14 **Abstract.** Winter persistent aerosol pollution frequently occurs in the Sichuan Basin (SCB) due to its  
15 unfavorable weather conditions, such as low wind, wetness, and cloudiness. Based on long-term  
16 observational data analyses from 2015–2021, it [has been](#) found that the four representative stations in  
17 the SCB often simultaneously experience PM<sub>2.5</sub> pollution accompanied by variations in meteorological  
18 conditions above 850 hPa, which indicates a connection between regional winter air pollution in the  
19 SCB and large-scale synoptic patterns. The dominant 850 hPa synoptic patterns of winter SCB were  
20 classified into six patterns using T-model principal component analysis: [\(1\) strong high pressure in the](#)  
21 [north, \(2\) east high west low \(EHWL\) pressure, \(3\) weak high pressure in the north, \(4\) weak ridge of](#)  
22 [high pressure after the trough, \(5\) low trough \(LT\), and \(6\) strong high pressure.](#) Pattern 2  
23 [characterized with](#) EHWL pressure system, and Pattern 5 [featured with](#) LT, were identified as key  
24 synoptic patterns for the beginning and accumulation of pollution processes. Pattern 1, characterized by  
25 a strong high pressure in the north, was the cleanest pattern associated with reduced PM<sub>2.5</sub>  
26 concentrations. The EHWL and LT patterns were associated with a remarkably high cloud liquid  
27 content, attributed to upper southerly winds [introducing](#) humid air. Clouds reduce solar radiation  
28 through reflection and scattering, resulting in more stable stratification and aerosol accumulation. This  
29 cloud radiation interaction (CRI) [was](#) more pronounced in the LT pattern due to denser isobaric lines  
30 and stronger southerly winds than in the EHWL pattern. [Numerical simulation experiments utilizing](#)  
31 [WRF-Chem indicated that there is a upper-level heating during afternoon and surface cooling in the](#)  
32 [morning forced by the aerosol radiation interaction \(ARI\) under the EHWL and LT patterns.](#)  
33 [Additionally, strong surface cooling in the evening influenced by valley winds could be found.](#) With  
34 wet and cloudy synoptic forcing, ARI directly affects the stability of the boundary layer and is  
35 modulated through CRI inhibition. For example, Chongqing [exhibited](#) lower PM<sub>2.5</sub> concentrations and  
36 stronger ARI [compared to the](#) western and southern SCB due to [lower](#) cloud liquid content and weaker  
37 CRI inhibition on ARI. The CRI inhibition caused a 50 % reduction in solar radiation and boundary  
38 layer height during the daytime under the LT pattern, which was larger than that under the EHWL

39 pattern. This study comprehensively analyzed the [spatial disparities in](#) cloud inhibition on ARIs, their  
40 impacts on the boundary layer structure, [and the discrepancies of these interactions](#) under [different](#)  
41 synoptic [patterns](#) during pollution processes. [The findings hold important implications for effective](#)  
42 [management of pollution processes in cloudy and foggy weather](#) .

43 Key words: Synoptic patterns, [Cloud radiation interaction inhibition](#), [Aerosol radiation interaction](#),  
44 [Boundary layer structure](#), Sichuan Basin.

## 45 **1 Introduction**

46 Particulate matter (PM) pollution has become a significant environmental concern in China (Xie  
47 et al., 2016a; 2016b; Che et al., 2019). High concentrations of aerosols [not only](#) worsen air quality  
48 and [pose serious health risks to](#) residents, [but also have implications for](#) weather and climate  
49 through their effects on radiation and clouds (Li et al., 2019; Zhao et al., 2020; Alexeeff et al.,  
50 2021; Yang et al., 2021). The interactions between aerosols and clouds present the largest  
51 uncertainty in anthropogenic radiative forcing of the Earth's climate (Liao et al., 2017; Haywood  
52 et al., 2021). [Studying interactions among cloud, aerosol and radiation from an air quality perspective](#)  
53 [is crucial for a scientific understanding of relationship between weather and pollution](#).

54 [Excessive emissions are the essential cause of air pollution, with primary aerosol and secondary](#)  
55 [aerosol formation playing significant roles in comprehending the complete picture of air pollution](#)  
56 [\(Peng et al., 2021\)](#). [Besides, meteorological conditions not only influence on the formation of](#)  
57 [secondary aerosols, but also govern the transportation and distribution of both primary and](#)  
58 [secondary aerosols, and thereby impact regional and long-range air pollution](#) (Zhu et al., 2018;  
59 Luo et al., 2018; Nichol et al., 2020; Zhang et al., 2020; Jiang et al., 2021). PM and gaseous  
60 pollutants, [primarily transported](#) by the planetary boundary layer (PBL), are directly or indirectly  
61 influenced by [various](#) meteorological factors [such as](#) wind, relative humidity, PBL height ([PBLH](#)),  
62 and solar radiation. [These](#) factors contribute to the multi-temporal and spatial distribution  
63 characteristics through vertical and horizontal diffusion, physicochemical reactions, and dry and  
64 wet deposition (Park et al., 2017; Shu et al., 2017; Zhan et al., 2019; Huang et al., 2019). Large-  
65 scale synoptic forcing is considered the primary driving condition for meteorological factors, PBL  
66 structure, and the resulting distribution of atmospheric pollutants (Miao et al., 2019; Ning et al.,  
67 2019; Jiang et al., 2020; Li et al., 2021). Specific synoptic patterns can induce advection, which  
68 largely determines the local PBL structure and development. PBL, located at the bottom of the  
69 atmosphere, is responsible for the main exchange of heat, moisture, and matter between the surface  
70 and the free troposphere (Stull, 1988). The fate of pollutants emitted near the surface, a significant  
71 source of aerosols in the air, is largely controlled by the PBL (Garratt, 1994). The [PBLH](#) is often  
72 used [as a metric](#) to characterize the capacity and dilution of pollutants (Seidel et al., 2010).  
73 Synoptic patterns can directly determine the meteorological conditions of emitted pollutants and  
74 influence their transport by regulating PBL thermal stratification and mechanical turbulence (Stull,  
75 1988; Ning et al., 2018; Zhan et al., 2019; Jiang et al., 2021; Zhang et al., 2022).

76 Unfavorable meteorological conditions [play a significant role in](#) contributing to aerosol pollution.  
77 When pollutants accumulate to a certain degree, aerosols [can](#) reduce surface solar radiation  
78 [through](#) backscattering or absorbing solar radiation, leading to surface cooling. This decrease in  
79 solar radiation and temperature near the ground weakens turbulent diffusion, suppresses the  
80 convective development of the PBL, and lowers [PBLH](#), which in turn exacerbates aerosol pollution  
81 (Ding et al., 2016; Wang et al., 2018). Moreover, the increase in humidity caused by the decreased  
82 surface saturation vapor pressure and inhibited water vapor diffusion enhances aerosol  
83 hygroscopic growth accelerates liquid-phase and heterogeneous reactions, and contributes to  
84 aerosol pollution (Pilinis et al., 1989). The positive feedback between unfavorable PBL  
85 meteorology and increasing aerosols [was found to be responsible for](#) the majority of the increase  
86 in PM<sub>2.5</sub> during cumulative stages [in various regions of eastern China affected by aerosol pollution,](#)  
87 [including the North China Plain, the Guanzhong Plain, the Yangtze River Delta, the Two Lakes](#)  
88 [Basin, the Pearl River Delta and the Northeast China Plain. But in the Sichuan Basin \(SCB\), the](#)  
89 [feedback is weak due to the suppression of the cloudy mid-upper layer \(Zhong et al., 2018; Zhong](#)  
90 [et al., 2019\).](#) As for the aerosol-cloud interactions, arise from increasing aerosols acting as cloud  
91 condensation nuclei in cloud and translating into larger concentrations of smaller cloud droplets,  
92 leading to an increased cloud albedo reflecting more radiation back to space (Twomey, 1977;  
93 Lohmann and Feichter, 2005). Even a marginal increase in cloud droplets above pristine conditions  
94 in deep convective clouds causes more droplets to reach supercooled levels, which enhances latent  
95 heat release and invigorates convection (Rosenfeld et al., 2009; Possner et al., 2015). Further  
96 increases in cloud droplets result in direct radiative effects, reducing downward solar radiation,  
97 cooling the surface, and inhibiting convection (Scott et al., 2016).

98 The SCB is surrounded by high mountains with cloudy and wet weather conditions. The mean  
99 annual relative humidity [in the SCB is around 75%, with](#) cloud [fraction exceeding 80%](#), and [an](#)  
100 [average of 1200 hours of](#) sunshine [per year](#). The Chengdu–Chongqing city cluster in the SCB  
101 serves as the economic center of the upper reaches of the Yangtze River in China, accounting for  
102 approximately 10 % of the [country's](#) population. [However, rapid](#) industrialization and urbanization  
103 in this region have resulted in severe air pollution. [The SCB is recognized as](#) one of the most  
104 polluted regions in China, with high black carbon concentrations (Li et al., 2016; Cao et al., 2021).  
105 The Qinghai–Tibet Plateau on the western edge of the SCB significantly influences the transport  
106 and accumulation of pollutants through thermal and dynamic effects (Ning et al., 2017; Shu et al.,  
107 2021). In addition, the Qinghai–Tibet topography leads to higher cloud water content over the SCB  
108 than the other regions (Yu et al., 2004; Yang et al., 2012). [Many studies have emphasized the](#)  
109 [importance of the interactions between cloud, aerosols and radiation in air pollution processes \(Wang et](#)  
110 [al., 2018; Hu et al., 2021\).](#) [High pollutant emissions, combined with the prevalence of cloudy and](#)  
111 [foggy weather, make these interactions in the SCB even more complex than those in other regions. The](#)  
112 [aerosol radiation interactions \(ARI\) can be inhibited by cloud in cities like Chengdu \(Zhong et al.,](#)  
113 [2019\).](#) [However, there is a lack of in-depth quantitative discussions regarding this aspects in the SCB.](#)  
114 [On one hand, the complex terrain in the SCB leads to differences in the meteorological conditions](#)

