12 **Abstract.** Tropospheric ozone (O₃) and peroxyacetyl nitrate (PAN) are both photochemical pollutants harmful to the
13 ecological environment and human health. In this study, measurements of O₃ and PAN as well as their precursors were
14 conducted from May to July 2019 at Nam Co station (NMC), a highly pristine high-altitude site in the southern Tibetan
15 Plateau (TP), to investigate how distinct transport processes and photochemistry contributed to their variations. Results
16 revealed that, despite highly similar diurnal variations with steep morning rises and flat daytime plateaus that were caused by
17 boundary layer development and downmixing of free tropospheric air, day to day variations in O₃ and PAN were in fact
18 controlled by distinct physiochemical processes. During the dry spring season, airmasses rich in O₃ were associated with
19 high altitude westerly airmasses that entered the TP from the west or the south, which frequently carried high loadings of
20 stratospheric O₃ to NMC. During the summer monsoon season, a northward shift of the subtropical jet stream shifted the
21 stratospheric downward entrainment pathway also to the north, leading to direct stratospheric O₃ entrainment into the
22 troposphere of the northern TP, which travelled southwards to NMC within low altitudes via northerly winds in front of
23 ridges or closed high pressures over the TP. Westerly and southerly airmasses, however, revealed low O₃ levels due to the
24 overall less stratospheric O₃ within the troposphere of low latitude regions. PAN, however, was only rich in westerly or
25 southerly airmasses that crossed over polluted regions such as Northern India, Nepal or Bangladesh before entering the TP
26 and arriving at NMC from the south during both spring and summer. Overall, the O₃ level at NMC was mostly determined
27 by stratosphere-troposphere exchange (STE), which explained 77% and 88% of the observed O₃ concentration in spring and
28 summer, respectively. However, only 0.1% of the springtime day-to-day O₃ variability could be by STE processes, while 22%
29 was explained during summertime. Positive net photochemical formation was estimated for both O₃ and PAN based on
30 observation-constrained box modelling. Near surface photochemical formation could not explain the high O₃ level observed
31 at NMC and was also not the factor determining the day-to-day variability of O₃, however, it captured events with elevated
32 PAN concentrations and was able to explain its diurnal variations. Both O₃ and PAN formation were highly sensitive to NO_x
33 levels, with PAN being also quite sensitive to VOCs concentrations. Under the rapid development of transportation network

34 and the urbanization inside the TP, increased emissions and loadings in NO_x and VOCs might lead to strongly enhanced O_3
35 and PAN formation in downwind pristine regions, which should be paid more attention in the future.

36

37 **1 Introduction**

38 Ozone (O_3) and peroxyacetyl nitrate (PAN) are both key photochemical pollutants within the troposphere, that are harmful to
39 vegetation and human health (Kleindienst et al., 1990; Yukihiro et al., 2012; Taylor, 1969; Lefohn et al., 2017). Since O_3 and
40 PAN are both produced during the oxidation of volatile organic compounds (VOCs) in the presence of nitrogen oxides (NO_x),
41 they often share highly similar variational characteristics (Fischer et al., 2014). However, PAN is formed only from a limited
42 number of oxygenated VOCs (OVOCs), which are typically oxidation products of alkenes (with low carbon numbers),
43 aromatics and isoprene (Xu et al., 2021), while O_3 can be practically formed from all VOCs. Additionally, the photochemical
44 formation of O_3 depends highly nonlinearly on its precursor concentrations, being insensitive to VOCs changes under NO_x -
45 limited conditions and vice versa, while PAN varied nearly proportional to its OVOCs precursors, with additional influences
46 from the NO_2 to NO ratio (Xu et al., 2021). Thus, photochemistry can sometimes result in distinct variations of O_3 and PAN,
47 especially during cold seasons (Xu et al., 2021; Zhang et al., 2020). From the aspect of physical transport, O_3 and PAN can be
48 both transported over large distances. Since PAN is easily thermal decomposed under high temperatures, its transport is
49 more favored in cold seasons or at higher altitudes. Early simulation studies suggested PAN to be an important reservoir for
50 NO_x in the troposphere and lower stratosphere (Singh and Hanst, 1981) and redistributes NO_x far from its source regions
51 (Moxim et al., 1996). Different from PAN, O_3 is naturally produced within the stratosphere and can be transported into the
52 troposphere via stratosphere-troposphere exchange (STE) processes that are often associated with the occurrence of
53 tropopause folds, cut-off lows, streamers near the polar-front jet and subtropical jet stream and mid-latitude cyclones
54 (Langford, 1999; Stohl et al., 2003; Sprenger et al., 2007; Tang et al., 2011). STE elevates tropospheric O_3 and oxidation
55 capacity at distinct latitudes during different seasons, with overall largest mass fluxes in summer occurring mostly in higher
56 mid latitudes, followed by spring occurring mostly in lower mid latitudes (Tang et al., 2011; Škerlak et al., 2014). Deep STE
57 intrusions reaching the planetary boundary layer (PBL) and associated mass fluxes are largest during spring in China and the
58 western part of North America.

