachmethod</u> for estimating the <u>sensitivity rate</u> of <u>increase in young</u> water fraction to <u>stream discharge with increasing Q</u> by fitting the <u>following</u> sinusoid function (Eq. 1), <u>with amplitude  $A_s^*(Q) = A_P F^*_{vw}(Q)$ , directly to the <u>seasonal variation of the</u>-isotopic <u>signal data</u> of stream water: (Eq. 1):</u>

85

$$\begin{aligned} \epsilon_{S} \, C_{S}(Q,t) &= A_{\mu} \left[ F_{yw}^{*}(Q) \right] \sin(2\pi f t - \varphi_{S}^{*}) A_{S}^{*}(Q) \sin(2\pi f t - \varphi_{S}^{*}) + k_{S}^{*} = \\ &= A_{P} \left[ F_{yw}^{*}(Q) \right] \sin(2\pi f t - \varphi_{S}^{*}) + k_{S}^{*} = \\ &= \underline{A}_{P} \left[ 1 - (1 - F_{0}^{*}) \exp(-Q S_{d}^{*}) \right] \sin(2\pi f t - \varphi_{S}^{*}) + k_{S}^{*} \end{aligned} \tag{1}$$

Where  $F_0^*$ ,  $S_d^*$ ,  $\varphi_S^*$  and  $k_S^*$  parameters are obtained through non-linear fitting. The  $S_d^*$  (d mm<sup>-1</sup>) parameter is defined as the discharge sensitivity of young water fraction,  $F_0^*$  (-) is the virtual young water fraction when Q = 0,  $\varphi_S^*$  (rad) is the phase of the seasonal cycle, f is the frequency (equal to 1  $y^{-1}$  for a seasonal cycle) and  $k_S^*$  (‰) is a constant representing the vertical offset of the seasonal cycle. As is evident from Eq.Referring to the expression enclosed in square brackets in Eq. (1), the young water fraction is assumed to vary with discharge following an exponential-type equation that converges toward 1 at the highest flows (see supplementary material for additional methodological details), but which does not converge toward 0 at the lowest flows, thus theoretically admitting  $F_0^* < 0$ .

Because of this mathematical relationship between young water fraction and Q (see Eq. (6) in Gallart et al., 2020b), young water fraction time series can in theory be calculated at the same temporal resolution as Q. However, the uncertainties

of such time series can be substantial because the underlying isotope data, due to the low sampling frequency, are generally are not able to capture the entire range of flow regimes, especially the (very) high flow rates (Xia et al., 2023). This becomes evident in Figs. 1 and 3 of Gallart et al. (2020b) where standard errors of flow-specific  $F_{yw}$  are largest during the highest flows. From these considerations emerges the need for a new method to reliably estimate the time series of young water fractions, and to better constrain the discharge sensitivity of young water fractions at very low and very high flow conditions.

In this regard, we propose a new multi-tracer method which combines both stable water isotopes (δ<sup>18</sup>O) and the Multiyear stable water isotope datasets are typically available at relatively low (e.g., biweekly, or monthly) temporal resolutions because of high costs for sampling and laboratory analysis (Mosquera et al., 2018). For the same reasons, high resolution isotopic datasets are often limited to relatively short time-windows (Wang et al., 2019). However, the information provided by isotope data depends on when the respective sample was taken (Wang et al., 2019). Consequently, sampling at low temporal resolution results in information gaps that could potentially be filled by using additional tracers sampled at higher temporal resolution. As a tracer, electrical conductivity (EC), which is a bulk measure of the major ions in water (Riazi et al., 110 2022). As a tracer, EC is advantageous because it, can be measured over extended periods at high temporal resolution, while costs for installation and maintenance remain low (Cano-Paoli et al., 2019; Mosquera et al., 2018). However, EC is not an inerta conservative tracer (as stable water isotopes) because it is affected by geochemical reactions and dissolution of nonconservativercactive solutes in streamwater (Cano-Paoli et al., 2019; Benettin et al., 2022). Stable water isotopes, on the other hand, are typically sampled at much lower temporal resolutions than EC because costs for sampling and laboratory analysis are much higher (Mosquera et al., 2018). Isotopes are considered conservative tracers that do not undergo chemical reactions. Because of these characteristics, the tracers EC and stable water isotopes complement each other well, and thus ean be Because of these characteristics, the tracers EC and stable water isotopes complement each other well, and thus can be jointly used to constrain model parametrizations and to inform transit time models (Cano-Paoli et al., 2019; Benettin et al., 2022). The main objective of this paper is to leverage high-resolution and low-cost EC measurements and bi-weekly δ<sup>18</sup>O data to develop a method for reducing the uncertainty of discharge sensitivity of young water fraction and for estimating the young water fraction at higher temporal resolution.

A time-source separation is generally performed using isotope hydrograph separation, IHS (Klaus and McDonnell, 2013), while major ions (approximated by EC) have been previously used for geographic-source separation in endmember mixing analysis (Hooper, 2003; Penna et al., 2017). Major ions concentration in streamwater derives from mineral weathering. Weathering processes can be viewed as a series of geochemical reactions influenced by characteristics of fluid movement, such as the contact time between the flowing water and mineral surfaces (Benettin et al., 2015, 2017). Thus, the longer a water particle remains within the subsurface, the higher its solute concentration (and thus EC) will be once it will be released as streamflow (Benettin et al., 2017). Indeed, Mosquera et al. (2016), investigating the mean transit time (MTT) of water and its spatial variability in the wet Andean páramo, found that the mean electrical conductivity is an efficient predictor of mean transit time in this high-elevation tropical ecosystem. More recently, Riazi et al. (2022), modelling the EC variation using a travel time distribution approach, assumed that the salinity of water in catchment storages is a function of

water age. Ognjen Bonacci and Tanja Roje-Bonacci (2023) used EC measurements of a karst spring to estimate the time that water spent in the karst aquifer. In addition, Kirchner (2016b) stated that the concentration of reactive chemical species, such as EC, can be used to construct mixing relationship with young water fraction, which provides information about the water 135 age. Overall, these studies suggest that EC may provide useful information on water age (Riazi et al., 2022). Indeed, past studies used EC for time-source hydrograph separation (HS) in event and pre-event water with promising results that favourably compared with those obtained from conservative tracers (Riazi et al., 2022). For instance, Laudon and Slaymaker (1997), applied HS in two small nested alpine /subalpine catchments by using different tracers ( $\delta^{18}$ O,  $\delta^{2}$ H, EC and silica) overall returning comparable results. Cey et al. (1998), with the aim of quantifying groundwater discharge in a small 140 agricultural watershed, separated the hydrograph in event and pre-event water (assumed to be groundwater) obtaining only slight different results utilizing  $\delta^{18}$ O and EC. Pellerin et al. (2008) performed HS on 19 low-to-moderate intensity rainfall events in a small urban catchment through the use of EC, silica and δ<sup>2</sup>H obtaining similar outcome regardless of the tracer used. In a similar environment, Meriano et al. (2011) revealed a high level of agreement between flow partitioning results during a midsummer event using HS via δ<sup>18</sup>O and EC as tracers. Camacho Suarez et al. (2015), to identify the mechanisms 145 of runoff in a semi-arid catchment, applied HS by using both EC and  $\delta^{18}$ O highlighting no major disadvantages by using EC. More recently, Mosquera et al. (2018) used the TraSPAN model to simulate storm flow partitioning in a forested temperate catchment revealing similar portions of pre-event water regardless of the tracer ( $\delta^{18}O$  and EC) used. Cano-Paoli et al. (2019), by investigating the streamflow separation into event and pre-event components in an alpine catchment, obtained consistent results by using  $\delta^{18}O$ ,  $\delta^{2}H$  and EC. Lazo et al. (2023) showed that, in a tropical alpine catchment, the use of EC returned similar results of event and pre-event water than those obtained with  $\delta^{18}$ O for a wide range of flow conditions reflected by the 37 monitored rainfall-runoff events. Overall, the findings of these studies suggest a quasi-conservative behaviour of EC under a wide range of hydrological and lithological conditions, also if its behaviour depends on specific characteristics (e.g., water partitioning between the surface and the subsurface, spatial distribution of minerals and subsurface properties, kinetics of rock dissolution, individual ions concentrations) of each watershed (Laudon and Slaymaker, 1997; Benettin et al., 2022; 155 Lazo et al., 2023). Nevertheless, these studies have been limited to compare results obtained by applying the HS with different tracers but did not integrate the information obtainable from stable water isotopes and EC to generate new insights into transit times, hydrological processes, and the links between water quality and water age variations (Benettin et al., 2022, 2017).

In this regard, we develop here a new multi-tracer method which combines biweekly stable water isotopes data ( $\delta^{18}O$ ) with EC measurements. This study aims at both reducing the standard error of  $S_d^*$  and estimating the young water fraction at higher temporal resolution than two weeks, which will lead to new insights in the catchments under study.

#### 2.11.1 Study sites and data set

165

170

To test the applicability of our method (section 2.2), we use data from the Erlenbach (ERL), Lümpenenbach (LUE) and Vogelbach (VOG) catchments, located in the pre-Alpinealpine Alptal valley in central Switzerland. The geographical framework of the three study sites is reported in Fig. 1.