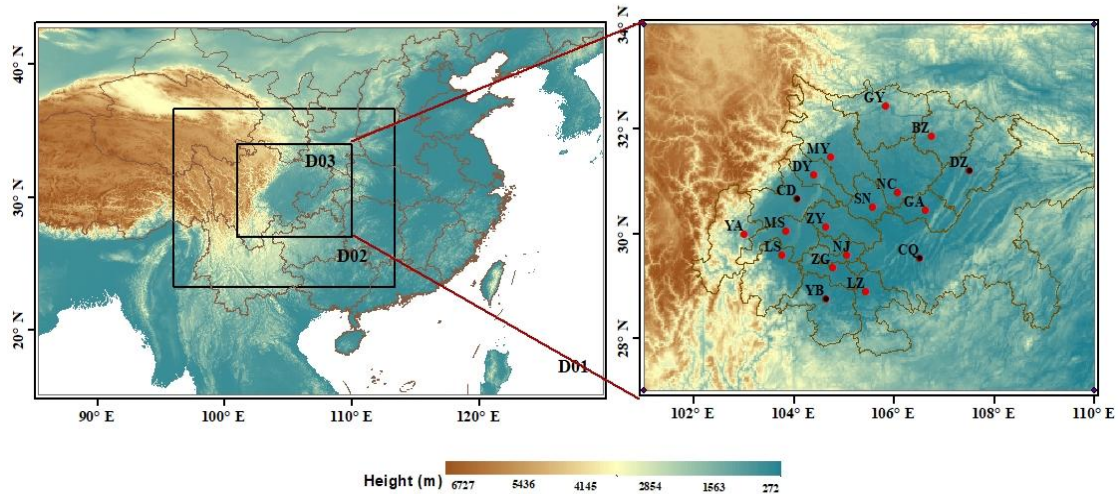

115 [between them \(Ning et al., 2017; Lu et al., 2022\)](#). For example, Chengdu is a typical basin city while  
116 [Chongqing is a mountain city located on the basin slope, so they have markedly different climate](#)  
117 [conditions. It remains to be elucidated whether these conditions will result in spatial disparities in cloud](#)  
118 [inhibition on the ARI. On the other hand, synoptic forcing, as the primary driver of meteorological](#)  
119 [variations, undoubtedly play an unneglectable role in shaping cloud cover and boundary layer](#)  
120 [structures \(Miao et al., 2020; Wang et al., 2022; Painemal et al., 2023\)](#). The discrepancies in cloud  
121 [inhibition on ARI under different synoptic patterns also need to be revealed. Addressing these issues is](#)  
122 [crucial for understanding the persistent pollution processes and the intricate interactions between](#)  
123 [weather and pollution in the SCB. It holds important implications for the effective management of](#)  
124 [pollution processes in cloudy and foggy weather.](#)

125 [Characterized with high aerosol loadings and semi-permanent cloudy weather, the SCB](#)  
126 [provides an ideal region for studying the complex interactions between clouds, aerosols, and the](#)  
127 [PBL. This study objectively classifies the synoptic patterns influencing the SCB based on long-](#)  
128 [term data. By conducting an integrated analysis of pollutants and meteorological factors, the](#)  
129 [primary pollution sources and clean synoptic patterns are identified. To further investigate the](#)  
130 [inhibition of cloud radiation interaction \(CRI\) on ARI under different synoptic patterns in the SCB,](#)  
131 [WRF-CHEM simulation experiments are conducted. The results contribute to a deeper](#)  
132 [understanding of CRI, ARI, and the PBL interactions in regions influenced by plateau-basin](#)  
133 [topography with wet and cloudy weather. The data and methods are presented in Section 2,](#)  
134 [whereas Section 3 describes the synoptic patterns and their corresponding impacts on clouds,](#)  
135 [aerosols, radiation, and PBL. Finally, the conclusions are presented in Section 5.](#)

## 136 **2 Data and method**

### 137 **2.1 Observation data**

138 Air quality monitoring data [used in this study](#) were obtained from air quality monitoring sites  
139 established by the Ministry of Ecology and Environment of China across the SCB. Hourly PM<sub>2.5</sub>  
140 observations from 18 stations in the SCB were collected during the winter period from 2015 to 2021  
141 for data analysis and model verification [purposes](#) (Fig. 1b). [The abbreviations](#) CQ, CD, MY, DY,  
142 LS, MS, YA, ZY, ZG, YB, LZ, NJ, GA, NC, SN, GY, DZ, and BZ represent [the following cities](#):  
143 Chongqing, Chengdu, Mianyang, Deyang, Leshan, Meishan, Yaan, Ziyang, Zigong, Yibin,  
144 Luzhou, Neijiang, Guangan, Nanchong, Suining, Guangyuan, Dazhou, and Bazhong, respectively.

**Figure 1.** (a) Three layers of simulation domains in WRF-Chem with topography map as shading; (b) the locations of 18 air quality monitoring stations (red dots) and 4 sounding stations (black dots) in the Domain 3.

145

146 The SCB has four sounding stations: Wenjiang (CD), YB, DZ, and Shapingba (CQ), situated in  
 147 the western, southern, northwestern, and eastern regions of the basin, respectively (Fig. 1b), and  
 148 represent different pollution and meteorological conditions in different regions within the SCB. In  
 149 all, the air pollution over the SCB exhibits a gradual decrease from southwest to northeast.  
 150 Statistical analysis indicates that the western and the southern basin experience the most severe  
 151 pollution. The western basin shows the highest pollution proportion, while the southern basin  
 152 exhibits the highest occurrence of heavy pollution. In the northeastern basin, specifically in DZ,  
 153 heavy pollution is more likely to occur during winter, which verifies it to be the third highest  
 154 pollution zone outside the western and southern basin. This makes the spatial distribution during  
 155 winter differs from the overall annual pollution pattern in the SCB (Lu et al., 2022; Qi et al., 2022).  
 156 Regarding meteorological conditions, research reveals that DZ has the lowest ventilation  
 157 coefficient during winter, while CQ has the highest. The SCB experiences frequent temperature  
 158 inversions, with CD having a higher occurrence of inversions compared to the other three cities.  
 159 CD also exhibits the strongest inversion intensity and is prone to multi-layer inversions. On the  
 160 other hand, YB and CQ have greater inversion thickness, while CD has the smallest inversion  
 161 thickness (Feng et al., 2020). The vertical distribution of the meteorological factors used in the  
 162 study was obtained from an L-band sounding radar, collecting temperature, pressure, humidity,  
 163 and wind data at 00:00 and 12:00 Coordinated Universal Time (UTC) on vertical levels every  
 164 second from the surface up to 30 km. Ground observation data from the four cities, including  
 165 temperature and dew point temperature, were used for meteorological factor simulation verification.  
 166 All meteorological data were obtained from the China Weather Website Platform maintained by  
 167 the China Meteorological Bureau. As for the calculation of PBLH, there are various methods to  
 168 determine the PBLH, and differences in methods, data or threshold values may yield quite  
 169 different PBLH results (Seibert et al., 2000; Eresmaa et al., 2006; Jiang et al., 2021). The bulk

170 [Richardson number \( \$Ri\$ \) method was adopted to calculate the PBLH with sounding data in](#)  
171 [the study by assuming that the PBLH is the height at which  \$Ri\$  reaches its critical value \( \$R\_c\$ \).](#)  
172  [\$Ri\$  at a certain height  \$h\$  is calculated as follows:](#)

$$173 \quad Ri = \frac{(g / \theta_{v0})(\theta_{vh} - \theta_{v0})h}{u_h^2 + v_h^2}$$

174 [Where  \$g\$  is the acceleration of gravity,  \$\theta\_{v0}\$  and  \$\theta\_{vh}\$  are the virtual potential temperature at surface](#)  
175 [and the height  \$h\$ , respectively, and  \$u\_h\$  and  \$v\_h\$  are the meridional and zonal wind components at  \$h\$ .](#)  
176 [We adopted the  \$Ri\$  method and  \$R\_c\$  to be 0.25, because the EAR5 and YSU schemes use the same](#)  
177 [method and threshold value when calculating PBLH \(Hong et al., 2006; ECMWF, 2017\).](#)

178 ERA5 reanalysis data from the ECMWF, which assimilates comprehensive observation data,  
179 including ground observation, sounding data, aircraft observation data, and satellite observation  
180 data, were obtained for synoptic pattern classification and their impact on meteorological factors  
181 in four representative cities. The EAR5 data at the 850 hPa pressure level were collected for the  
182 synoptic pattern study. Additionally, cloud liquid water content [and](#) downward solar radiation  
183 derived from the EAR5 single-level datasets were obtained to assess the influences of synoptic  
184 forcing on CRI studies, while PBLH were adopted to conduct the simulation verification. [Previous](#)  
185 [studies have demonstrated the reliability of ERA5 data in estimating cloud properties, including](#)  
186 [the cloud liquid content \(Yao et al., 2019; Nandan et al., 2022; Ojo et al., 2023\).](#)

## 187 **2.2 Synoptic pattern classification**

188 The objective classification was conducted on the synoptic patterns of the SCB using ERA5 data,  
189 including geopotential height,  $u$ , and  $v$  components of winds at the 850 hPa pressure level. The  
190 analysis covered an area of 97–117° E and 24–37° N with a horizontal resolution of  $0.25^\circ \times 0.25^\circ$ .  
191 [Given that](#) PM pollution in the SCB [is](#) primarily [prevalent during](#) winter [months](#) (Zhao et al., 2018;  
192 [Lu et al., 2022](#)), the synoptic pattern classification was performed for winter [seasons from](#) 2015 [to](#)  
193 2021 (December, January, and February) using the principal component analysis in the T-model  
194 (T-PCA) objective method. Compared with the subjective classification method, the objective  
195 method can process large amounts of data without relying on subjective experience (Huth et al.,  
196 2008; Miao et al., 2017). Among various classification methods, the T-PCA method accurately  
197 reflects the characteristics of the original synoptic circulations and exhibits spatial and temporal  
198 stability (Huth et al., 1996; Huth et al., 2008). Consequently, the T-PCA has been widely used in  
199 synoptic pattern classification [researches](#) (Ning et al., 2019; Miao et al., 2020; Li et al., 2021).