59 While the variational characteristics, influence of photochemical formation and transport on O_3 and PAN have been widely
60 investigated in polluted urban regions of China (Liu et al., 2018; Yao et al., 2019; Hu et al., 2020; Wei et al., 2020; Qiu et al.,
61 2021; Zhang et al., 2021; Xu et al., 2021), those at remote background sites received less attention, especially for PAN. The
62 Tibetan Plateau (TP), located in western China, is often called the “Third Pole” with its average altitude over 4000 m. Due to
63 its harsh environment, the TP is only scarcely populated and thus highly pristine. The topography of the TP affects large
64 scale circulations with its strong thermal forcing, thereby influencing the weather, climate and air quality in eastern China
65 (Yang et al., 2014). Surface O_3 as a crucial greenhouse gas and with its deterministic role on atmospheric oxidation capacity

66 has been paid certain attention in the TP and special concern has been paid to the photochemical formation of O₃ under the
67 strong radiative conditions at such high altitudes. Ma et al. (2002) investigated the photochemical formation of O₃ at Mt.
68 Waliguan (WLG) in the Northeastern TP through box-modelling and suggested wintertime net production and summertime
69 net loss in O₃. Xue et al. (2013) further constrained the box model with VOCs sampling results, which mainly included
70 hydrocarbons and aromatic compounds (no oxygenated compounds), and found net O₃ formation at WLG during both spring
71 and summer 2003. Transport from central and eastern China was found to be frequent during summertime (Xue et al.,
72 2011; Xu et al., 2018a), which revealed higher O₃ production efficiencies (Xue et al., 2011) and was responsible for rising O₃
73 trends during summer and autumn (Xu et al., 2016; Xu et al., 2018a). Due to its high altitude, the TP revealed the largest deep
74 STE O₃ mass fluxes, with higher fluxes in spring and winter and lower ones in summer and autumn, especially in the
75 southeastern TP (Škerlak et al., 2014). At WLG, O₃ was observed to be strongly influenced by STE associated with the
76 subtropical jet during spring and summer in 2003, with stronger impacts during summer than spring (Ding and Wang,
77 2006; Zheng et al., 2008). STE was estimated to contribute an annual average of 10.2% to tropospheric O₃ at WLG based on
78 EMAC model simulations using tagged tracers, revealing a peak contribution in June (Liu et al., 2020). At Nam Co station
79 (NMC) in the southern TP stratospheric influence was also mainly observed during spring and summer, which was estimated
80 to contribute 20% and 10%, respectively, based on model simulations (Yin et al., 2017). Measurements from Dangxiong, a
81 lower site not far from NMC, also revealed significant stratospheric impacts on surface O₃ (Lin et al., 2015). At Xianggelila
82 station in the southeastern TP, the STE impact was suggested to be most pronounced during winter and weakest during
83 spring and summer based on surface observations (Ma et al., 2014), which however was in disagreement with modelling
84 results revealing strongest STE during April and May, with an annual average contribution of 4.3%. In comparison, PAN
85 was far less investigated, the few existing studies mainly focused on the impact of transport on local PAN variations. Zhang
86 et al. (2009) made measurements of O₃ and PAN at WLG station during summer 2006 and found that the two oxidants
87 exhibited distinct diurnal variations and only weak correlations to each other, suggesting they were controlled by different
88 processes, with PAN being strongly influenced by regional transport of polluted air plumes. Xue et al. (2011) analyzed the
89 same set of observations and reported PAN to be one of the most abundant reactive nitrogen species (NO_y) at WLG,
90 contributing 32% to total NO_y. Xu et al. (2018b) made measurements of O₃ and PAN at NMC station in summer 2011 and
91 late spring to early summer 2012, detecting highly similar diurnal variations in both gases caused by boundary layer
92 development and elevated PAN in connection with transport of air plumes crossing over Nepal, North Pakistan or North
93 India.