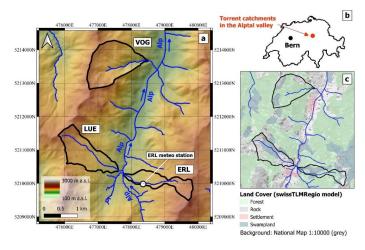

Figure 1 a) Location of the three study catchments with indication of the stream networks and elevation (DHM25 ©swisstopo) as background. The Alp river is marked in the map with blue arrows indicating its flow direction. b) Location of the Alptal valley in Switzerland. c) Land cover of the three study catchments from the ©swissTLMRegio 2D landscape model.

The three study catchments cover areas between 0.7 and 1.6 km², and mean elevation ranges from 1335 to 1359 m a.s.l (Table 1, Fig. 1a). Mean catchment slopes are 13.53°, 12.49° and 18.42° in the ERL, LUE and VOG catchments, respectively, but the hillslopes can be much steeper locally (20°-40°) (Stähli et al., 2021). According to the *swissTLMRegio* model (Fig. 1c), the ERL catchment is mainly constituted by forest (45%) and swampland (49%) which are the dominant classes also in the LUE (21% and 39%, respectively) and VOG (72% and 13%, respectively) catchments. Most of the southern Alptal valley is characterized by shallow gleysols with low permeability that limit the deep infiltration of water and

lead to shallow groundwater tables (Stähli et al., 2021). The percentage of soils with low storage capacity is about 4% in both ERL and LUE, while it is 51% in the VOG catchment; a large fraction of the soils is saturated (≥ 95% in ERL and LUE, 49% in VOG; von Freyberg et al., 2018). The geological substratum of the three study sites consists mainly of sedimentary rock (flysch). The catchment area covered by Quaternary deposits is much higher in the ERL and LUE catchments than in the VOG catchment (Table 1). Therefore, although the study catchments are located within close proximity, they differ in 185 terms of soil wetness and unconsolidated sediments.

The average hydro-climatic conditions are generally similar for all three catchments. The average annual precipitation in the period January 2000 - December 2015, based on interpolated data from the PREVAH model, was about 1853 mm, 1803 mm and 1800 mm at the ERL, LUE and VOG catchments, respectively (von Freyberg et al., 2018a). The average monthly discharge is similar among the catchments: it is 138.9, 152.0, and 117.4 mm month<sup>-1</sup> at the ERL, LUE and VOG catchments, respectively (von Freyberg et al., 2018a). These watersheds reveal an hybrid hydro-climatic regime (Staudinger et al., 2017; von Freyberg et al., 2018a), since we observe an ephemeral snowpack formation (typically from December to April) that also during winter rapidly melts away so that the snowpack may not last throughout the entire winter season (Stähli et al., 2021).

Daily resolution Q and streamwater EC data have been downloaded from the Swiss Federal Office for Forest, Snow and Landscape Research (WSL, Birmensdorf, Switzerland) data portal. We have estimated the Q-EC relationships with a log-type fit (Fig. 2). As daily Q increases, daily EC decreases in the three study sites. This pattern arises due to the contribution of different sources (i.e., ages) of water to the stream. At the three study sites, stream discharge increases due to rainfall or snowmelt, which are generally low in EC, resulting in a dilution of streamwater EC. In addition, during wet conditions (high Q), more rapid flow paths are activated leading to a prevalence of the younger hydrograph component. Because of the short interaction time with mineralized rocks and soils, young water can be assumed to be poor of dissolved ions (i.e., low EC). The other extreme, low Q and high streamwater EC, occurs during baseflow conditions when the stream is mainly fed by old (i.e., highly-mineralized, high-EC) subsurface water (Schmidt et al., 2012).

200

205

This study uses  $F_{yw}$ ,  $F^{2}_{yw}$ ,  $F^{2}_{yw}$  and  $S^{*}_{d}$  (Table 2, Table 4), which were estimated in past studies (Gallart et al., 2020b; von Freyberg et al., 2018a) by considering streamflow  $\delta^{18}$ O data from biweekly grab sampling over a period of approximately 5 years for the three study catchments. For values refer to young water fractions estimated by separating the streamwater isotope time series into different discharge ranges and calculating the seasonal isotope cycles ( $A^{Q_S}$ ) values individually for each of these flow regimes (von Freyberg et al., 2018a).  $F_{\nu_{pw}}^Q$  values refer to young water fractions estimated in discrete flow regimes (Kirchner, 2016b). Indeed, it is possible to separate the streamwater isotope data collected into different discharge ranges and fitting sinusoids separately to the isotope content in each range. For each of these individual 210 flow regimes, this method leads to obtaining the streamwater seasonal isotope cycles amplitude  $(A^{Q}_{S})$  values that will be divided by  $A_P$  to obtain  $F_{yw}^Q$  (von Freyberg et al., 2018a; Kirchner, 2016b). For more details about  $F_{yw}^Q$  estimation, the reader is referred to Kirchner (2016b) and von Freyberg et al. (2018a).

Table 1 Topographic, geological and hydro-climatic properties of the three study sites. Superscript "1" refers to data published in von Freyberg et al. (2018a); Superscript "2" refers to data published in Gentile et al. (2023).

Catchment-ID	ERL	LUE	VOG

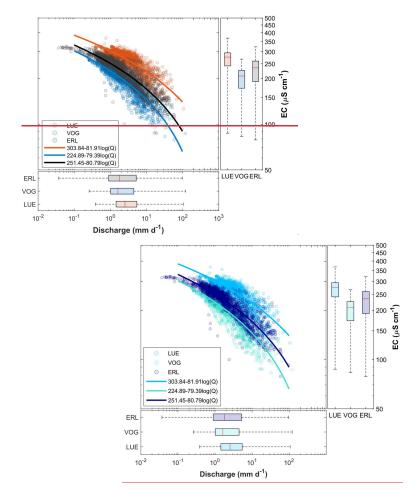

Figure 2 Relation between daily EC and daily Q for the three study sites. As discharge increases, the electrical conductivity (EC)
decreases in the three study catchments. This pattern arises mainly due to the age (source) of water contributing to the stream: if a substantial amount of recent, low-EC water contributes to streamflow during rainfall or snowmelt, streamwater EC decreases while discharge increases.

Table 2 Young water fractions of distinct flow regimes  $(F^0_{pv})$ , as well as average time-weighted  $(F^0_{pv})$  unweighted  $(F^0_{pv})$  young water fractions  $(F_{pv})$  and  $F^*_{pv}$ , respectively) with corresponding standard errors (SE). The number of samples used

225 for estimating F<sup>Q</sup><sub>pw</sub> and along side the median Q and EC of each flow regime are also reported. These data, excluding the median EC, were previously obtained by von Freyberg et al. (2018a).

## 2.2 The EXPECT method: two-component Electrical Conductivity-based hydrograph separaTion employing an EXPonential mixing model

In the realm of catchment hydrology, the use of additional hydrochemistry data together with stable water isotopes can provide unprecedented insights into transit time research, hydrological processes, and the links between water quality and water age variations (Benettin et al., 2022, 2017). The multi-tracer method we present in this paper lays its foundations on the statement that the isotope-based  $F_{yw}$  and  $F^*_{yw}$  Eq. (2.1) and Eq. (2.2), accurately estimate the time-weighted and the flow-weighted average young water fractions in streamflow, respectively (Kirchner, 2016b).

$$\frac{F_{yyy}}{F_{yyy}} = \frac{A_S}{A_P}$$

$$\frac{(2.1)}{F_{yyy}} = \frac{A_S}{A_P}$$

Accordingly, if we knew the young water fraction over a generic time step  $t_i$ ,  $F_{yw}(t_i)$  (e.g., daily young water fraction), we could calculate the time-weighted and the flow-weighted average young water fraction in streamflow through Eq. (3.1) and Eq. (3.2), respectively:

$$240 \quad \frac{\tilde{F}_{yw}}{\tilde{F}_{yw}} = \frac{\sum_{i=1}^{n} F_{yw}(i)}{\sum_{i=1}^{n} F_{yw}} \simeq F_{yw} \tag{3.1}$$

$$\frac{F_{yw}^{\pm}}{F_{yw}^{\pm}} = \frac{\sum_{i=1}^{n} \Phi(i_i)^{\mu} y_{iw}(i_i)}{\sum_{i=1}^{n} \Phi(i_i)} \simeq F_{yw}^{\pm} \tag{3.2}$$

where n is the number of time-steps (e.g., days) in the period of isotope sampling and  $Q(t_t)$  is the discharge at the time  $t_t$  (e.g., daily discharge). The hat " " symbol is simply used to visually differentiate the average young water fractions obtained with both approaches. Please, note that Eq. (3.2) was previously presented in Gentile et al. (2023). The definition of the fraction of the streamflow younger than a threshold age (varying modestly from 2 to 3 months) at the generic time  $t_t$ ,  $F_{yw}(t_t)$ , implicitly defines the existence of a complementary fraction of streamflow older than that threshold age at the same time  $t_t$ ,  $F_{yw}(t_t)$ . Thus, mass conservation requires:

$$F_{yw}(t_i) + F_{ow}(t_i) = 1, \qquad (4)$$

245

250

255

To estimate  $F_{yw}(t_1)$ , and thus  $F_{ow}(t_1)$ , we separate the hydrograph into young and old water by using EC as a tracer. A time-source separation is generally performed using isotope hydrograph separation, IHS, (Klaus and McDonnell, 2013), while major ions (approximated by EC) have been previously used for geographic-source separation in endmember mixing analysis (Hooper, 2003; Penna et al., 2017). The young water fraction may be useful in inferring chemical processes from streamflow concentrations of reactive chemical species (Kirchner, 2016b). Indeed, since it is known how the fraction of young water varies in discrete flow regimes, it is possible to construct mixing relationship between  $F^Q_{yw}$  and the concentration of reactive chemical species (Kirchner, 2016b). Accordingly, we calculate the median EC within each individual discharge range, reported in Table 2, and we investigate how the median EC varies with  $F^Q_{yw}$  (Fig. 3).