## 200 **2.3 Model configuration and simulation experiments**

201 To understand the combined effects of synoptic patterns and CRI inhibition on ARI and PBL, a  
202 series of parallel experiments were conducted on the simulation of a typical pollution episode  
203 using the Weather Research and Forecasting model with Chemistry (WRF-Chem v3.9.1) (Grell et  
204 al., 2005). [The Advanced Research WRF \(ARW\) dynamics solver integrates the compressible,](#)

205 [nonhydrostatic Euler equations, for example, the momentum equation, the continuity equation, the](#)  
 206 [thermodynamic equation, the moisture equation and the ideal-gas equation of state \(Skamarock et](#)  
 207 [al., 2008\)](#). The model domain (Fig. 1a) was centered over the SCB and utilized three layers of  
 208 nested grids with horizontal resolutions of 27, 9, and 3 km, [respectively](#). [A total of 32 vertical](#)  
 209 [layers spanning from the surface to 100 hPa were defined](#). Initial [and boundary](#) meteorological fields  
 210 were obtained from the National Centers for Environmental Prediction Final reanalysis data with a  
 211 horizontal resolution of  $1^\circ \times 1^\circ$  and 6 h time interval. For chemical process simulations,  
 212 anthropogenic emissions were sourced from the Multiresolution Emission Inventory for China  
 213 (MEIC) in 2016, featuring a grid resolution of  $0.25^\circ \times 0.25^\circ$ . [To address the empirically](#)  
 214 [overestimated PM<sub>2.5</sub> emissions by the MEIC in the SCB \(Zhan et al., 2023\), the ensemble square](#)  
 215 [root Kalman filter were implemented on the PM<sub>2.5</sub> emission during simulation \(Wu et al., 2018;](#)  
 216 [Lu et al., 2021\)](#). Biogenic emissions were calculated online using the Guenther scheme (Guenther  
 217 et al., 2006). Table 1 provides a summary of the chosen physical and chemical parameterization  
 218 schemes. [The parameterization schemes employed in this study is the one used by the Chongqing](#)  
 219 [Meteorological Bureau in the daily operational activities. The schemes have been obtained](#)  
 220 [through multiple sets of control experiments and are considered suitable for the simulation in the](#)  
 221 [SCB](#).

223

224 To assess the impact of CRI inhibition on ARI and ARI under typical synoptic pollution patterns,  
 225 four parallel experiments were conducted [using simulation models](#). The selected simulation period

226 [for these experiments was](#) January 1-7, 2017. [The period was selected for several reasons: it is](#)  
 227 [close to the time of MEIC emission inventory used,](#) the Chinese government [had](#) announced [the](#)  
 228 [clean air action with 2017 as a key year for reducing](#) PM<sub>2.5</sub> pollution (Wang et al., 2020) [and the](#)  
 229 [selected period encompassed](#) both typical pollution and clean weather patterns.

230 The baseline experiment (BASE) [included](#) both CRI and ARI [in the simulations. In contrast,](#) the  
 231 three sensitivity experiments [focused on excluding either](#) ARI or CRI. Experiment 1 (EXP1) did not  
 232 [consider](#) ARI, Experiment 2 (EXP2) did not [include](#) CRI, and Experiment 3 (EXP3) [omitted](#) ARI  
 233 when CRI was not [included](#). The differences between BASE and EXP1 represented the  
 234 disturbances caused by ARI, while EXP2 and EXP3 represented the influences of ARI without  
 235 CRI inhibition. [Detail differences between the experiments could be found in Table 2.](#) The  
 236 numerical experiments [were initiated at](#) 00:00 UTC on December 30, 2016, [and ran until](#) 00:00  
 237 UTC on January 8, 2017, with the [first 48 hours designated as](#) a model spin-up [period](#).

## 240 **3 Results and discussions**

### 241 **3.1 Relationships between synoptic patterns and PM<sub>2.5</sub> pollution in the SCB**

242 Figure 2 illustrates the daily mean variations in PM<sub>2.5</sub> concentration and vertical distributions  
 243 of potential temperature (PT) during winter [period](#) from 2015 to 2021, [with a focus on](#) the pollution  
 244 episodes. The four sounding stations [located in separate areas of the](#) SCB (CD, YB, CQ, and DZ),  
 245 consistently experienced pollution processes [characterized by](#) simultaneous changes in vertical  
 246 thermal structures. For example, during the pollution events in January 2017 and December 2020,  
 247 [the](#) PM<sub>2.5</sub> concentrations in all four cities reached their [peak levels](#) at the same time before [rapid](#)  
 248 [declining](#) (Fig. 2). [Interestingly, these pollution episodes were accompanied by](#) warming [in the](#)  
 249 [upper layer atmosphere](#), while a decrease in PM<sub>2.5</sub> concentration correlated with cooling. Despite  
 250 the significant distances between these cities (approximately 200–400 km), the synchronized  
 251 changes in pollutant [concentrations](#) and vertical thermal structures [could](#) be attributed to large-  
 252 scale synoptic patterns (Miao et al., 2020; Li et al., 2021). While the four cities with sounding  
 253 stations were selected as representatives for vertical thermal structure analysis, other cities in the  
 254 SCB also experienced pollution episodes and relevant physical processes, [except for GY \(Fig. S1\).](#)  
 255 [GY is located in the northern edge of the SCB, bordering Shaanxi and Gansu Provinces. The proportion](#)

256 of heavy  $PM_{2.5}$  pollution in GY is the lowest in the basin, but the proportion of  $PM_{10}$  pollution is higher  
 257 than other cities of SCB (Lu et al., 2022). Due to the lower  $PM_{2.5}$  concentration, the two pollution  
 258 processes in January 2017 in GY were not as significant as in other cities within the basin. However,  
 259 the warming of upper air coincided with  $PM_{2.5}$  increase could still be observed.

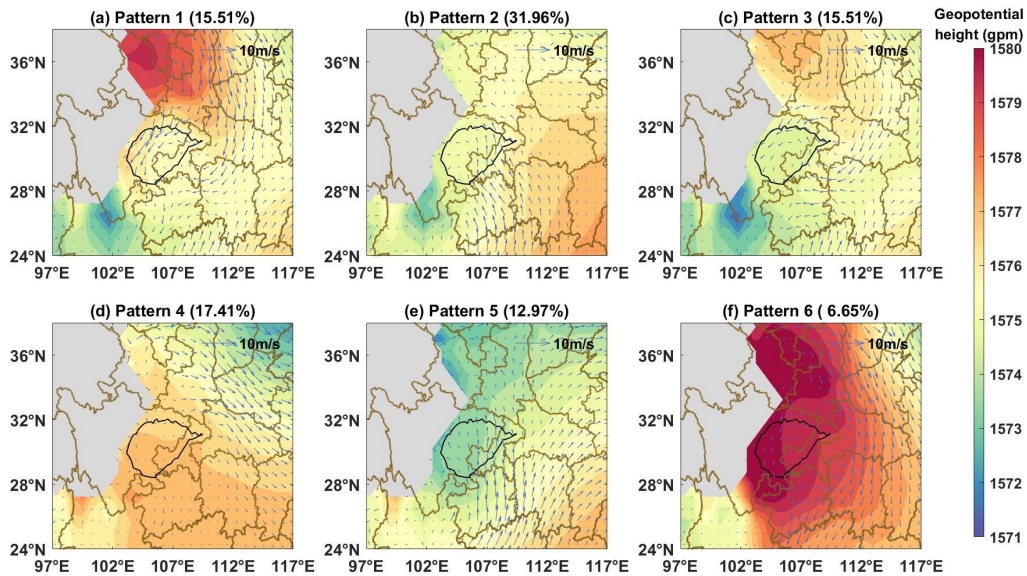

**Figure 2.** Time series of daily mean  $PM_{2.5}$  and potential temperature derived from the sounding data during 2015-2021 winter months. The  $PM_{2.5}$  pollution episodes are marked with black dotted boxes.

260

261 The time series of daily mean  $PM_{2.5}$  from air quality monitoring sites and the accompanying  
 262 vertical distributions of temperature, relative humidity, and wind in CD, CQ, YB, and DZ derived from  
 263 the sounding stations are shown in Fig. S2, focusing on January 2017 as an example for analysis.  
 264 During this month, two severe  $PM_{2.5}$  pollution episodes occurred: one from January 1 to 7 and another  
 265 from January 24 to 31 in 2017. The highest daily  $PM_{2.5}$  concentrations recorded during these episodes  
 266 were  $291.17 \mu\text{g}/\text{m}^3$  in CD and  $276.21 \mu\text{g}/\text{m}^3$  in YB, influencing all four cities. Pollution in early January  
 267 exhibited a gradual increase in  $PM_{2.5}$  levels from January 1 to 3, with upper air warming and the  
 268 emergence of an inversion above the PBL. Additionally, lower humidity and higher wind speeds above  
 269 1500 m were observed during the pollution accumulation period. Similarly, the late January pollution  
 270 episode showed a rapid increase in  $PM_{2.5}$ , from January 24 to 27, together with warming, dryness, and  
 271 high wind speed above 1500 m in all four cities. These consistent meteorological conditions during the  
 272 pollution periods indicated significant synoptic forcing. The previous study has found that winter heavy  
 273 pollution processes in the SCB are usually associated with abnormal warming above the 850 hPa (Lu et  
 274 al., 2022). The warming is induced by strong southerly airflow above the basin. The southerly airflow  
 275 in winter over the SCB originates from the Yunnan-Guizhou Plateau or the Indian Peninsula,  
 276 characterized with high temperature, dryness, and high wind speed. The strong southerly airflow forms  
 277 a warm lid over the basin, suppressing the vertical exchange of pollutants within the basin. As a result,  
 278 pollutants accumulate rapidly, which may explain the phenomenon of rapid  $PM_{2.5}$  growth accompanied  
 279 by warming, dryness, and strong winds above 1500 m. Notably, the key layer for studying the  
 280 connection between synoptic patterns and  $PM_{2.5}$  pollution is approximately 850 hPa, corresponding to a

281 height of approximately 1500 m within the PBL, where changes in specific meteorological conditions  
282 primarily affect surface-emitted pollutants.