94 Despite the findings in previous literature, the physiochemical factors determining the variation of O₃ and PAN in the TP and
95 their relative contributions have not been comprehensively investigated mainly due to the lack of comprehensive online
96 VOCs observations and accurate NO_x measurements. In this study, we present integrated real-time measurements of
97 O₃, PAN, NO₂, VOCs, CH₄, CO, photolysis rates and other meteorological parameters during spring and summer 2019 at
98 NMC station and analyzed them in combination with reanalysis data, utilizing trajectory modelling and box-modelling
99 approaches. The different impact of distinct transport processes and photochemical formation on O₃ and PAN, as well as

100 differences in sensitivities towards their precursors are intercompared using improved box-model constraints and the relative
101 contributions of physical and chemical processes to O₃ and PAN variability are evaluated.

102 2 Experimental and analysis methods

103 2.1 Site, observations and data

104 As the first part of the @Tibet series campaign, a campaign was carried out at NMC Station (30.77° N, 90. 95° E, 4730m
105 a.s.l.), which is a highly pristine site in the southern TP (Fig. 1). The site campus is located within the natural reserve of
106 NMC Lake, thus far away from anthropogenic activities and emissions. The nearest county (Dangxiong) and city (Lhasa) are
107 located 40 and 125 km to the southeast of NMC, respectively. The NMC Lake was ~1 km north to our observation site,
108 while the foothills of the northern Nyainqêntanglha Mountains were ~15 km to the south.

109 Measurements were performed from 1 May to 31 July 2019. Instruments for gases (including O₃, PAN, NO₂, CO, CH₄ and
110 non-methane volatile organic compounds (NMVOCs)) were housed in an air-conditioned container. O₃ was measured
111 alternatingly at the heights of 1.8 and 6.8 m (switching between two heights at 15-minute intervals) using a Model TE-49C
112 commercial O₃ analyzer, which was calibrated with a TE-49iPS O₃ calibrator (both from Thermo Electronics, USA). A Los
113 Gatos Research (LGR) NO₂ Analyzer was adopted for the measurements of NO₂, which has a measurement range of 0.01-
114 1000 ppb and was calibrated using NO₂ standard gas at the beginning and end of the experiment. PAN measurements were
115 made using a GC-ECD analyzer (Meteorologie Consult GmbH, Germany) which was calibrated using PAN instantly formed
116 in the reaction of a NO reference gas with acetone in the internal calibration unit of the instrument. CO and CH₄ were
117 measured (until 2 July) by a cavity ring-down spectroscopy (CRDS) analyzer (Model G2401, PICARRO, USA) at a high
118 precision (0.4 and 0.04 ppb, respectively, for CO and CH₄). The CRDS instrument was calibrated twice using a mixed CO
119 and CH₄ standard gas, which was pressurized in 29.5 L treated aluminum alloy cylinders (Scott-Marrin Inc.) fitted with high-
120 purity, two-stage gas regulators, and calibrated with cylinders assigned by the Global Atmosphere Watch (GAW) CO
121 Central Calibration Laboratory operated by National Oceanic and Atmospheric Administration (NOAA) Earth System
122 Research Laboratory (ESRL). NMVOCs were measured (only from 29 April to 21 May) using an online GC-MS/FID
123 analysis system (TH-PKU 300B, Wuhan Tianhong Instrument Co. Ltd., China) at a 1-hour time resolution, with detection
124 limits in the range of 0.004 to 0.066 ppb. Multipoint calibrations were performed using Photochemical Assessment
125 Monitoring Stations (PAMS) standard mixture and TO-15 standard mixture (100 ppb, Spectra Gases Inc., New Jersey, USA).
126 To account for the reactivity of different VOCs species, Propy-Equivalent VOCs concentrations were calculated as:

$$127 C_{Propy-Equiv}(i) = C(i) \frac{k_{OH}(i)}{k_{OH}(C_3H_6)}, \quad \text{Eq. (1)}$$

128 where C(i) is the ppbC concentration of species *i* (calculated using ppb mixing ratios multiplied by carbon numbers of
129 species *i*), *k*_{OH}(*i*) the reaction rate of species *i* with OH radicals (obtained from master chemical mechanism,
130 <http://mcm.york.ac.uk/MCM/>), and *k*_{OH}(C₃H₆) the reaction rate of propene with OH.