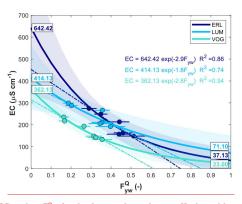

Figure 3 Median flow-specific EC against  $F^Q_{pw}$  for the three study catchments. Horizontal bars indicate the  $F^Q_{pw}$  standard error. The solid lines indicate the exponential fits (which expressions with corresponding  $\mathbb{R}^2$  are also indicated). The coloured areas indicate the 90% prediction bounds. The textboxes corresponding to  $F^Q_{pw}=0$  indicate a first-order estimate of old water endmembers  $(EC^{raw}_{ow})$  by using the exponential expression. Similarly, the textboxes corresponding to  $F^Q_{pw}=1$  indicate a first-order estimate of young water endmembers  $(EC^{raw}_{pw})$  by using the exponential expression. The dashed lines indicate the linear fits to data that point to a negative EC endmember of young water (i.e., EC value corresponding to  $F^Q_{pw}=1$ )

265

270

275

280

As visible in Fig. 3, the relationship between  $F_{yw}^Q$  and median flow-specific EC is well described by an exponential mixing model. Indeed, the widely used linear mixing model proves to be poorly suited here since it is pointing to a negative EC endmember of young water (i.e., EC value corresponding to  $F_{yw}^Q = 1$ , Fig. 3). This will be thoroughly discussed in the Appendix A. By considering the exponential mixing model, we can estimate the "idealized" old water and young water endmembers evaluating the fitted exponential expressions for  $F_{yw}^Q = 0$  and  $F_{yw}^Q = 1$ , respectively. Accordingly, a first order estimate of the two endmembers  $(EC_{yw}^{raw}, EC_{yw}^{raw}, respectively)$  is reported in Fig. 3 and Table 3. It is evident that the measured  $F_{yw}^Q$  for the three study catchments ranges from approximatively 0.1 to 0.5 (Fig. 3). Since the measurable range of young water fractions is not wide enough, the parameters estimated with the exponential fit are highly uncertain since the curve is poorly constrained at very low (< 0.1) and very high (> 0.5) young water fractions. In this regard, we propose hereafter a new methodology to estimate the EC endmembers of young and old water, respectively, and to perform a continuous hydrograph separation with an alternative mixing model.

The definition of the fraction of the streamflow younger than a threshold age (varying modestly from 2 to 3 months) at the generic time  $t_i$ ,  $F_{yw}(t_i)$ , implicitly defines the existence of a complementary fraction of streamflow older than that threshold age at the same time  $t_i$ ,  $F_{ow}(t_i)$ . Thus, mass conservation requires:

$$F_{yw}(t_i) + F_{ow}(t_i) = 1_{\underline{\phantom{a}}},$$

Nevertheless, the choice to employ EC for a time-source separation is justified here by considering that water from different sources within the catchment is likely to have different ages. Hence, EC can potentially provide useful information

on water age (Riazi et al., 2022) because a longer residence time of a water parcel inside the catchment will likely result in increased solute concentration once it will be released as streamflow (Benettin et al., 2017).

To2)

285

To estimate  $F_{yw}(t_i)$ , and thus  $F_{ow}(t_i)$ , we use EC as a tracer to separate the hydrograph into young (transit time  $\leq 2$ -3 months) and old (transit time  $\geq 2$ -3 months) water. A solid support from the scientific literature justifying the use of EC for a time-source hydrograph separation has been illustrated in Section 1.

As suggested by the analysis reported in Fig. 3, to perform the hydrograph separation, we assume that streamwater EC at the generic time  $t_i$ ,  $\frac{EC_S(t_iEC(t_i))}{EC_S(t_iEC(t_i))}$ , decreases exponentially with increasing young water contributions to streamflow: $F_{yw}(t_i)$ :

$$290 \quad \frac{EC_{s}(t_{i}EC(t_{i}))}{EC_{s}(t_{i}EC(t_{i}))} = EC_{ow}e^{-aF_{yw}(t_{i})}, \tag{52}$$

where,  $EC_{ow}$  is the old water EC endmember and a is a parameter. The exponential decay proposed in Eq. (53) guarantees a realistic scenario for the case  $F_{yw}(t_i) = 0$ , i.e. streamflow contains only old water  $(F_{ow}(t_i) = 1)$  and streamwater EC is equal to  $EC_{ow}$  ( $EC_{w}(t_i) = EC_{ow}$ ). Conversely, if  $F_{yw}(t_i)$  is equal to 1, streamflow is made up entirely of young water. Accordingly, we can include the following condition: if  $F_{yw}(t_i) = 1$ ,  $EC_{w}(t_i) = EC_{yw}$  where  $EC_{w}$  is the young water EC endmember (Eq. 6).4):

$$EC_{vw} = EC_{ow}e^{-a}, ag{64}$$

Furthermore, we assume  $EC_{yw} \le EC_{ow}$ -simply because old water had longer contact with mineral surfaces in . A solid support from the subsurface, and thus weathering-derived solute concentrations scientific literature for this assumption will be higher in old water compared to that in young water-illustrated in Section 3.1 alongside the discussion of the results.

By further considering the law of water mass conservation (Eq. 42), it is possible to solve the system of three equations (Eq. 2, 3, 4, 5, 6) with three variables  $(a, F_{yw}(t_i), F_{ow}(t_i))$ , thus obtaining the explicit expression of a (Eq. 75) and, accordingly, of  $F_{yw}(t_i)$  (Eq. 86).

$$a = -\ln\left(\frac{EC_{yw}}{EC_{ow}}\right),\tag{75}$$

$$F_{yw}(t_i) = \frac{\frac{\ln\left(\frac{BC_S(t_i)}{EC_{ow}}\right)}{\ln\left(\frac{BC_{ow}}{EC_{ow}}\right)} \frac{\ln\left(\frac{BC(t_i)}{EC_{ow}}\right)}{\ln\left(\frac{EC_{yw}}{EC_{ow}}\right)},$$

305 (8

300

Despite the relatively simple mathematical approach, the The main difficulty in applying Eq. (86) to estimate  $F_{yw}(t_i)$  is that we generally cannot accurately determine the endmembers  $EC_{yw}$  and  $EC_{ow}$  neither from the analysis reported in Fig. 3 nor from measurements as they. Indeed, such endmembers correspond to the (rare) scenarios in which  $F_{yw}(t_i)$  is either 0 or

1. The first scenario  $(F_{yw}(t_i) = 0)$  might occur only after prolonged periods without rainfall or snowmelt while the second scenario  $(F_{yw}(t_i) = 1)$  is unlikely to occur in most natural catchments where baseflow is usually older than 3 months (Gentile et al., 2023), and thus we cannot directly measure  $EC_{yw}$  (Kirchner, 2016b). In this regard, we present hereafter a novel methodology to estimate the endmembers. Such methodology lays its foundations on the statement that the isotope-based  $F_{yw}$  and  $F^*_{yw}$ . Eq. (7.1) and Eq. (7.2), see supplementary material for further details, accurately estimate the unweighted and the flow-weighted average young water fractions in streamflow, respectively (Kirchner, 2016b).

315 
$$F_{yw} = \frac{A_S}{A_P}$$
 (7.1)

$$F_{yw}^* = \frac{A_S^*}{A_P} \tag{7.2}$$

Accordingly, if we know the young water fraction over a generic time step  $t_i$ ,  $F_{yw}(t_i)$  (e.g., daily young water fraction), we can calculate the unweighted and the flow-weighted average young water fraction in streamflow through Eq. (8.1) and Eq. (8.2), respectively:

$$20 \quad \tilde{F}_{yw} = \frac{\sum_{i=1}^{n} F_{yw}(t_i)}{\sum_{i=1}^{n} F_{yw}} \simeq F_{yw}$$
 (8.1)

$$\tilde{F}_{yw}^* = \frac{\sum_{i=1}^n Q(t_i) F_{yw}(t_i)}{\sum_{i=1}^n Q(t_i)} \simeq F_{yw}^*$$
(8.2)

where n is the number of time-steps (e.g., days) in the period of isotope sampling and  $Q(t_i)$  is the discharge at the time  $t_i$  (e.g., daily discharge). The hat " $\sim$ " symbol is simply used to visually differentiate the average young water fractions obtained with both approaches. Please, note that Eq. (8.2) was previously presented in Gentile et al. (2023).