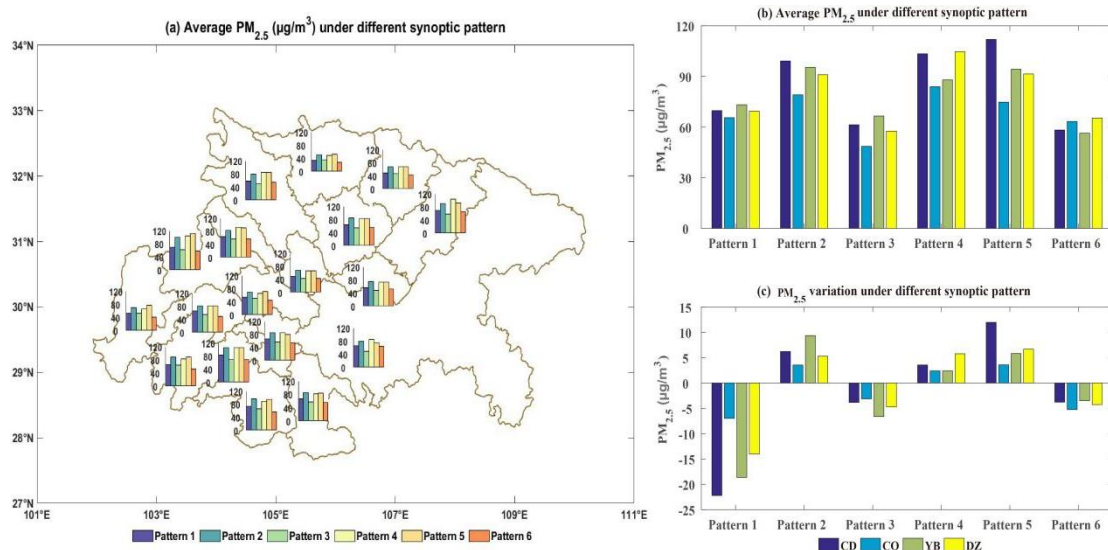

283 Using ERA5 reanalysis data for winter (December, January, and February) from 2015 to 2021,  
284 the 850 hPa synoptic patterns over the SCB were objectively classified into six types (Fig. 3).  
285 According to the relative positions of the high-pressure and low-pressure systems in the basin,  
286 these synoptic patterns could be described as follows: (1) strong high pressure in the north, (2) east  
287 high west low (EHWL) pressure, (3) weak high pressure in the north, (4) weak ridge of high  
288 pressure after the trough, (5) low trough (LT), and (6) strong high pressure. Patterns 1 and 3  
289 exhibited high pressure in the northern SCB, which differed from the high-pressure intensity. With  
290 strong high pressure, the basin was primarily controlled by northerly airflow. Under weak high-  
291 pressure conditions, the basin was dominated by an easterly backflow. Patterns 2 and 5 had high  
292 and low pressures near the basin, forming a relatively dense isopotential altitude gradient and  
293 resulting in strong southerly winds over 850 hPa. Pattern 4 was a weak high-pressure ridge after a  
294 trough controlled the SCB with sparse isobaric lines and weak winds leading to static and stable  
295 weather conditions. During Pattern 6, the SCB was controlled by the cold high-pressure system,  
296 accompanying weak northerly airflow on the basin. Pattern 6 usually evolved from either Pattern 1  
297 or Pattern 3.

298 **Figure 3.** The 850hPa geopotential height field (shading) with wind vector fields (blue  
299 vectors), and frequency of occurrence for 6 synoptic patterns during 2015-2021 winter months.  
300 The SCB was outlined with an altitude contour of 750 m terrain height (black lines).

301 Patterns 2, 4, and 5 exhibited higher frequencies of pollution occurrence ( $PM_{2.5}$  daily  
302 concentration  $\geq 75 \mu g/m^3$ ) according to statistical results from 18 cities in the SCB during the  
303 2015–2021 winters (Fig. 4a). These patterns were associated with high  $PM_{2.5}$  concentrations in 50–  
304 70 % days, including CD, DY, and MY in the northern SCB, 40–60 % for cities in the southern  
305 SCB, such as ZG and YB, and also 40–60 % of days for cities in the northern SCB, such as CQ, DZ,  
306 NC, and GA. Furthermore, the average  $PM_{2.5}$  concentrations in the respective cities for the six

305 synoptic patterns were calculated (Fig. 4b), aligning with the frequency of pollution occurrence.  
 306 The days under Patterns 2, 4, and 5 exhibited higher average daily PM<sub>2.5</sub> concentrations. The average  
 307 concentrations under these three synoptic patterns were 99.19, 103.43, and 111.97 μg/m<sup>3</sup> for CD,  
 308 95.44, 87.98, and 94.26 μg/m<sup>3</sup> for YB, 79.14, 83.96, and 74.771 μg/m<sup>3</sup> for CQ, and 91.02, 104.64,  
 309 and 91.51 μg/m<sup>3</sup> for DZ, respectively. Regarding the impact of synoptic patterns on the  
 310 accumulation or dispersion of PM<sub>2.5</sub>, Fig. 4c illustrates the average daily changes in PM<sub>2.5</sub>  
 311 concentration compared with the previous day for CD, CQ, YB, and DZ under the six synoptic  
 312 patterns. Patterns 2 and 5 exhibited the most significant PM<sub>2.5</sub> accumulation under the influence of  
 313 southerly airflow. The average PM<sub>2.5</sub> concentration under Pattern 1, 3 and 6 was lower in all cities  
 314 of SCB than other three pollution patterns (Fig. 4a). Besides, the day to day PM<sub>2.5</sub> variations under  
 315 Pattern 1, 3 and 6 exhibited negative growth trend in the four representative cities (Fig. 4c). As a  
 316 result, Pattern 1,3 and 6 were identified as the “clean pattern”. In addition, the pollution  
 317 occurrence frequency of which was found higher for cities located in the eastern part of the SCB  
 318 than other parts. Under Pattern 6, strongest northerly airflow affects the basin. The eastern part of  
 319 the basin consists of parallel ridges and valleys, which reduces wind speed. The stronger the wind  
 320 is, the more obvious the reduction of wind by terrain is. In contrast, the western part is relatively  
 321 flat, which can result in higher surface wind speeds. The difference in wind impacted by terrain  
 322 led to a weaker pollution removal effect in the eastern region, thus contributing to a higher  
 323 proportion of pollution days under Pattern 6. Besides, differences in precipitation rates between  
 324 eastern cities and other regions were not significant (the proportion of rainfall with a daily  
 325 accumulated precipitation exceeding 10 mm in CD, CQ, YB and DZ under Pattern 6 were all less than  
 326 3%) , which might not the main reason why eastern cities in the SCB experience higher pollution  
 327 frequency.

**Figure 4.** (a) The pollution occurrence frequency at 18 air pollution stations in SCB, (b) average PM<sub>2.5</sub> concentrations and PM<sub>2.5</sub> day to day variations at 4 representative SCB cities, under 6 synoptic patterns.

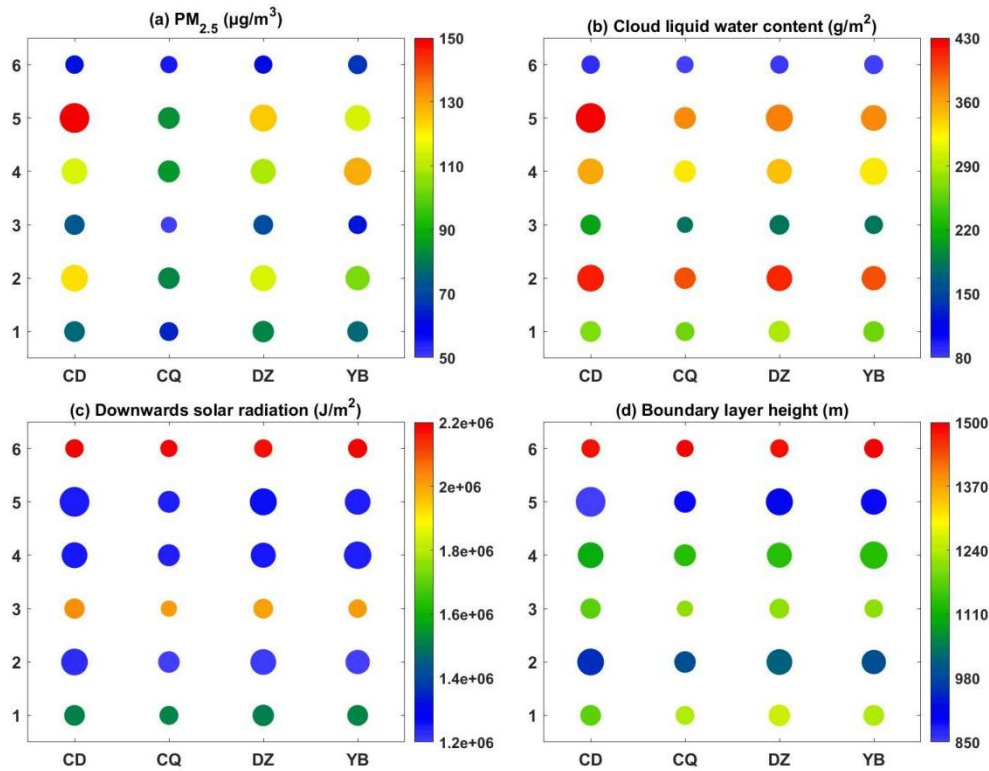

328

329 The time series of [daily mean](#) PM<sub>2.5</sub> and the day-to-day classification of 850 hPa synoptic  
330 patterns are shown in Fig. [S3](#), from December 2016 to January 2017. Six pollution episodes  
331 occurred during this period (December 03–12 and 16–26, 2016; January 1–7, 16–19, and 20–28,  
332 2017; and February 14–23). It is [observed](#) that pollution episodes consistently began with Pattern 2  
333 and ended with Pattern 1, accompanied by a rapid decline in PM<sub>2.5</sub>. [This finding](#) suggests that  
334 Pattern 2 [acted as a](#) key synoptic forcing for [the initiation of](#) pollution episodes. [Additionally,](#)  
335 [statistical results revealed](#) that Pattern 2 accounted for a high proportion of PM<sub>2.5</sub> increase [during](#) the  
336 six pollution episodes, reaching 48.48 %, while Pattern 5 had the second highest proportion of  
337 21.88 %, with Patterns 2 and 5 combined accounting for more than 70 % [of the pollution episodes](#).  
338 For example, during the two heavy pollution events in early and late January 2017, PM<sub>2.5</sub> rapidly  
339 accumulated with the interplay of Patterns 2 and 5. [These two patterns](#) represented a [substantial](#)  
340 proportion of 31.96 % and 12.97 %, respectively, during winters from 2015 to 2020 [at](#) 850 hPa  
341 [level](#) in the SCB ([Fig. 3](#)). Based on this analysis, Patterns 2, 4, and 5 were identified as synoptic  
342 pollution patterns, whereas Patterns 1, 3, and 6 were [as](#) clean patterns. [In summary,](#) Patterns 2 and  
343 5 [played](#) crucial roles in the initiation and accumulation of PM<sub>2.5</sub> during pollution episodes.