131 Photolysis rates (J values) were obtained using a Metcon CCD-spectrograph (Meteorologie consult GmbH, Germany),
132 whose receptor optics were mounted on top of the container at the height of 2 m. Conventional meteorological parameters
133 including temperature (T), relative humidity (RH), surface pressure (P), wind speed (WS) and wind direction (WD) were
134 recorded by an Automatic Weather Station. In addition, meteorological reanalysis data (ERA5) from the European Centre for
135 Medium-Range Weather Forecasts (ECMWF) were used for complimentary analysis.

136 2.2 Backward trajectory analysis and PSCF calculations

137 The HYSPLIT model (version 5) from NOAA Air Resources Laboratory (Draxler and Hess, 1997; Draxler and Hess,
138 1998; Draxler, 1999) was used for backward trajectory calculations, with 0.25° resolution GFS data from the National Center
139 for Environmental Prediction (NCEP) adopted as input. The trajectory endpoint was set at 250 m above the ground level of
140 NMC station. 7-day (168 hours) backward trajectories were calculated at an hourly interval for the entire period of the
141 campaign.

142 The potential sources of high O₃ and PAN were studied using the potential source contribution function (PSCF) analysis,
143 which has been widely applied to detect possible source regions (Ara Begum et al., 2005; Lucey et al., 2001; Zhou et al.,
144 2004). The PSCF on grid (i,j) is defined as:

$$145 \text{PSCF} = m(i,j)/n(i,j), \quad (1)$$

146 where m(i,j) is the residence time of a subset of trajectories, whereas n(i,j) is the residence time of all the trajectories in that
147 grid. Each trajectory was associated with O₃ and PAN concentrations observed at its time of arrival. To pin out the potential
148 source regions for high O₃ and PAN, the m(i,j) was calculated using the subset of trajectories that were associated with O₃ or
149 PAN concentrations higher than their respective 75th percentiles.

150 Abnormally high PSCF values may be produced for certain grids with very small n(i,j) values, which would induce large
151 uncertainties. Thus, a weighting factor W(n_{ij}) is introduced that was proposed by Zeng and Hopke (1989), giving grids with
152 few trajectories passing through less weight:

$$153 W(n_{ij}) = \begin{cases} 1.0, & n_{ij} > \bar{n}_{ij} \\ 0.7, & 0.1 \cdot \bar{n}_{ij} < n_{ij} \leq \bar{n}_{ij} \\ 0.4, & 0.05 \cdot \bar{n}_{ij} < n_{ij} \leq 0.1 \cdot \bar{n}_{ij} \\ 0.2, & n_{ij} \geq 0.05 \cdot \bar{n}_{ij} \end{cases}, \quad (2)$$

154 where \bar{n}_{ij} is the average number of n_{ij}.

155 The PSCF analysis was respectively performed for O₃ and PAN, separately for spring and summer periods. Based on
156 meteorological variations, spring and summer periods were defined as 1 May to 15 June and 15 June to 31 July, respectively.