- We therefore determine  $EC_{yw}$  and  $EC_{ow}$  through calibration, respecting the following three constraints:
- i.  $EC_{ow}$  and  $EC_{yw}$  are greater than or equal to 0.

310

325

330

- ii.  $\tilde{F}_{yw}$ , where  $F_{yw}(t_i)$  is obtained through Eq. (86), must match the  $F_{yw}$  estimated with the amplitude ratio technique
- iii.  $\tilde{F}_{yw}^*$ , where  $F_{yw}(t_i)$  is obtained through Eq. (86), must match the  $F_{yw}^*$  estimated with the amplitude ratio technique (Eq. 27.2).

In summary, we perform a constrained EC-based hydrograph separation in which the two endmembers ( $EC_{yw}$  and  $EC_{ow}$ ) are calibrated through an optimization procedure. Specifically, we use the © Matlab *finincon* solver, the *sqp* (sequential quadratic programming) algorithm, within the *GlobalSearch* procedure that runs repeatedly the local solver for generating a global solution. To satisfy point i), we search the endmember values within the range  $[0, +\infty)$ . We consider  $\infty$  as upper limit since catchments can also have immobile storages that potentially will never participate to the water cycle (Staudinger et al., 2017). In addition, we calibrate the EC endmembers by minimizing the following objective function, which is designed for satisfying points ii) and iii).

$$obj = \frac{(\bar{F}_{yw} - F_{yw})^2 + \frac{F_{yw}^2}{F_{yw}}(\bar{F}_{yw}^* - F_{yw}^*)^2}{\left(1 + \frac{F_{yw}^2}{F_{yw}}\right)},\tag{9}$$

We are giving a greater weight to the second term,  $(\bar{F}_{yw}^* - F_{yw}^*)^2$ . The weight is proportional to how much  $F_{yw}^*$  is higher than  $F_{yw}$ , since Gallart et al. (2020a) showed that the flow-weighted analysis produces a less biased estimation of young water fraction. The outputs of the optimization procedure are the calibrated young water and old water endmembers  $(EC_{yw}^{opt})$  and  $EC_{ow}^{opt}$ , respectively). Subsequently, we calculate the  $F_{yw}^{opt}$  (at every time step  $t_i$ ) with Eq. (86) by using the optimal endmembers  $(EC_{yw}^{opt}, EC_{ow}^{opt})$  and we plot  $F_{yw}^{opt}$  against Q, thus visualizing an empirical relationship between the two variables. Finally, we fit the expression enclosed in square brackets in Eq. (1) (corresponding to Eq. (6) from Gallart et al. (2020b)) to our  $F_{yw}^{opt}$  data:

$$F_{vw}^{opt} = 1 - (1 - F_0^{EXP}) \exp(-Q S_d^{EXP}), \tag{10}$$

We then compare the discharge sensitivity,  $S_d^*$ , previously determined from using only streamwater isotope data; (see Eq. (1), and the discharge sensitivity,  $S_d^{EXP}$ , determined from Eq. (10). We further compare our results to the  $F_{yw}^Q$  values (Table 2) previously obtained by von Freyberg et al. (2018a).

350

355

360

We apply our method at two different time-resolutions that are reflected in our data set—At; daily resolution (DR),  $EC_S(t_i)$  and sampling resolution (SR). At DR,  $EC(t_i)$  and  $Q(t_i)$  refer to daily average EC and Q, respectively, and thus,  $F_{yw}(t_i)$  is the average young water fraction of each day. Analogously, at sampling resolution (SR),  $EC_S(t_i)$  at SR, please note that the "EC samples" are not referring to physical samples in this specific application. Accordingly,  $EC(t_i)$  and  $Q(t_i)$  are obtained by sub-setting those EC and Q values from the daily time series that correspond to the daily-average EC and Q values recorded approximately every 2 weeks (i.e., at the datetime of isotope streamwater grab sampling), respectively. In this sense, we can say that the number of EC samples and isotope samples is the same. Nevertheless, the method can be potentially applied at SR in catchments in which EC is only measured from water samples. At SR,  $F_{yw}(t_i)$  values are estimated only for those days on which an isotope sample was taken.

Last, but not least, since our method consists in a two-component *E*lectrical *C*onductivity-based hydrograph separa *T*ion employing an *EXP* onential mixing model, we decide to name it *EXPECT*. A schematic representation of the *EXPECT* method is reported in Fig. 3.

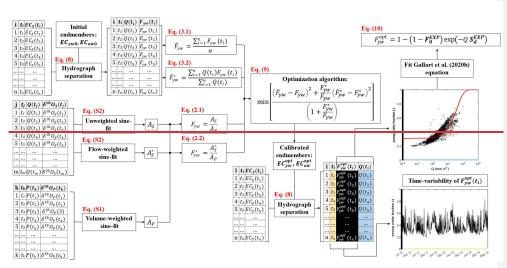

Figure 3-Schematic representation of the EXPECT method. The subscript "P" refers to precipitation, while the subscript "S" refers to streamwater,  $P(t_k)$  indicates the volume of precipitation used for the volume weighted fit of precipitation isotopes  $(\delta^{18}O_p(t_k))$ . The sampling times of  $EC_S(t_1)$ ,  $Q(t_1)$ ,  $\delta^{18}O_S(t_j)$ ,  $\delta^{18}O_R(t_k)$  are generally not the same, and thus the times  $t_i$ ,  $t_j$  and  $t_k$  have different indices

365

375

380

We quantify the uncertainty of  $EC_{yw}^{opt}$  and  $EC_{ow}^{opt}$  by repeating the global optimization procedure by sampling randomly 10000 couples of  $F_{yw}$  and  $F^*_{yw}$  from the intervals  $F_{yw} \pm SE$  and  $F^*_{yw} \pm SE$ , respectively. The SE values are reported in Table 2. The random sampling assumes that the values within the two intervals have a Gaussian probability of extraction, thus favoring the sampling of the core values. Therefore, we obtain 10000 couples of endmembers of which we compute statistics. We further calculate the uncertainty of  $F_{yw}^{opt}(t_i)$ : we apply Eq. (86) using the 10000 couples of endmembers, thus obtaining  $10000 F_{yw}^{opt}(t_i)$  values at each time step  $t_i$ , of which we calculate the standard deviation.

Please, note that the initial conceptualization of the *EXPECT* method was based on testing the hydrograph separation by using the widely established 2-component endmember linear mixing approach (Buttle, 1994; Genereux, 1998; Klaus and McDonnell, 2013). However, this approach was not successful because it can represent only a limited hydrological behaviour of catchments that does not capture that of our three study catchments. A detailed explanation of the limits regarding the linear mixing model is provided in the appendix A of this paper.

Please, note that the initial conceptualization of the mixing model was based on testing the hydrograph separation by using the 2-component endmember linear mixing approach with EC as tracer (e.g., Cano-Paoli et al. 2019). As could already be inferred from Fig. 3, this approach was not successful because it can represent only a limited hydrological behaviour of

catchments that does not capture that of our three study catchments. A detailed explanation of the limits regarding the linear mixing model is provided in the appendix A of this paper.

Last, but not least, since our method consists in a two-component *Electrical Conductivity*-based hydrograph separa*T*ion employing an *EXP*onential mixing model, we decide to name it *EXPECT*. A schematic representation of the *EXPECT* method is reported in Fig. 4.

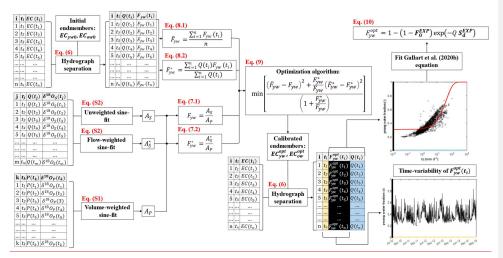

Figure 4 Schematic representation of the *EXPECT* method. The subscript "P" refers to precipitation, while the subscript "S" refers to streamwater  $P(t_k)$  indicates the volume of precipitation used for the volume-weighted fit of precipitation isotopes  $[\delta^{18}O_p(t_k)]$ . The sampling times of  $EC(t_i)$ .  $Q(t_i)$ .  $\delta^{18}O_S(t_j)$ .  $\delta^{18}O_P(t_k)$  may not be aligned, and consequently, the time series typically have different lengths. Thus, the times  $t_i$ ,  $t_j$  and  $t_k$  have different indices and usually  $n \neq m \neq k$ .