344 The discussion above showed that pollution in the SCB [tended to occur](#) when [southerly](#) airflow  
345 controlled the upper-layer of the basin (Pattern 2 and 5), while the dispersion of pollutants [was](#)  
346 accompanied by northerly winds, which [aligns](#) with [the findings of](#) Lu et al. (2022). Southerly  
347 airflow in the upper-layer [could](#) bring warm air, leading to warming above the basin and forming a  
348 “warm lid”. [The surrounding mountains and plateau with the “warm lid” contributed to the](#)  
349 [formation of](#) a relative enclosed space [within](#) the SCB, [facilitating](#) local circulations and allowing  
350 for the thorough mixing and secondary reactions of local emission and pollutants transported from  
351 outside. As a result, persistent and severe pollution often [occurred](#) under the influence of southerly  
352 airflow. When the northerly airflow [began](#) to dominate the SCB, the “warm lid” and local  
353 circulation [were](#) disrupted, leading to dispersion of pollutants through advection and vertical  
354 transport. [Northerly winds were](#) often associated with cold air and sometimes accompanied by  
355 weak precipitation, resulting to wet deposition [and the removal of pollutants](#). Therefore, the arrival  
356 of northerly airflow often signified the ending of the pollution episode.

357 [Due to](#) the convergence of air moving eastward across the Tibetan Plateau, the SCB experiences  
358 [frequent](#) wet and cloudy weather, with cloud cover fraction exceeding 80 % (Yu et al., 2004;  
359 Zhang and Lin, 1985). [Clouds undoubtedly play an unneglectable role](#) in the interactions of  
360 aerosols, radiation, and the PBL under typical synoptic forcing [in this region](#). This study evaluated  
361 the average cloud liquid water content, downward solar radiation, and PBL under the influence of  
362 the six classified synoptic patterns in CD, CQ, DZ, and YB, using data from ERA5 ([Fig. 5](#)). [The](#)  
363 [reanalysis data revealed significant higher cloud liquid water contents with Patterns 2 and 5, likely](#)  
364 [triggered by robust southerly air prevailing at 850 hPa over the SCB \(Fig. 3\).](#) This southerly air  
365 [brought](#) warm and moist air, contributing to cloud formation. Dense clouds [reduced](#) solar radiation  
366 through reflection and scattering, resulting in surface cooling and inhibiting PBL development.  
367 The PBLH under Patterns 2 and 5 [was](#) approximately 900–1000 m, lower than that under the

368 influence of clean synoptic Pattern 6 at 1500 m [or Pattern 1 and 3 at 1200–1300 m](#) (Fig. 5). In  
 369 contrast, the clean synoptic Pattern 1 [was](#) characterized by a strong northerly flow at 850 hPa,  
 370 resulting in lower cloud liquid water content over the basin and increased solar radiation, promoting  
 371 PBL development. The lower PBLH with more stable stratification caused by the CRI in Patterns 2  
 372 and 5 [could](#) partially explain the rapid accumulation of PM<sub>2.5</sub> during these two pollution patterns.  
 373

[Figure 5.](#) The averaged (a) PM<sub>2.5</sub> concentrations, (b) cloud liquid water contents, (c) downwards solar radiation and (d) boundary layer height derived from 2015-2021 winter months ERA5 reanalysis data, at 4 representative SCB cities under 6 synoptic patterns, the dot sizes represent PM<sub>2.5</sub> concentrations.

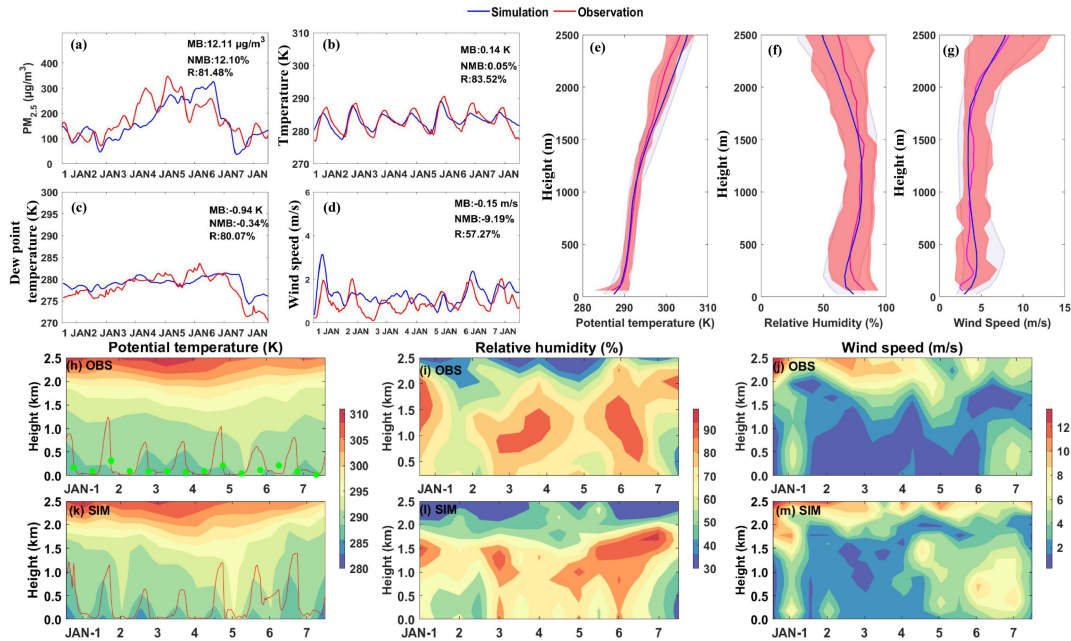

374

### 375 3.2 Integrate impacts of synoptic patterns and the CRI inhibition on ARI

376 Based on the above analysis, Patterns 2 and 5 were identified as the key pollution synoptic  
 377 patterns accompanying dense clouds and, thus, [strong](#) CRI. However, the effects of pollution  
 378 patterns on ARI and their interaction with CRI in the SCB remain unclear and warrant further  
 379 investigation. A typical pollution episode from January 1–7, 2017, was selected to understand these  
 380 complex processes and simulated using WRF–Chem. The BASE simulations were verified with  
 381 observations to determine the accuracy and reliability of the simulation results. The [simulation and](#)  
 382 [observation of PM<sub>2.5</sub>, T<sub>2</sub>, TD<sub>2</sub> and wind speed](#) values [with some statistical metrics in CD](#) from  
 383 January 1–7 are shown in Fig. [6a-d](#). [Similar information at CQ, YB and DZ can be found in the](#)  
 384 [Fig. S4](#). The MB of the simulated and observed PM<sub>2.5</sub> concentrations were -15.59, -13.42, 2.10

385 and  $-13.11 \mu\text{g}/\text{m}^3$ , with NMB values of  $-4.12\%$ ,  $-4.22\%$ ,  $6.01\%$  and  $-0.68\%$  at four cities,  
386 respectively, which are within the acceptable standards ( $\text{NMB} < \pm 15\%$ ). The R of  $\text{PM}_{2.5}$  were  
387  $78.91\%$ ,  $57.23\%$ ,  $61.15\%$  and  $62.86\%$  for four representative cities, respectively. The statistical  
388 metrics for  $\text{PM}_{2.5}$  are consistent with previous studies (Wang et al., 2020; Shu et al., 2021; Zhan et  
389 al., 2023), indicating that our model results for  $\text{PM}_{2.5}$  are reasonable and acceptable. Regarding to  
390 the surface meteorological factors, low MB and high R for both temperature and dew point  
391 temperature suggested good simulation performance for these variables. However, the simulation  
392 results for wind speed were poor, which was expected under conditions of low wind and complex  
393 terrain. The high observed calm wind frequency, influenced by the starting speed of the  
394 anemometer, led to an overestimation in the simulation (Shu et al., 2021; Zhan et al., 2023).  
395 Additionally, it could be argued that unresolved topographic features introduce additional drag,  
396 beyond that generated by vegetation, which was not considered in the WRF model (Jimenez and  
397 Dudhia, 2012).

398 In addition, the temporal averaged and variations of vertical profiles for potential temperature,  
399 relative humidity and wind speed in the model were compared with the sounding data in CD (Fig.  
400 6e-m). Model evaluation of vertical structures in CQ, YB and DZ can be found in Fig. S5. The  
401 SCB is characterized with cloudy and foggy conditions, which result in abundant water vapor and near  
402  $100\%$  relative humidity above the nocturnal boundary layer. Models often underestimate the humidity  
403 above the boundary layer during night in the SCB (Shu et al., 2021). Furthermore, due to complex  
404 terrain and measurement bias of the anemometer for weak winds, the evaluation of simulation results  
405 for wind speed often exhibit certain deviations (Jimenez and Dudhia, 2021; Shu et al., 2021; Zhan et al.,  
406 2023). For the verification of PBLH, sounding data are commonly regarded as reliable vertical  
407 observation records, and PBLH calculated based on sounding data can be used as the true values to  
408 compare with other data for long-term validation (Guo et al., 2016). However, for short-term studies,  
409 due to limited availability of sounding data at only 00:00 and 12:00 UTC, the ERA5 data were also  
410 incorporated for the model evaluation of PBLH in this study (Fig. 6 and Fig.S5). The simulation PBLH  
411 showed a consistent trend with those calculated from ERA5 and sounding data. Overall, the simulation  
412 results can capture the meteorological and  $\text{PM}_{2.5}$  variation trends. According to the simulation  
413 evaluation standards for the SCB in previous studies (Wang et al., 2020; Zhan et al., 2023), the results  
414 is acceptable and reasonable; thus, the simulation can be used for subsequent analysis and discussion.