157

158 **2.3 Box modelling of local photochemistry**

159 The Master Chemical Mechanism (version 3.2) was used within the F0AM (version 3.1) box-model framework developed
160 by Wolfe et al. (2016), to simulate the impacts of local photochemistry on O₃ and PAN and to evaluate how much of their
161 variations can be explained through local photochemistry. Observation data of VOCs, NO₂, J values and meteorological
162 parameters were either averaged or interpolated into 10-minute averages and used as constraints in the model. Model
163 simulations were only performed for the period from 1 to 21 May, when VOCs observation data were available. To evaluate
164 local O₃ and PAN formation, three sets of simulations were performed for each, respectively using measurement constraints
165 on OVOCs, NO₂ or both of them. In O₃ simulation cases, PAN was constrained by observations, while in PAN simulations
166 O₃ was constrained. Daytime O₃ and PAN increments ($\Delta O_{3,mod}$ and ΔPAN_{mod}) were calculated and compared against
167 observed ones ($\Delta O_{3,obs}$ and ΔPAN_{obs}), with their ratios used to reflect how much modelled local photochemistry can explain
168 observed daytime increases in O₃ and PAN. Simulated O₃ and PAN net formation rates in distinct modelling scenarios were
169 intercompared and to evaluated the sensitivity of their formation to VOCs and NO_x concentrations.
170

171 **2.4 Impact of stratospheric-tropospheric exchange**

172 A Y index was defined as the ratio between normalized O₃ and water vapor concentrations, calculated using the following
173 equation:

$$174 Y_{ind} = \frac{O_3/\bar{O}_3}{H_2O/\bar{H}_2O}. \quad \text{Eq. (3)}$$

175 The Y index adopted in previous studies for the identification of stratospheric air intrusions has additionally divided Eq. (3)
176 by normalized CO concentrations (Ma et al., 2014). Due to the lack of CO measurements after 2 July, the Y index was
177 modified to the current form (in Eq. 3), which compared well with those calculated when incorporating normalized CO
178 concentrations (Fig. S1), since CO revealed very small variability during the entire observation period.

179 Additionally, O₃ mass mixing ratios from the ERA5 hourly reanalysis dataset were converted to volume mixing ratios and
180 applied in the investigation of STE impacts, since the ERA5 data are simulated with simple stratospheric O₃ chemistry
181 consideration and thus mainly represents the physical transport of stratospheric O₃ (Sprenger and Wernli, 2003).
182 Additionally, ERA5 O₃ data has been verified to be well representative of observed O₃ profiles and ground concentration
183 levels at remote polar regions (Wang et al., 2021), indicating that it can well represent stratospheric O₃ and the influence of
184 its transport.

185 **3 Results and discussions**

186 **3.1 Variational characteristics of O₃, PAN and their precursors**

187 The time series of observed O₃, PAN, NO₂, CO, photolysis rates of O₃ (jO^1D) and NO₂ (jNO_2), as well as meteorological
188 parameters observed at NMC from 1 May to 31 July are displayed in Figure 2. From 1 May to 15 June (defined hereafter as
189 the spring period), NMC experienced cold temperatures, strong winds, and dry conditions with low relative humidity (RH)
190 and hardly any precipitation except for three small snow events. While during 15 June to 31 July (defined hereafter as the
191 summer period), temperatures increased, average wind speeds were smaller and frequent precipitation events occurred under
192 the influence of the Asian summer monsoon (Fig. 2a, Table 1). Despite more frequent precipitation events, observed average
193 daytime photolysis rates were similar between spring and summer periods.

194 Under such meteorological variations, O₃ and PAN exhibited higher average concentrations in the spring (59.8 ± 13.4 and
195 0.27 ± 0.08 ppb) and lower ones in the summer period (53.6 ± 13.2 and 0.20 ± 0.05 ppb), with O₃ levels being overall in
196 accordance with previous observations (Xu et al., 2018b; Yin et al., 2017), while PAN levels were significantly lower than
197 those observed in 2012 (Xu et al., 2018b). VOCs concentrations were only obtained for the first half of the spring period,
198 reaching average concentrations of 4.1 ± 3.5 Propy-Equiv. ppbC, to which OVOCs contributed $61 \pm 12\%$ (reaching
199 2.5 ± 2.2 Propy-Equiv. ppbC on average), followed by alkenes (0.6 ± 0.6 Propy-Equiv. ppbC), aromatics (0.6 ± 1.3 Propy-Equiv.
200 ppbC) and alkanes (0.47 ± 0.5 Propy-Equiv. ppbC), which made up similar fractions ($14 \pm 6\%$, $13 \pm 7\%$, and $11 \pm 4\%$,
201 respectively), while other components (including alkynes, halogenated VOCs and nitriles) had negligible impacts ($1 \pm 1\%$) on
202 the overall VOC concentration and reactivity (Fig. S2). While daytime concentrations of OVOCs and alkenes were
203 significantly higher than those during nighttime, other VOCs species did not display much day-night discrepancy. NO₂
204 revealed averaged concentrations 0.12 ± 0.05 and 0.09 ± 0.05 ppb during spring and summer periods, respectively, with no
205 evident day to night differences.