#### 3 Results and Discussion

385

395

#### 3.1 Physical likelihood of calibrated endmembers and discharge sensitivity of young water fraction

The application of the *EXPECT* method showed, at both daily and sampling resolution, that the old water EC endmembers,  $EC_{ow}^{opt}$ , are about one order of magnitude larger than the young water EC endmembers,  $EC_{yw}^{opt}$ , for all three experimental catchments (Table 3, Fig. 5).—). This result can be explained by considering that old water had longer contact with mineral surfaces in the subsurface (Benettin et al., 2015, 2017), and thus weathering-derived solute concentrations (and correspondingly EC) will be higher in old water compared to that in young water. Moreover, young and old streamwater components can derive from different reservoirs in a catchment (Riazi et al., 2022). Among these reservoirs, old water is

generally assumed to represent groundwater. This is also supported by the fact that the fraction of baseflow (representing groundwater contribution to streamflow) resulted to be complementary to young water fraction in the framework (including the three Swiss catchments of this study) investigated by Gentile et al. (2023). In this regard, different papers that characterized groundwater EC showed notable differences with EC of precipitation and/or meltwater. Indeed, Zuecco et al. (2018), by investigating the hydrological processes in an alpine catchment, found that EC of rain water and of recent snow is 19.2 µS/cm and 12.2 µS/cm, respectively. Conversely, they found that groundwater from springs had an EC of 166 µS/cm. 405 Moreover, by investigating the conceptualization of meltwater dynamics in an alpine catchment through hydrograph separation, Penna et al. (2017) defined the snowmelt endmember ranging from 2.9 to 15.3 μS/cm, the glacier melt endmember ranging from 2 to 2.7 µS/cm and the groundwater endmember ranging from 210 to 317.7 µS/cm (average values from springs or streams in fall/winter). These examples are intended to show that groundwater (main source of old water) generally reveals an EC value much higher (around 10÷100-fold) than other sources in a catchment that should preferentially 410 contribute to the young streamwater component. Differences in young and old water EC endmembers can also be partially justified by looking at differences in event and pre-event water EC endmembers. Indeed, old (transit times > 2-3 months) water is a large fraction of pre-event (transit times > few days) water, whereas event water (transit times < few days) is a portion of young water (transit times < 2-3 months). Due to this overlap, it would not be surprising a similarity of the old water and pre-event water EC endmembers, as well as the young water and event water EC endmembers. Cano-Paoli et al. 415 (2019) used streamwater EC to investigate hydrological processes in alpine headwaters by separating the hydrograph into event and pre-event water. In this regard, they defined the event water end-member equal to 8 µS/cm (Penna et al., 2014) and the pre-event water endmember equal to 95 µS/cm (mean value during baseflow conditions). Laudon and Slaymaker (1997), by investigating the hydrograph separation using EC at the lower station of an alpine catchment, defined the rain water EC endmember equal to 6.15 µS/cm and the pre-event water endmember equal to 39 µS/cm. However, young and old water EC endmembers are expected to be higher than event and pre-event water EC endmembers, respectively. Accordingly, these past results taken from the scientific literature support our assumption that  $EC_{yw} \le EC_{ow}$ .

400

420

425

430

The highest  $EC_{ow}^{opt}$  values were obtained for ERL (501  $\mu S cm^{-1}$ , DR), and the lowest values in VOG (319  $\mu S cm^{-1}$ , DR). The  $EC_{ow}^{opt}$  values are in line with those measured in groundwater: (Fig. 5): in a 6.8-m deep monitoring well at the ERL meteorological station, groundwater EC varies generally between 400 (spring-summer) and 500 µS cm<sup>-1</sup> (fall-winter; data not shown), whereas in a neighbouring catchment of ERL, EC in groundwater in up to 1.5 m depth was generally around 400-450 μS cm<sup>-1</sup> during no-snowmelt conditions (Kiewiet et al., 2020). Fig. 4 shows further that the interquartile ranges of the  $\frac{EC_{ow}^{opt}}{The}$  optimal endmembers are also in line with the first-order estimates of endmembers,  $EC_{ow}^{raw}$ ,  $EC_{vw}^{raw}$ , derived from the exponential model fitted on median EC vs FQ<sub>pw</sub> (Table 3, Fig. 3, Fig. 5), except for EC<sub>ow</sub> in ERL catchment. This can be explained by considering the high standard error (Table 3) of the parameter (corresponding to  $EC_{ow}^{raw}$ ) in the exponential model that is for ERL (more than LUE and VOG) poorly constrained at low young water fractions (Fig. 3). The optimized EC values of the young water fractions appear slightly elevated compared to data derived from Central European <u>Precipitation (Monteith et al., 2023)</u>. However, it is plausible to posit that the young water fraction encompasses some soil water with higher EC.

Fig. 5 shows further that the interquartile ranges (IQR) of the  $EC_{ow}^{opt}$  empirical distributions are much larger than those of  $EC_{yw}^{opt}$ . Assuming that the solute concentration in streamwater increases with water age (Riazi et al., 2022), this can possibly be explained with the much wider range of transit times (from approximately 0.2 to  $\infty$  y) of the old water compared to that of young water (0 to 0.2 y). Consequently, the concentrations of weathering-derived solutes in old water are not only higher but also more variable than in young water.

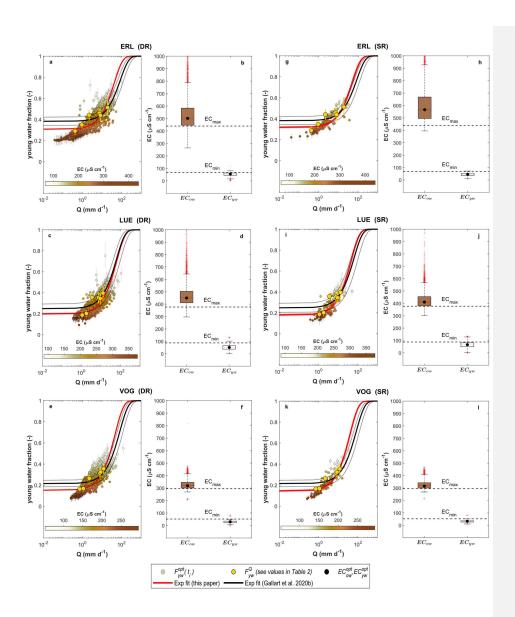

435

455

Our method estimates the EC endmember values for the cases  $F_{yw}(t_i) = 1$  and  $F_{yw}(t_i) = 0$  that are generally difficult to determine experimentally, thus providing additional information about young and old water in the systemsystems under study. In this regard, in each one of the three study sites, the theoretical endmembers  $EC_{yw}^{opt}$  are lower than the minimum EC value measured in the streams; analogously, the calibrated  $EC_{ow}^{opt}$  values are higher than the maximum measured EC value (boxplots *versus* horizontal dashed lines in Fig. 5). This is expected for a natural, heterogeneous system where incoming precipitation mixes with stored water, and thus streamwater never contains 100% young or old water, respectively. Instead, streamwater is a mixture of these two components that, depending on catchment wetness conditions and hydroclimatic forcing, contribute in different proportions to catchment outflow. This is supported by the fact that  $F_{yw}^{Q}$  cover only a limited range young water fractions (roughly from 0.1 to 0.5). This result demonstrates that the choice of the old water endmember based on tracer values sampled during baseflow conditions can result in an underestimation of the theoretical old water endmember. Although these stream conditions suggest the prevalence of old water, if the percentage of old water is less than 100%, then the measured tracers still reflect some mixing (albeit limited) with young water.

Table 3 Optimized endmembers obtained through the *EXPECT* method. 1st, 2nd, 3rd quartile (q1, q2 and q3, respectively) and IQR of optimized endmembers empirical distribution are also reported. First order estimates of endmembers derived from the exponential model fitted on median EC vs  $F^{Q}_{pw}$  (see also Fig. 3) with related standard errors are reported on the right side of this table. Values are in  $\mu S$  cm<sup>-1</sup>.

The estimated discharge sensitivity of the young water fraction,  $S_d^{EXP}$ , based on the *EXPECT* method satisfactorily describes the  $F_{yw}^{opt}(t_i)$ -  $Q(t_i)$  relationships of the three catchments, as reflected by  $R^2$  values of 0.58 and higher (Table 4; red curves in Figure 4). Moreover, the red curve also fits well the  $F_{yw}^{O}$  values of the distinct flow regimes (Table 2). By taking advantage of the consecutive  $F_{yw}^{opt}(t_i)$  values at daily or sampling resolution, we better constrain the parameters of Eq. (10) at very low and very high discharges compared to the fit obtained with Eq. (1) that is using only streamwater  $\delta^{18}$ O data at sampling resolution (black curve in Figure 4,Fig. 5, Table 4; see the supplement for methodological details). As a result, our estimated discharge sensitivity  $S_d^{EXP}$  is higher for the ERL and VOG catchments and similar (within error) for the LUE catchment compared to  $S_d^*$ , whereas our estimates of  $F_0^{EXP}$  for all three sites are slightly smaller than the respective  $F_0^*$  values obtained with Eq. (1).

We also find that the  $S_d^{EXP}$  values obtained at SR can differ from those at DR. For LUE,  $S_a^{EXP}$  at SR is larger than at DR (Table 4), whereas it is the other way around for ERL. Such differences can be attributed to the different flow regimes represented by the isotope samples that influences the EC endmember estimations at each site (Table 3). Moreover, at DR we are calibrating the EC endmembers by using  $F_{yw}$  and  $F_{yw}^*$  based on isotope data at SR. To be fully consistent in terms of temporal resolution, we theoretically need daily streamwater isotope data to derive  $F_{yw}$  and  $F_{yw}^*$ . The influence of sampling frequency is one of the limitations of the *EXPECT* method as explained in section 3.3. Nevertheless, the  $F_0^{EXP}$  values are consistent between the two temporal resolutions.