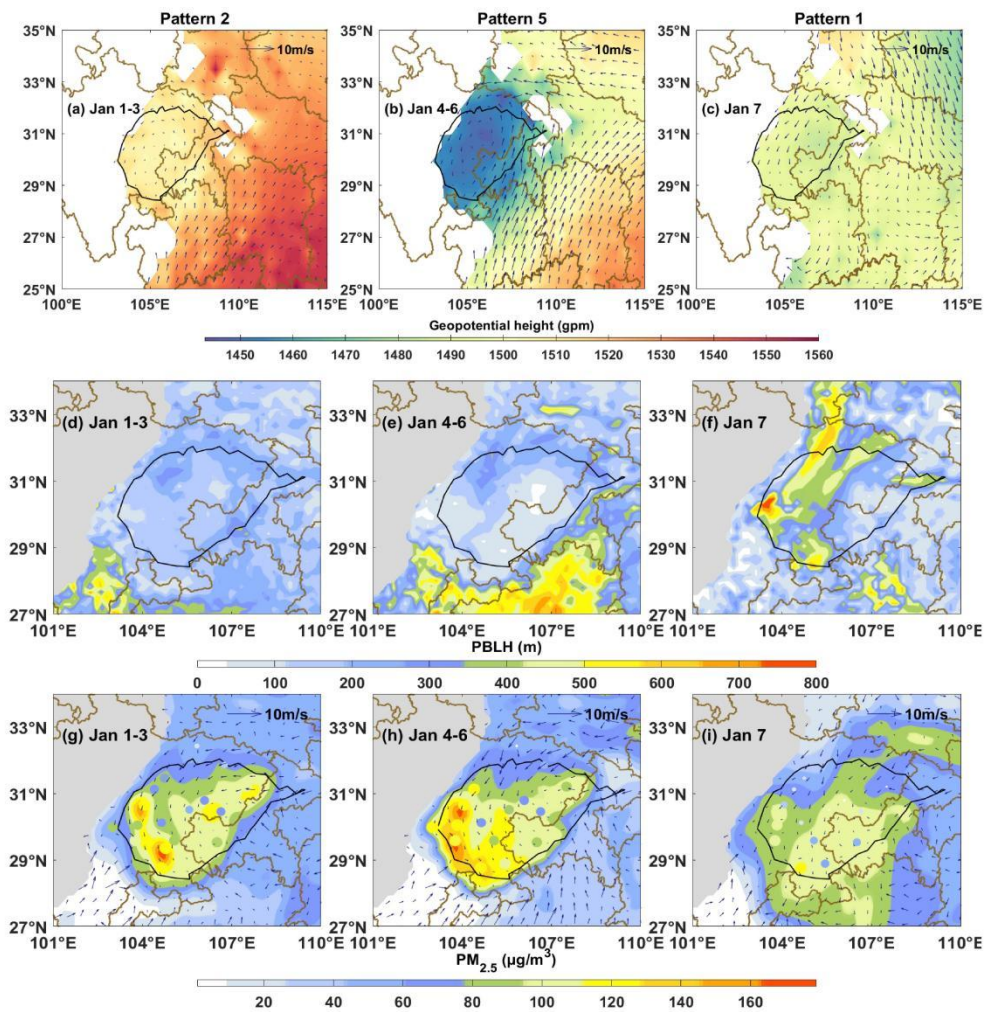

**Figure 6.** Time series of hourly simulated and observed (a)  $PM_{2.5}$  concentration, (b) temperature at 2 m, (c) dew temperature at 2m and (d) wind speed near surface, and comparison of simulated and observed mean vertical profile of (e) potential temperature, (f) relative humidity and (g) wind speed, the red and grey shaded areas represent deviations to the mean values of observation and simulation, respectively. The simulated and observed time-height sections of (h)(k) potential temperature, (i)(l) relative humidity and (j)(m) wind speed are also given, while the red lines in (h)(k) are time series the boundary layer heights derived from ERA5 data and simulation with green dots representing boundary layer heights calculated with sounding data. The above figures display information in CD. Additionally, the model verification information regarding CQ, YB and DZ can be found in Supplement Figure 3 and 4.

415

416 During the pollution episode that occurred from January 1 to 7, 2017, the pollution synoptic  
 417 patterns controlled the SCB as follows: Pattern 2 from January 1 to 3, Pattern 5 from January 4 to 6,  
 418 and Pattern 1 on January 7. Consequently,  $PM_{2.5}$  pollution in the SCB occurred on January 1–6 and  
 419 rapidly dissipated on January 7 (Fig. 7). The mean geopotential height at 850 hPa derived from the  
 420 simulation of January 1–3 under Pattern 2 showed EHWL, with southerly flow prevailing over the  
 421 SCB (Fig. 7a). The resulting upper air warming suppressed PBL development (Fig. 7d). During  
 422 January 1–3 under Pattern 2, the average PBL heights were lower (Fig. 7d), acting as a lid above the  
 423 SCB and hindering the airflow within the basin due to the surrounding mountains. Low wind  
 424 speeds provided adverse diffusion conditions for pollutants emitted into the basin, resulting in  
 425 severe pollution in the western and southern SCB (Fig. 7g). From January 4 to 6, the low pressure  
 426 over the SCB evolved into a LT pattern, termed Pattern 5 in the previous analysis. Compared with  
 427 Pattern 2, the isobaric lines were denser under the influence of the LT, leading to stronger southerly

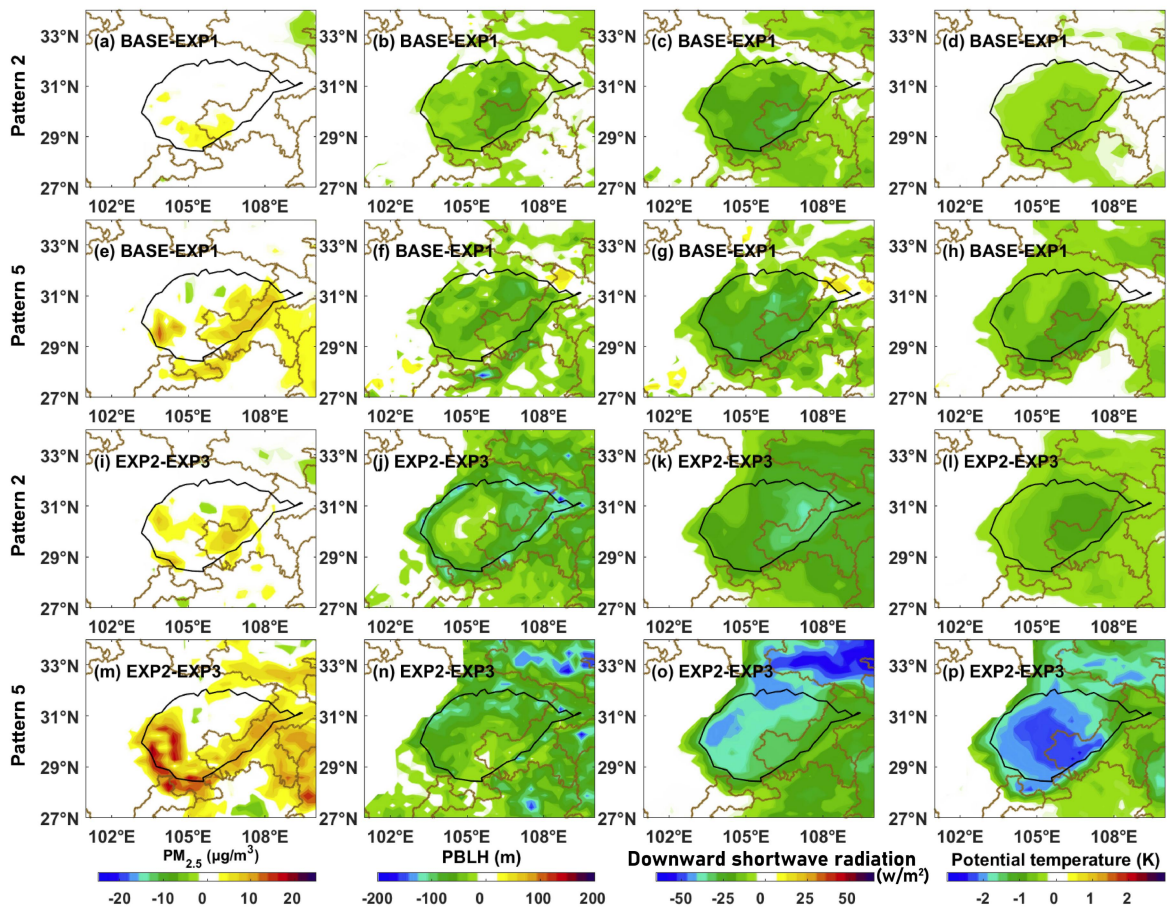

428 winds above the SCB (Fig. 7a–b). Lower average PBL heights were observed during January 4–6  
 429 under Pattern 5 compared with those of January 1–3 under Pattern 2 (Fig 7d–e), primarily due  
 430 stronger upper air warming and more stable stratification. Pollutants that accumulated during  
 431 January 4–6 from the earlier pollution episode (January 1–3) further increased (Fig. 7g–i). On  
 432 January 7, high pressure in the north dominated the SCB, with a prevailing northerly flow over the  
 433 basin (Fig. 7c). The PBL height quickly increased due to upper-layer cold advection (Fig. 7f),  
 434 resulting in a rapid decrease in PM<sub>2.5</sub> (Fig. 7i). Overall, synoptic patterns play a key role in the  
 435 accumulation and diffusion of PM<sub>2.5</sub> during pollution episodes by modulating PBL development  
 436 and stratification stability.