206 Averaged diurnal variations of O₃ and PAN resembled each other (Figs. 3a1-2), both revealing decreases after sunset,
207 reaching lowest values at 7:00 Beijing Local Time (LT) and increasing quickly after sunrise simultaneous to PBL height
208 (PBLH, Figs. 3b1-2) and exhibiting a flat plateau afterwards. Both O₃ and PAN revealed higher levels in spring and lower
209 ones in summer, however, PAN concentrations have decreased more significantly than O₃ (26% versus 10%), revealing a
210 very flat and broad plateau during the day. OVOCs, aromatics and alkenes determined the variations of VOCs, with OVOCs
211 and alkenes displaying diel variations similar to those of O₃ and PAN, revealing increases from 7:00 to 9:00 LT, fluctuating
212 around its daily maximum value over daytime and decreasing after 17:00 LT (Figs. 3b1-2). NO₂ was typically higher during
213 nighttime and lower during daytime, which is caused by combined effects of weakened dilution under nighttime shallow
214 boundary layers, natural and anthropogenic NO_x emissions, as well as chemical transformations. Additionally, springtime
215 NO₂ concentrations were higher than those during the summer period (Figs. 3c1-2). CO, however, revealed only slightly
216 higher concentrations during the summer period, staying overall flat during the day, without any diurnal variations (Figs.
217 3c1-2). Both RH and absolute water vapor concentrations were higher during the summer period. RH revealed a diurnal

218 maximum by 7:00 LT during both periods, decreased rapidly after sunrise and reached its diurnal minimum at 16:00 and
219 18:00 LT in spring and summer, respectively (Fig. 3e1-2). Water vapor, however, increased further after sunrise, possibly
220 due to surface evaporation processes of frost and dew during the morning. While the diurnal peak in photolysis rates were
221 similar between spring and summer periods, the averaged diurnal variations displayed a narrower peak during summer,
222 especially for jNO_2 , due to more frequent precipitation and higher cloud coverage.

223 The day-to-day evolution of diurnal O_3 and PAN variations as well as those of winds and PBLH are more clearly displayed
224 by Figs. 4). Downward winds were strongest during the afternoon under high PBLH (Figs. 4a,d). Due to the local
225 topography with the NMC Lake to its west and north and the Nyainqêntanglha Mountains to its south, the site was
226 susceptible to both influences from land-lake and mountain-valley breezes. Accordingly, local surface winds displayed clear
227 diurnal variations with southeasterly nighttime winds shifting to northwesterly winds during daytime (Figs. S3b-d, Fig. S3
228 the same as Fig. 4, with winds replaced by 2 m wind measurements). 550 hPa winds from ERA5 over the 0.25° grid
229 containing NMC station (representing near surface conditions, since surface pressure was on average 573 ± 2 hPa) revealed
230 stronger diurnal variations in zonal winds (Fig. 4b), overall agreeing with variations in surface winds, while meridional
231 winds were dominated by southerly wind directions (Fig. 4c), with occasional changes to northerly winds, suggesting that
232 local circulations had stronger impacts on zonal winds.

233 Broad peaks in O_3 often lasted until late evening hours, while nighttime O_3 frequently revealed increases under westerly
234 winds and could reach daytime concentration levels, which can only be attributed to transport processes. High nighttime O_3
235 was not always accompanied by simultaneous PAN increases, while vice versa, elevated nighttime PAN was also not always
236 synchronized with those of O_3 , indicating that they might have originated from distinct sources and processes. O_3 levels were
237 continuously high throughout the spring period, especially during 6-13 May. Despite overall lower levels in the summer
238 period, two O_3 episodes occurred during 7-8 July and 24-25 July, respectively, exhibiting the highest concentrations
239 observed during the entire campaign (Fig. 2a, Fig. 4e). Compared to O_3 , PAN displayed much larger day to day variability,
240 with an evident high PAN episode occurring from 13 to 16 May under southeasterly winds from aloft (Fig. 4f). Summertime
241 PAN was distinctly lower than that during spring season, with no increases detected during the two high O_3 episodes.