As can be seen in Fig. 5, the  $F_{yw}^{opt}(t_i)$  values obtained with the EXPECT method form a data cloud around the idealized discharge sensitivity function of Eq. (10). Specifically, for a given discharge value, we obtain various  $F_{yw}^{opt}(t_i)$ 

values, which can be explained by the delayed response of old water during precipitation events: while the young water fraction is generally highest during the rising limb of the hydrograph, it decreases during the falling limb when old water reaches the stream (von Freyberg et al., 2018b)

### 3.2 An immediate application of the *EXPECT* method: flow duration curves of young/old water and the temporal variability of young water fractions.

Because the *EXPECT* method allows for estimating young water fractions  $F_{yw}^{opt}(t_i)$  at up to daily resolution, we can determine the flow duration curves of young and old water discharge, respectively. Moreover, we calculate  $Q_{50/50}$ , i.e., the median discharge value at which  $50 \pm 1\%$  of both young and old water exist in streamflow. In the ERL catchment, Fig. 6a shows that a shift from old-water dominated towards young-water dominated streamflow occurs for discharges larger than approximately 7.7 mm d<sup>-1</sup> ( $Q_{50/50}$ ; Fig. 6a). In the LUE and VOG catchments, the streamflow contains more old water than young water for most of the flow regime (Fig. 6b, Fig. 6c); only for relatively few occasions, when Q exceeds  $Q_{50/50}$  (23.2 and 17.5 mm d<sup>-1</sup>, respectively), the relative contribution of young water was slightly larger than that of old water.

By comparing  $Q_{50/50}$  with the median stream discharge ( $Q_{med}$ ), we observe that in all three study catchments  $Q_{50/50}$  is higher than  $Q_{med}$  (Fig. 6). This result suggests that more than 50% of the time a major proportion of old water reaches the stream. In both the LUE and VOG catchments,  $Q_{50/50}$  is higher than in the ERL catchment, revealing that the LUE and VOG streams are longer dominated by old water than the ERL stream. This explains why the isotope-based average young water fraction is higher in the ERL than in the LUE and VOG catchments (Table 2).

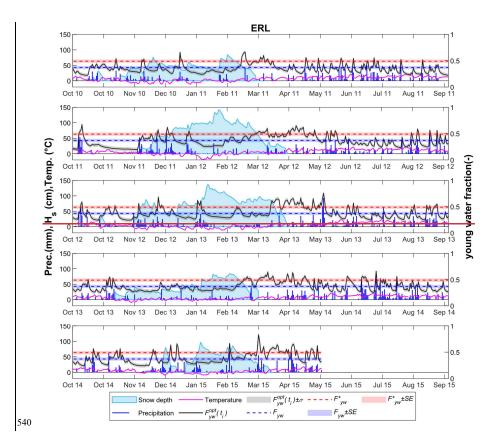

With the *EXPECT* method, the time-variability of  $F_{yw}^{opt}(t_i)$  can be explored in detail, e.g. through comparing time series of  $F_{yw}^{opt}(t_i)$  with those of other hydro-climatic variables (Fig. 7). Accordingly, we show hereafter a comparison

between  $F_{vw}^{opt}(t_i)$  and hydro-climatic observations at daily resolution of the ERL catchment since it has the most complete hydro-climatic data set (including discharge, precipitation, snow depth and temperature measurements; all data available from WSL) compared to the other two catchments. As visible from Fig. 7, daily young water fractions in the ERL catchment respond directly to precipitation events, which is further reflected by a strong positive correlation between  $F_{vw}^{opt}(t_i)$  and the daily precipitation volumes ( $\rho_{Spearman} = 0.41$ , p-value  $\ll 0.01$  considering only days with precipitation, Fig. 8). We estimate that after a rainfall- or snowmelt event, the growth rate of  $F_{yw}^{opt}(t_i)$  is on average 0.062±0.058 d<sup>-1</sup> (to reach the local  $F_{yw}^{opt}(t_i)$ maximum next to the previous  $F_{yw}^{opt}(t_i)$  local minimum, Fig. S1). On the other side, during the recession phase, the average rate of decrease of  $F_{yw}^{opt}(t_i)$  is  $-0.041\pm0.036$  d<sup>-1</sup> (to reach the  $F_{yw}^{opt}(t_i)$  local minimum next to the previous  $F_{yw}^{opt}(t_i)$  local maximum, Fig. S1). Accordingly,  $F_{yw}^{opt}(t_i)$  rapidly increases after an event (peak  $F_{yw}^{opt}(t_i)$  is reached on average after  $1.98\pm1.25$  days), while it recedes slower during no-input days (the next minimum  $F_{vw}^{opt}(t_i)$  is reached on average after 3.36±3.10 days). The largest daily young water fractions in the ERL catchment occurred during spring snow melt (March-May), suggesting that the melt water of the ephemeral snowpack is an important source of young water (since no relevant water aging is observed in such snowpack) that flows off quickly in the stream (Gentile et al., 2023). Rapid surface runoff of snow melt can occur due to soil freezing (temperatures < 0°C) or high soil moisture contents (temperatures > 0°) both of which can limit infiltration (Harrison et al., 2021; Keller et al., 2017; Fig. 7). During the periods of snow accumulation and persistent snow cover, typically from November to February,  $F_{yw}^{opt}(t_i)$  values were often as low as 0.3 and did not vary much (except during snowmelt and rain-on-snow events). Thus, streamflow in ERL was mainly composed of old water during this period, likely originating from the soil- and groundwater storages.

535

Figure 6 Total flow, young flow and old flow duration curves of a) ERL, b) LUE and c) VOG catchments.  $O_{S0/S0}$  indicates the median discharge value at which  $50 \pm 1\%$  of both young and old water exist in streamflow.  $O_{med}$  represents the median stream discharge.

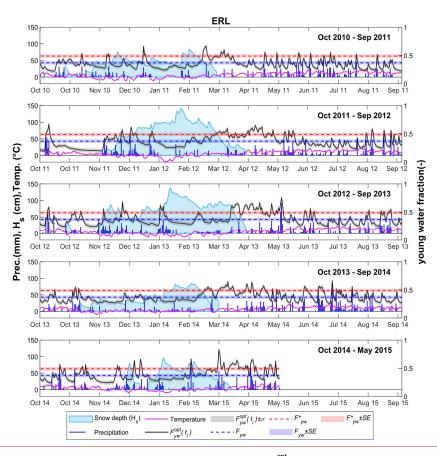

Figure 7 Time series of daily precipitation, snow depth, air temperature and  $F_{yw}^{opt}$  for the ERL catchment. Each panel reports a different hydrologic year.

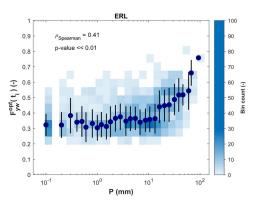

Figure 8 Correlation between daily  $F_{yw}^{opt}$  and daily precipitation when precipitation is higher than 0. Blue points indicate the median  $F_{yw}^{opt}$  observed in the stream corresponding to different ranges of daily precipitation with error bars indicating the standard deviation. These median  $F_{yw}^{opt}$  are plotted against the median daily precipitation in each range. The blue intensity of the bins indicates the number of observations within each bin. A rapid increase in young water fraction is observed when the daily precipitation is about 10 mm/d, thus reflecting hydrological connectivity and the generation of rapid flow paths.

#### 550 3.3 Limitations of the EXPECT method and recommendations for future applications

555

560

565

While the EXPECT method can offer valuable insights into the young water fraction's discharge sensitivity and its time-variability, it is not without its limitations. The assumption of considering EC as a proxy of streamwater age may not hold true in all hydrological systems. For example, human activities, such as mining, irrigation or waste-wastewastewater inputs can alter the streamwater EC in unpredictable ways. Another example involves catchments with highly soluble rocks in the aquifers (e.g., limestone or gypsum), that are susceptible to dissolution by water. It has been shown that EC can increase with Q in some karst systems due to remobilization of the circulating water in the fractured areas (Balestra et al., 2022). Therefore, the  $F_{yw}$ -EC relationship (Eq. 5) can be very different from that in our three study catchments that are mainly groundwater influenced.3) can be very different from that in our three study catchments that are mainly groundwater influenced. Indeed, also an early study advised to be mindful of EC behaviour since it depends on specific characteristics of each catchment (Laudon and Slaymaker, 1997). Accordingly, for future applications of the method presented in this paper, we recommend to start visualizing the relationship between flow-specific young water fractions and flow-specific electrical conductivities with the aim of constructing a site-specific mixing relationship, as suggested by Kirchner (2016b). Please, note that this relationship could be potentially different from an exponential mixing model. Indeed, the use of the exponential mixing model is not pretended to be the definitive answer to the problem of choosing the right mixing model for flow partitioning in young and old water. Accordingly, if the most suitable mixing model turns out to be different from an exponential mixing model, the equations presented in this study will need to be adapted to the specific case study. However,

the method's application scheme for calibrating the endmembers can still be employed. Nevertheless, in some catchments with short and sparse isotope timeseries, flow-specific young water fractions cannot be estimated reliably (von Freyberg et al., 2018b), von Freyberg et al. (2018a) were able to estimate reliable flow-specific young water fractions for nine Swiss catchments that disposed of isotope timeseries 4 to 5 years-long with a minimum number of samples from 81 to a maximum of 140, where streamwater grab samples were collected approximately fortnightly. Thus, we suggest an isotope data set with these characteristics to construct a reliable site-specific mixing model with both flow-specific EC and  $F^Q_{yyz}$ .