**Figure 7.** The simulated (a)–(c) 850 hPa geopotential height field (shading) with wind vector fields (blue vectors), (d)–(f) boundary layer height and (g)–(i) PM<sub>2.5</sub> concentrations (shading) and wind vector fields at 900hPa (blue vectors) for 1-3, 4-6 and 7 January. The size and color of scatters in (g)–(i) show corresponding observed PM<sub>2.5</sub> concentrations at 18 air quality monitoring stations. The SCB was outlined with an altitude contour of 750 m terrain height (black lines).

437  
 438 Pollutant accumulation can regulate the PBL structure through the ARI, further exacerbating  
 439 pollution (Wang et al., 2018; Miao et al., 2020). In the SCB, this positive feedback is weaker than  
 440 in the other regions and may be inhibited by cloud radiation (Zhong et al., 2019). A series of

441 simulation experiments were conducted to [investigate](#) the aerosol radiation feedback in the SCB  
 442 under the influence of two typical synoptic pollution patterns, as described in Section 2.4. BASE-  
 443 EXP1 represents the perturbations caused by ARI, whereas EXP2-EXP3 demonstrates changes  
 444 through ARI without CRI inhibition. Aerosols led to surface cooling through absorbing and  
 445 scattering solar radiation, thereby inhibiting the development of the PBL, which in turn facilitated  
 446 pollutant accumulation (Fig. 8). Compared with Pattern 2, the aerosol concentrations in Pattern 5  
 447 were higher, resulting in greater reduction of downward solar radiation reduction due to ARI,  
 448 leading to more pronounced cooling near the ground and a lower [PBLH](#). Overall, the ARI in Pattern  
 449 5 was more significant than that in Pattern 2, regardless of CRI inhibition (Fig. 8).

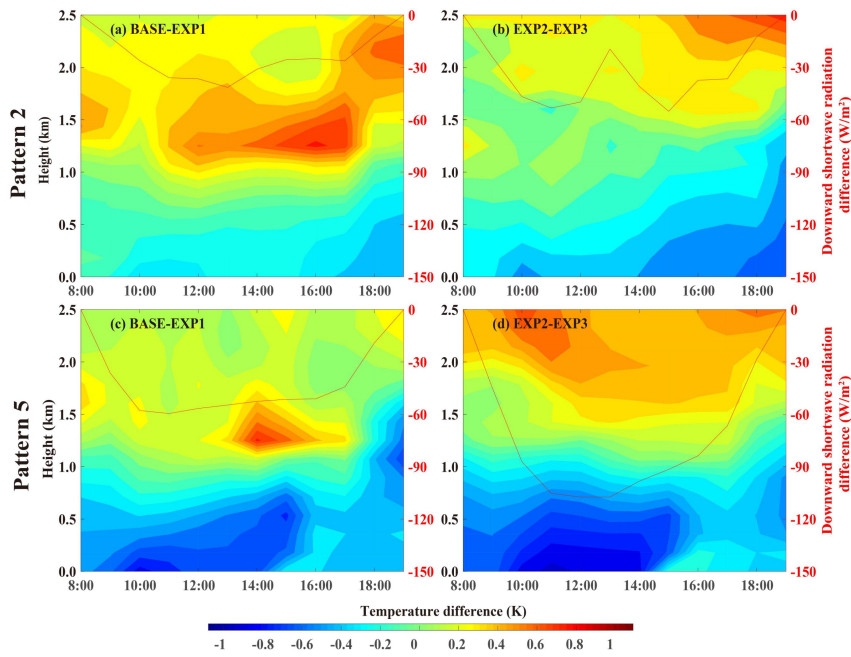

[Figure 8. Spatial distribution of perturbations induced by \(a\)-\(h\) aerosol radiation interactions \(ARI\), and \(i\)-\(p\) ARI without the cloud radiation interaction \(CRI\) inhibition during 1-3 and 4-6 January representing Pattern 2 and Pattern 5 synoptic forcing, respectively. The SCB was outlined with an altitude contour of 750 m terrain height \(black lines\).](#)

450

451 Furthermore, parallel simulation experiments [revealed](#) that the CRI significantly attenuated the  
 452 ARI in the SCB under both pollution synoptic patterns. When the CRI [was](#) not considered, more  
 453 solar radiation [penetrated](#) the PBL. Dense aerosols accumulated [near](#) the surface, intercepting more  
 454 downward shortwave radiation, [and](#) resulting in stronger cooling near the ground. [This](#) suppressed  
 455 [the](#) development of the PBL, [and](#) contributed to a more remarkable ARI (Fig. 8). [Regarding](#) the  
 456 horizontal spatial distribution, a strong ARI was primarily observed in Chongqing, as well as [in](#) the

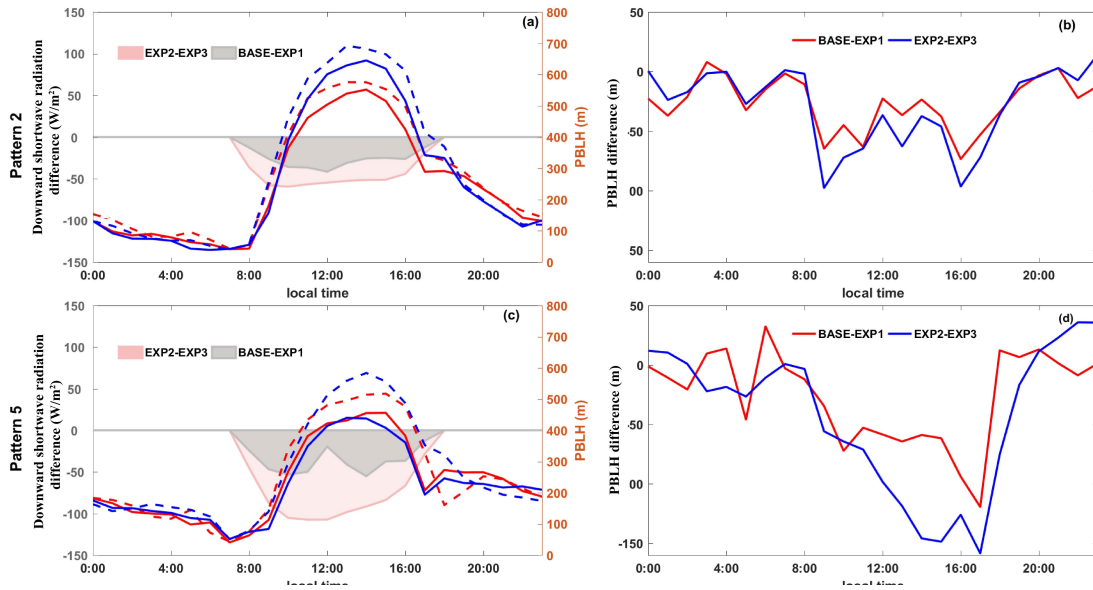

457 western and southern SCB, despite Chongqing experiencing lower pollutant concentrations  
458 [compared to](#) the other two regions (Figs. [S4](#) and [7](#)). This weaker ARI phenomenon in the western  
459 SCB was also reported by Zhong et al. (2019) and [was](#) attributed to CRI inhibition [on](#) ARI.  
460 Considering the statistical results in Fig. [5](#), the average cloud liquid water content in CD and YB  
461 [was](#) significantly higher than that in CQ under the influence of Patterns 2 and 5. [Consequently](#), a  
462 more remarkable CRI inhibition [on the ARI](#) would occur in the western and southern SCB  
463 [compared to](#) CQ, leading to a relatively weaker ARI distribution in [these](#) regions. Without  
464 considering the CRI, the ARI in the western and southern SCB would be much more pronounced  
465 than that in CQ.

466 Using the western SCB, which exhibited the highest pollution concentration, as an example, Fig.  
467 [9](#) illustrates the vertical diurnal variations in temperature and solar radiation caused by the ARI.  
468 The results in Fig. [9–11](#) were derived from the simulation experiments in CD, as CD is one of the  
469 most polluted cities with typical meteorological and geographical characteristics of the western SCB.  
470 The ARI caused surface cooling [in the morning](#) and upper-air warming [in the afternoon](#). As local  
471 solar radiation increased from 8 am to 12 pm, the [reduction](#) in solar radiation caused by the ARI  
472 also increased. [Surface cooling reached](#) its peak at approximately 10 am to 12 pm, [and](#) gradually  
473 [weakened](#) in the afternoon. This [diurnal variation might](#) be [attributed](#) to [the](#) enhanced turbulence  
474 during morning PBL evolution (Wang et al., 2018). Afternoon surface cooling was partly  
475 compensated by the turbulent transport of warm air above the PBL. In addition, strong surface  
476 cooling between 5 pm and 8 pm in the SCB, [was](#) possibly influenced by remarkable valley wind  
477 circulations forced by the Qinghai–Tibet Plateau adjacent to the western SCB ([Lu et al., 2022](#)).  
478 The evening cooling of the plateau induced [strong](#) mountain winds, promoting surface cooling,  
479 while the upper-layer warming mainly occurred [around](#) 1–1.5 km in the afternoon. In general, the  
480 ARI reduces solar radiation, causing surface cooling and upper air warming, thereby regulating the  
481 vertical atmospheric thermal structure, suppressing convection, and consequently decreasing PBL  
482 heights (Fig. [10](#)).