242 Overall, while O_3 and PAN revealed highly similar average diurnal variation patterns, their temporal variations often differed
243 from each other, suggesting that they were determined by distinct transport or formation processes, which will be further
244 investigated in the following sections.

245

246 **3.2 Impact of local circulation**

247 In previous studies, diurnal variations in O_3 and PAN were mainly attributed to local circulations, particularly the
248 development of the PBL. At pristine mountain sites such as WLG, surface O_3 was influenced by free tropospheric air during
249 nighttime and by boundary layer airmasses during daytime, which resulted in a diurnal cycle with lower daytime and higher
250 nighttime O_3 with very small diurnal variation amplitudes. Despite its high altitudes, NMC is located at the foot of the
251 northern Nyainqêntanglha Mountains, and thus experienced local circulation distinct from those at WLG. Free tropospheric

252 air was suggested to be richer in O₃ and PAN concentrations and was mixed down upon the rapid development of the
253 convective boundary layer (CBL) after sunrise, while O₃ and PAN concentrations decreased upon the establishment of the
254 nocturnal boundary layer (NBL), due to the dominance of local boundary layer airmasses during nighttime, which were low
255 in O₃ and PAN, since barely any surface O₃ and PAN precursor emission sources existed at NMC, added by effects of dry
256 deposition (Xu et al., 2018b). The broad O₃ peaks that often lasted until late evenings and the frequent events of elevated
257 nighttime O₃ (Fig. 4e) both supported the idea that under favorable meteorological conditions, high surface O₃ levels after
258 sunlight hours could be sustained by continuous downmixing of free tropospheric air. The fact that nighttime O₃ could reach
259 the same level as noontime O₃ is why previous studies suggested that physical transport was determining O₃ variations at
260 NMC, while photochemistry played a minor role.

261 Diurnal variations of O₃ and PAN followed their averaged diel pattern on 72% and 75% out of the days with valid records,
262 respectively. While O₃ diurnal cycles revealed more days with such daytime increases during summer (69% in spring vs. 74%
263 in summer), PAN conformed better to its averaged diurnal cycle in spring (90% in spring vs. 63% in summer), suggesting
264 that despite being under the same meteorological influences and despite highly similar average diurnal concentration profiles,
265 O₃ and PAN often revealed different variations. O₃ and PAN increasing rates (on days with daytime increases) between 7:30
266 and 10:30 LT both displayed linear correlations to temperature increasing rates (Fig. S4), confirming again that their
267 morning increases were closely connected to boundary layer development upon radiative heating. Prenoon (6:00 to 12:00 LT)
268 O₃ concentrations also increased with PBLH during both spring (Fig. 5a) and summer (Fig. 5b), however, revealing slightly
269 distinct slopes during distinct seasons. Weaker prenoon winds that mainly occurred during early morning under low PBLH
270 conditions were associated with evidently lower O₃ concentrations. During early morning hours when PBLH was still low,
271 strong winds that mostly came from the W-NW direction were associated with O₃ concentrations as high as those observed
272 during noontime in the spring period (Fig. 5a). During the afternoon (12:00 to 18:00 LT), when the CBL has fully
273 established, O₃ hardly displayed any more variation with PBLH (Fig. S5a), indicating that once boundary layer and free
274 tropospheric air was fully mixed, O₃ did not further increase with PBLH. In the summer period, W-NW winds were less
275 frequent and O₃ associated with these winds only increased weakly with PBLH, whereas N-NE winds resulted in more
276 significant rise in O₃ over prenoon hours. Summertime afternoon PBLH was significantly lower than during spring due to
277 frequent cloudy and rainy conditions, mostly falling into the range of 0.5-1.5 km (Fig. S5b). O₃ still increased with PBLH,
278 however, revealing large variability under the same PBLH, indicating that PBLH was not the deterministic factor for
279 afternoon O₃ levels. PAN did not replicate the variation of O₃ with PBLH during prenoon hours, displaying large variability
280 at lower PBLH and moderate concentration levels under high PBLH. This suggests that free tropospheric O₃ levels were
281 consistently and significantly higher than boundary layer O₃ levels, indicating for weak surface formation of O₃ (further
282 discussed in Sect. 3.3), which resulted in significant increases in observed surface O₃ upon down mixing. Whereas free
283 tropospheric PAN or the surface formation of PAN might have had higher variability, which resulted in largely different
284 responses of PAN with the down mixing of free tropospheric air during afternoon hours.