Another major limitation of the *EXPECT* method is its strong dependency on reliable  $F_{yw}$  and  $F^*_{yw}$  estimates (i.e., assumptions ii) and iii) in section 2.2). If streamwater isotope data are short or sparse,  $F_{yw}$  or  $F^*_{yw}$  can be highly uncertain and the EC endmembers cannot be constrained sufficiently well. Recently, Gallart et al. (2020a) revealed that by using a weekly sampling frequency, time-weightedunweighted and flow-weighted young water fractions were significantly lower than results with virtual (perfect) sampling. Thus, for the same catchment, we could potentially obtain different EC endmembers if stable water isotopes were sampled at higher or lower temporal resolution. Accordingly, we strongly recommend evaluating how the uncertainty in  $F_{yw}$  or  $F^*_{yw}$  propagates in the uncertainty of the calibrated endmembers as described in section 2.2.

For many catchments, Q and EC values are measured at sub-hourly resolution. Thus, theoretically the *EXPECT* method could provide reasonable young water fraction estimates results at these resolutions as well. However, we should consider that short-term variations in EC may not necessarily represent short-term variations in water age. For example, Calles (1982) showed for a small stream in Sweden that diurnal variations in EC seem to be due to evapotranspiration, but also the influence from gravity variations may play a role. Moreover, a past study in a pre-alpine river in Switzerland revealed that diurnal fluctuation of EC can be due to biogeochemical processes, such as calcite precipitation and photosynthesis (Hayashi et al., 2012). Accordingly, the biological (photosynthesis and respiration) and chemical processes (carbonate equilibrium and calcite precipitation) can play a key role in controlling  $Ca^{2+}$  and  $HCO_3$  concentrations and, consequently, EC (Nimick et al., 2011; Hayashi et al., 2012). By calculating the average daily EC, thus removing diurnal and nocturnal EC dynamics, it should better reflect variations in water age under the *EXPECT* method assumptions. Accordingly, we recommend applying the method by using daily mean of EC.

Finally, we have chosen here an exponential mixing model (because we have shown that the linear mixing model is inconsistent with our observations, see appendix A) but the choice of the mixing model depends on the catchment properties.

#### 4 Summary and Conclusions

570

580

585

The discharge sensitivity of the young water fraction  $(S_d^*)$  is a useful metric that quantifies how much the proportion of streamflow younger than 2–3 months changes as a catchment wetness-increases becomes wetter. In a past study,  $S_d^*$  was obtained by fitting a sine-function to the streamwater isotope values, assuming an exponential relationship between young water fraction and discharge (Gallart et al., 2020b). Most available streamwater isotope datasets are characterized by a

relatively low sampling frequency, which often fail to capture the entire flow regime from very low to very high discharges. This can result in highly uncertain or unrealistic estimates of the discharge sensitivity of young water fractions. Therefore, this paper aims at incorporating EC and  $\delta^{18}O$  data to develop a new method that a) estimates young water fractions at high temporal resolution by taking advantage of continuous EC measurements, and that b) better constrains the estimated discharge sensitivity.

We have designed the *EXPECT* method which combines two widespread techniques: the EC based hydrograph separation and the sine-wave models model of the seasonal isotope cycles. The method consists of a data driven approach where the daily or biweekly (sampling) young water fractions are estimated directly from EC measurements considered as a proxy of the water age. and an alternative EC-based hydrograph separation. Specifically, we use an exponential mixing model in which EC endmembers are calibrated by using time-weighted unweighted and flow-weighted young water fractions obtained from  $\delta^{18}$ O data. By considering the calibrated endmembers, daily and biweekly (sampling) young water fractions are estimated by using EC measurements considered as a proxy of the water age. The *EXPECT* method was tested in three small experimental catchments in Switzerland.

610

615

620

625

630

The application of this multi-tracer method has revealed that the optimal EC endmembers lie beyond the range of measured EC in streamwater. This result reflects that streams are commonly a mixture of young and old water and that corresponding EC endmembers are difficult to be obtained experimentally. The discharge sensitivities of the young water fractions for the three study sites, obtained with the EXPECT method, agree well with those obtained with the conventional approach that uses only isotope data. However, the EXPECT method significantly reduced the uncertainty of  $S^a_{ar}$  standard error of discharge sensitivity. In addition, the method allows for estimating young water fractions at daily resolution, which provides interesting insights into short-term variations of streamwater age with changes in meteorological conditions, e.g., during snow accumulation and snowmelt. Young water fractions at biweekly (i.e., sampling) resolution also revealed high reliability, thus highlighting the general applicability of this method also in ungauged catchments:  $\delta^{18}$ O and EC data can be both obtained from laboratory analysis of collected water samples while Q can be directly measured in the stream during sampling dates with conventional methods (e.g., current meter method, weir method) without the presence of fixed instrumentation for measuring stream discharge and electrical conductivity. Q and EC.

To conclude, a recent review paper (Benettin et al., 2022) highlighted the challenge of integrating non-conservative tracers in lumped models, and thus explaining the lack of multi-tracer studies in the scientific literature. The EXPECT method is a first attempt to leverage the ease of EC data acquisition with stable water isotope data to improve the time resolution of young water fraction estimates. This method can (theoretically) be used to better constrain hydrological models that aim at determining water ages or to obtain new insights into hysteresis patterns of the relationships between young water fractions and discharge due to a missed definition of catchment-scale chemical properties. Overall, the EC resulted for the three study catchments as an informative property that keeps track in an integrated way of faster (younger) and slower (older) flow paths at the catchment scale. Considering the necessary precautions regarding the use of EC, the methodology presented in this

paper can be applied (with possible adaptations) to other catchments to generate new insights into transit times, hydrologic flow paths and related sources.

#### Appendix A: Limitations of the linear mixing model

In order to use EC to separate the hydrograph into young and old water at a specified time t<sub>i</sub>, we may employ the 2-component EC-based Hydrograph Separation (ECHS), built on the water (Eq. A1) and tracer (Eq. A2) mass balance:

$$F_{yw}(t_i) + F_{ow}(t_i) = 1, (A1)$$

$$\frac{EC_{s}(t_{i}EC(t_{i}))}{EC_{yw}F_{yw}(t_{i})} + EC_{ow}F_{ow}(t_{i}),$$
(A2)

Where,  $EC_x(t_i)$  is the electrical conductivity measured in the stream at the time  $t_i$ ,  $EC_{yw}$  is the young water EC endmember,  $EC_{ow}$  is the old water EC endmember. By solving the system of two equations (Eq. A1 and Eq. A2) with two variables  $(F_{yw}(t_i))$  and  $F_{ow}(t_i)$ , we can obtain the explicit expression of  $F_{yw}(t_i)$ :

$$F_{yw}(t_i) = \frac{EC_S(t_i) - EC_{ow}}{EC_{yw} - EC_{ow}} \frac{EC(t_i) - EC_{ow}}{EC_{yw} - EC_{ow}},$$
(A3)

As mentioned in section 2.2, we assume EC<sub>yw</sub> < EC<sub>ow</sub>. However, by performing the constrained ECHS (section 2.2) in which the two endmembers (EC<sub>yw</sub> and EC<sub>ow</sub>) are calibrated, the optimization algorithm finds EC<sub>yw</sub> = 0, that is exactly the lower bound of the defined range [0, +∞) in which the optimization algorithm searches the solution. This result suggests that the algorithm wants to search the best solution below the lower bound of the specified range, thus potentially returning a negative EC<sub>yw</sub> value. This is consistent with the negative EC<sub>yw</sub> obtained by fitting a linear model on median EC vs FO<sub>yw</sub> of the three study catchments (Fig. 3). Obviously, this mathematical solution is not physically acceptable, but we can investigate this result to better understand the catchment functioning. Accordingly, if we make explicit EC<sub>x</sub>(t<sub>t</sub>EC(t<sub>t</sub>) from Eq. (A3), we find a linear decrement of EC<sub>x</sub>(t<sub>t</sub>EC(t<sub>t</sub>) with the increasing F<sub>yw</sub>(t<sub>t</sub>) (Eq. A4):

$$\frac{EC_g(t_i EC(t_i))}{EC_{yw}-EC_{ow}} F_{yw}(t_i) + EC_{ow} = \alpha F_{yw}(t_i) + EC_{ow} , \label{eq:ecg}$$
 (A4)

By requiring a negative  $EC_{yw}$  as best solution, the constrained ECHS suggests that, for an exhaustive description of the catchments behaviour,  $EC_S(t_i EC(t_i))$  needs to rapidly decrease at low  $F_{yw}(t_i)$ , as shown by the red lines in Fig. 9a. Nevertheless, physical reason limit the slope ( $\alpha$ ) of this line ( $\alpha \ge -EC_{ow}$ ); the most extreme, but still acceptable condition (i.e., when  $EC_{yw} = 0$  and  $\alpha = -EC_{ow}$ ) is indicated by the dashed black line in Fig. 9a. Accordingly, to obtain a rapid decrease of  $EC_S(t_i EC(t_i))$  at low  $F_{yw}(t_i)$ , but maintaining positive  $EC_{yw}$ , it is necessary to improve the linear mixing model. As

visible from Fig. 9b, the exponential mixing model described in section 2.2 resulted suitable to describe a rapid decrease of  $\frac{EC_x(t_i)EC(t_i)}{EC_x(t_i)}$  at low  $F_{yw}(t_i)$  by maintaining a positive  $EC_{yw}$ .