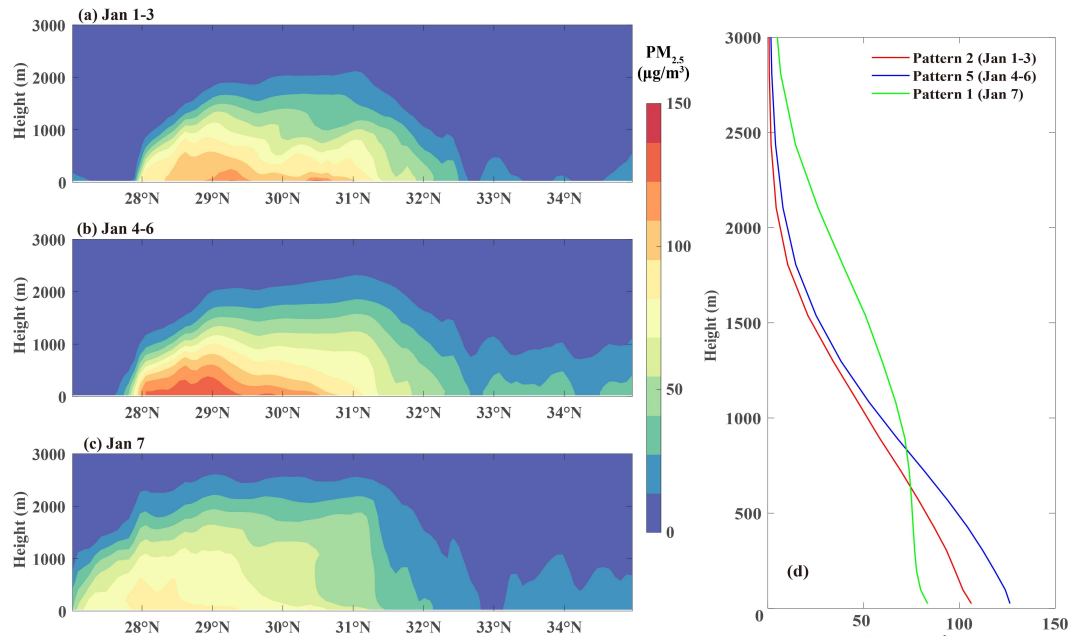

**Figure 9.** Diurnal variations of vertical temperature perturbations and downward solar radiation under influences of Pattern 2 and Pattern 5 induced by (a),(c)\_ARI and (b),(d)\_ARI without CRI inhibition.

483

**Figure 10.** Diurnal variations of (a),(c)\_boundary layer height(lines) and downward solar radiation(shading), and (b)(d)the perturbations of boundary layer height induced by ARI and ARI without CRI inhibition, under Pattern 2 and Pattern 5 synoptic forcing respectively.

484

**Figure 11.** Meridional vertical distribution of averaged PM<sub>2.5</sub> between 104°E and 105°E under (a) Pattern 2 and (b) Pattern 5, and (c) average profiles of PM<sub>2.5</sub> within 28°N and 31°N.

485

486  
 487 Synoptic patterns play a role in the interaction between the ARI and PBL (Wang et al., 2018;  
 488 Miao et al., 2020). Zonal average of PM<sub>2.5</sub> concentration between 104°E and 105°E was conducted,  
 489 and the meridional vertical distribution of PM<sub>2.5</sub> between 27°N and 35°N was illustrated in Fig.  
 490 11a-b. Fig. 11(c) provides an average of PM<sub>2.5</sub> concentration within 28°N and 31°N, showing the  
 491 vertical distribution profiles under Pattern 2 and 5. Due to the inhibition of “warm lid” above the  
 492 SCB, the vertical exchange was not prominent under both Pattern 2 and 5, and PM<sub>2.5</sub> was more  
 493 concentrated at the middle and lower levels. The PM<sub>2.5</sub> concentration under Pattern 5 was higher  
 494 than Pattern 2 throughout the atmospheric column, indicating stronger aerosol radiative forcing  
 495 and a more significant impact on the boundary layer structure under Pattern 5. During January 4–6,  
 496 the surface cooling reached 1 K, with cooling layers higher than those observed on January 1–3.  
 497 The differences in thermal structure modulations contributed to a lower diurnal PBLH in Pattern 5  
 498 than in Pattern 2 (Figs. 10a and c), indicating that Pattern 5 was more conducive to ARI. Based on  
 499 the simulation experiments, this study further discussed the impact of synoptic forcing on the CRI  
 500 inhibition of ARI. When the CRI was not considered, the solar radiation reduction at noon on  
 501 January 4–6 by the ARI was nearly twice as high as when the CRI was considered.  
 502 Correspondingly, surface cooling at noon was remarkably enhanced. In the evening, surface  
 503 cooling occurred earlier and was stronger without the CRI (Fig. 9). The regulation of CRI on ARI  
 504 was further reflected in changes in PBLH. Without the CRI, the diurnal PBLH increased  
 505 significantly, with the PBLH decreased more with ARI without CRI inhibition. The PBLHs were  
 506 decreased by the ARI during January 13–17 afternoon, reaching 2–3 times the decrease observed  
 507 with CRI inhibition (Fig. 10). More significant CRI inhibition of ARI was revealed under Pattern  
 508 5 compared with that under Pattern 2, owing to the stronger ARI itself with higher aerosol

508 concentrations in Pattern 5 and the more apparent CRI inhibition with denser cloud liquid water  
509 contents under the LT pattern (Fig. 5). Therefore, the intensity of CRI inhibition of ARI in the  
510 SCB was altered by synoptic forcing, with stronger effects under the influence of LT.

**Figure 12.** [The aerosol radiative effect can be significantly inhibited by cloud under influence of pollution synoptic patterns with dense cloud.](#)

511

#### 512 **4 Conclusion**

513 This study [utilized](#) synoptic classification and numerical simulation to [gain insights in to](#) the  
514 combined effects of synoptic patterns and CRI inhibition on ARI and PBL structures in the wet and  
515 cloudy SCB. [Based on the](#) long-term PM<sub>2.5</sub> observations and sounding data in the SCB, [it was](#)  
516 [found that](#) large-scale synoptic circulations [at](#) 850 hPa played [crucial](#) roles in [the](#) variations of  
517 PM<sub>2.5</sub> pollution. Synoptic classification was [performed](#) with the T-PCA method, [which revealed](#)  
518 that Pattern 2 and 5 characterized with low pressure system and southerly airflow on 850 hPa were  
519 key synoptic patterns for onset and accumulation of PM<sub>2.5</sub>, while Pattern 1 controlled by the  
520 northerly airflow represented a clean pattern associated with significant decrease in PM<sub>2.5</sub>.  
521 Moreover, [it was indicated that Pattern 2 and 5 exhibited](#) denser cloud liquid water content and  
522 [thus](#) stronger [compared to other patterns](#). [Among these patterns, Pattern 5 exhibited](#) the highest  
523 cloud liquid water content and CRI. [This could be attributed](#) to the robust southerly airflow  
524 induced by the dense isobaric lines, [which brought](#) warm and humid air masses [into the region](#).

525 To illustrate the interactions among cloud, aerosol and PBL under pollution synoptic patterns, a  
526 pollution episode [occurred from](#) January 1 [to](#) 7, 2017, was simulated with using WRF-Chem. The

527 [simulation](#) results showed that [ARI remarkably reduced](#) solar radiation was during the two  
528 pollution patterns. [This reduction led](#) to surface cooling [in the morning](#) and upper-air warming [in](#)  
529 [the afternoon](#). [Additionally,](#) the enhanced evening surface cooling was impacted by the mountain–  
530 valley wind circulations forced by the plateau–basin topography of the SCB. This modulation in  
531 the vertical thermal structure by the ARI would then suppress the development of the PBL,  
532 favoring pollution outbreaks (Fig. 12). [Furthermore,](#) parallel simulation experiments indicated that  
533 CRI impacted stratification stability and modulated the vertical thermal structure [by](#) inhibiting ARI  
534 (Fig. 12). [Regarding](#) the spatial distribution, a stronger ARI appeared in Chongqing, despite lower  
535 PM<sub>2.5</sub> concentrations [compared to](#) the western and southern SCB. [This was due to](#) the lower cloud  
536 liquid water content and weaker CRI inhibition of ARI in Chongqing. [When](#) CRI inhibition [was](#)  
537 [not considered,](#) the ARI in the western and southern SCB was significantly stronger than that in  
538 Chongqing. In addition, [under Pattern 5,](#) the reduction in solar radiation and PBLH during [the](#)  
539 daytime due to ARI could be more than doubled when the CRI influence [was neglected](#). [This was](#)  
540 primarily [due](#) to higher aerosol concentrations and cloud liquid water contents [associated](#) with a  
541 low trough [in Pattern 5](#). This study [provided insights into](#) the interaction [among aerosols, clouds,](#)  
542 [and PBL under different synoptic patterns,](#) considering [the](#) complex terrain and foggy/cloudy  
543 climate [of the SCB](#). The findings [highlighted the significant role of CRI inhibition on ARI during](#)  
544 [wet and cloudy conditions, shedding light in the multi-scale atmospheric physical processes in the](#)  
545 [SCB](#).

546 **Author contributions.** HL and MX had the original idea for the study, designed the experiments,  
547 conducted the numerical simulation and prepared the initial draft manuscript. BL, YZ and KZ  
548 collected the data. TW and BZ helped perform the analysis with constructive discussions, reviewed and  
549 edited the manuscript. HL, MX, TW and BL acquired financial support for the project leading to this  
550 publication. SL and ML reviewed the manuscript.

551 **Competing Interest:** The authors declare no conflict of interest.

#### 552 **Data Available Statement**

553 The ERA5 pressure layer and single layer data can be respectively downloaded from  
554 <https://cds.climate.copernicus.eu/cdsapp#!/dataset/reanalysis-era5-pressure-levels> and  
555 <https://cds.climate.copernicus.eu/cdsapp#!/dataset/reanalysis-era5-single-levels?tab=form>.  
556 The NCEP FNL data are available at <https://rda.ucar.edu/datasets/ds083.2/>. The MEIC data can  
557 be accessed in Zheng et al\_(2018) at <https://doi.org/10.5194/acp-18-14095-2018>. Air quality and  
558 meteorological monitoring data can be acquired from <https://doi.org/10.7910/DVN/USX59E>.

559 **Financial support:** This work was supported by the National Natural Science Foundation of China  
560 (42205186), the Chongqing Natural Science Foundation (cstc2021jcyj-msxmX1007), the open  
561 research fund of Chongqing Meteorological Bureau (KFJJ-201607) and the key technology research  
562 and development of Chongqing Meteorological Bureau (YWJSGG-202215; YWJSGG-202303).