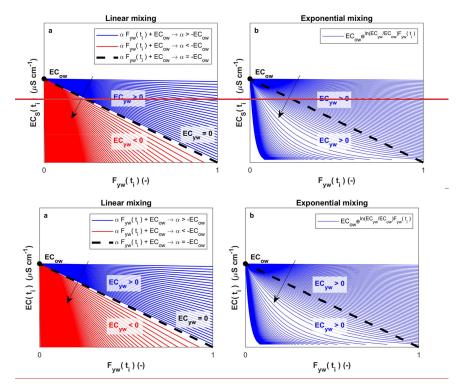

Figure 9 a) Limits of the linear decay of \( \frac{EC\_S(t\_tEC(t\_t)}{EC\_S(t\_t)} \) with increasing \( F\_{yw}(t\_t) \). Red lines with slope (\alpha \) lower than \( -EC\_{ow} \) are not physically admitted since they imply a negative \( EC\_{yw} \); b) the exponential mixing overcomes this limit. Black arrows indicate the direction in which \( EC\_{yw} \) decreases.

Data availability. Time series of δ<sup>18</sup>O in streamflow and precipitation for the ERL, LUE and VOG catchments are available in the data repository Zenodo at <a href="https://zenodo.org/record/4057967#.Y00oMHZBxPY">https://zenodo.org/record/4057967#.Y00oMHZBxPY</a> (Staudinger et al., 2020). Daily discharge and electrical conductivity data for the ERL, LUE and VOG catchments are available from the Swiss Federal Institute for Forest, Snow and Landscape research (WSL) data portal at <a href="https://www.envidat.ch/#/metadata/longterm-">https://www.envidat.ch/#/metadata/longterm-</a>

<u>hydrological-observatory-alptal-central-switzerland</u>. The shape files (.shp) of the ERL, LUE and VOG catchments are available at <a href="https://zenodo.org/record/4057967#.Y00oMHZBxPY">https://zenodo.org/record/4057967#.Y00oMHZBxPY</a> (Staudinger et al., 2020).

Author contributions. AG, JvF, and SF identified the research gap, designed the EXPECT method and prepared the paper. AG implemented the EXPECT method in a Matlab code with the support of DG and DC. All authors revised the manuscript and gave final approval to the submitted version.

775 Competing interests. The authors declare that they have no conflict of interest.

#### **Summary:**

This document contains a focus about the discharge sensitivity estimation following the approach used by Gallart et al. (2020b). Figure S1 shows the daily  $F_{yw}^{opt}$  timeseries of the three-study catchment with indication of local maxima/minima (left panels) and the distribution of  $F_{yw}^{opt}$  rising/falling limbs length (right panels).

#### The discharge sensitivity of young water fraction

The seasonal isotope cycles in precipitation  $e_{P}C_{P}(t)$  (%) and in streamflow  $e_{S}C_{S}(t)$  (%) can be modelled using a sinusoid function, as reported in Eq. (S1) and Eq. (S2):

$$\frac{e_{\mathbf{p}}C_P(t)}{e_{\mathbf{p}}C_P(t)} = A_P \sin(2\pi f t - \varphi_P) + k_P ,$$

$$-----(S1)$$

$$\mathbf{e}_{S}C_{S}(t) = A_{S}^{(*)}\sin(2\pi f t - \varphi_{S}^{(*)}) + k_{S}^{(*)}, \tag{S2}$$

where  $A_P$  and  $A_S$  are the amplitudes (‰) of seasonal isotope cycles, f is the frequency of the cycle (1 y<sup>-1</sup>), t is time (decimal years),  $\phi_P$  and  $\phi_S$  are the phases (rad) of seasonal cycles and  $k_P$  and  $k_S$  are the vertical shift (‰) of the seasonal cycles. The symbol "\*" refers to a streamflow-weighted variable. The coefficients  $A_P$ ,  $\phi_P$ ,  $k_P$  can be obtained by fitting volume-weighted Eq. (S1) on precipitation isotopic composition  $e_P C_P(t)$  using iteratively re-weighted least squares (IRLS), a robust estimation method that minimizes the influence of outliers. By using the same technique, the coefficients  $A^{(*)}_{S_S}$ ,  $\phi^{(*)}_{S_S}$ ,  $k^{(*)}_{S_S}$  can be obtained by fitting (unweighted or flow-weighted) Eq. (S2) on streamwater isotopic composition  $e_S C_S(t)$ . The amplitude ratio  $A^{(*)}_{S_S}/A_P$  can be used to estimate the time-weighted or flow-weighted average fraction ( $F_{yw}$  or  $F^*_{yw}$ ) of water younger than a threshold age ( $\tau_{yw}$ ). For a wide range of transit time distributions,  $\tau_{yw}$  is approximately 2.3  $\pm$  0.8 months (Kirchner, 2016a).

In order to understand the statistical sensitivity of  $F^*_{yw}$  to Q, Gallart et al. (2020b) assume an exponential-type  $F^*_{yw}(Q)$  relationship that converges toward 1 (i.e. streamflow is composed entirely of young water) at the highest flows, as reported in Eq. (S3):

<sup>&</sup>lt;sup>1</sup>Interuniversity Department of Regional and Urban Studies and Planning (DIST), Politecnico and Università degli Studi di Torino, 10125, Torino, Italy

<sup>&</sup>lt;sup>2</sup>School of Architecture, Civil and Environmental Engineering, EPFL, 1015, Lausanne, Switzerland

<sup>&</sup>lt;sup>3</sup>Mountain Hydrology and Mass Movements, Swiss Federal Institute for Forest, Snow and Landscape Research (WSL), 8903, Birmensdorf, Switzerland

$$A_S^*(Q) = A_P F_{yw}^*(Q) = A_P [1 - (1 - F_0^*) \exp(-Q S_d^*)],$$
(S3)

By inserting Eq. (S3) into Eq. (S2) yields:

$$c_S(Q,t) = A_P[1 - (1 - F_0^*) \exp(-Q S_d^*)] \sin(2\pi f t - \varphi_S^*) + k_S^*,$$
(S4)

Where  $S_d^*(Q^{-l})$  is called the discharge sensitivity of the young water fraction and  $F_0^*$  (-) is the virtual young water fraction for Q = 0. Such parameters can be estimated by fitting flow-weighted Eq. (S4) on streamwater isotopic composition  $e_S C_S(t)$  using IRLS method.

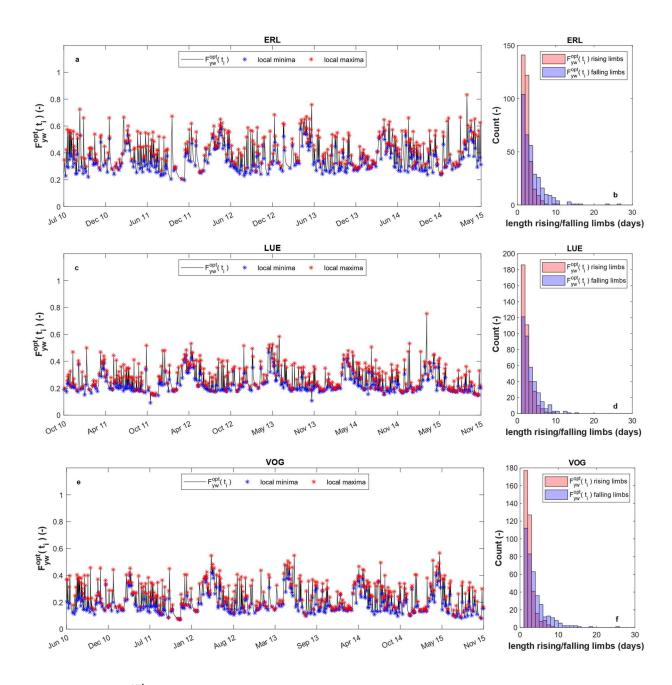

Figure S1. Daily  $F_{yw}^{opt}$  timeseries of the three-study catchment with indication of local maxima/minima (panels a,c,e) and distribution of  $F_{yw}^{opt}$  rising/falling limbs length (panels b,d,f). These distributions indicate that  $F_{yw}^{opt}$  rapidly increases after an event, while it recedes slower during no-input days.