285 To investigate what has caused the discrepancies in free tropospheric O₃ and PAN over NMC, the variations of surface O₃
286 and PAN with free tropospheric (500-550 hPa) winds during spring and summer are depicted in Fig. 6. At lower wind speeds,
287 both O₃ and PAN typically revealed lower concentrations. With increasing wind speeds, high concentrations of O₃ and PAN
288 were associated with distinct wind directions, in both spring and summer. During springtime, high concentrations of O₃ and
289 PAN both occurred with W winds, however, low O₃ and high PAN concentrations were detected under strong S winds.
290 During summertime, high O₃ dominantly occurred with N-NE winds, while PAN mainly revealed elevated concentrations
291 under S-SW winds. The distinct variation of O₃ and PAN with wind speed and wind direction suggests that the
292 concentrations of both gases might have been impacted by different long-range transport processes, which will be
293 investigated in the next section.

294

295 **3.3 Impact of inter-regional transport and stratospheric-tropospheric exchange**

296 Potential influence of pollution transport from India and other south Asian countries have been previously reported, which
297 had potential impacts on the transport of PAN (Xu et al., 2018b). However, the source regions of O₃ and PAN in the TP have
298 not been systematically investigated before. NO₂ and CO columns from TROPOMI revealed high concentrations in South
299 Asian regions south of the TP contrasting to the pristine environment within the TP (Fig. 7). CO was more severe and
300 widespread outside of the TP during the spring period, while NO₂ pollution was more severe during the summer period both
301 in South Asia and to the east of the TP in China. Inside the TP, NO₂ and CO columns were both higher during the summer
302 period, suggesting that summertime atmospheric circulations might have been more favorable for pollution transport into the
303 TP. The high-altitude Himalaya mountains along the southern border of the TP is highly effective in blocking out direct
304 intrusion of South Asian pollution, leading mostly to pollutant accumulation on its southern slope. High resolution satellite
305 observations clearly reveal high NO₂ and CO along mountain and river valleys, indicating that pollution might have
306 transported into the TP through these passageways. Belts of elevated CO extend from the western side (Kashmir) to the
307 southeastern corner of the TP, indicating that pollution from South Asia could not directly cross over the Himalayas,
308 especially not over those regions with very high altitudes, but had entered the TP by crossing either to its west or southeast.

309 To further identify possible source regions for high O₃ and PAN at NMC station, the PSCF for both gases were calculated
310 for spring and summer, respectively (Fig. 8). Spring time high O₃ concentrations were mainly associated with westerly
311 trajectories, which crossed over North India and Nepal before arriving at NMC (Fig. 8a). Although trajectories associated
312 with high springtime O₃ crossed over vast areas outside the southern TP border, they mainly entered the TP from two
313 passageways, one from the west and another from the southeast (near the border of Bhutan). Before entering the TP, the
314 majority of the airmasses associated with high O₃ came from higher altitudes (> 6 km), diving downwards to heights of 3-
315 6 km or even < 3 km near the southern border of the TP, and then entering the TP mainly from the west or south (Figs. 9a1-
316 3). Aside from that, trajectories from the NW mostly travelling within 0-6 km (above ground level) were also associated
317 with high springtime O₃. High springtime PAN, however, was only associated with trajectories crossing over South Asia and

318 entering the TP from the southeastern border. In addition, airmasses from the Indian Ocean that travelled within 0-3 km and
319 crossed over Bangladesh and Bhutan were also associated with high PAN, while not with high O₃ (Fig. 8b and Figs. 9b1-3).
320 During summer, the PSCF of O₃ revealed a largely different distribution from that in spring. High altitude westerly airmasses
321 that entered the TP from the west in spring have not been seen in summer, while airmasses sweeping along the southern
322 border of the TP (Nepal and northern India) at altitudes below 6 km and approaching NMC from its south were still partly
323 associated with high O₃ during summer (Fig. 8c and Figs. 9c1-3). Southerly low altitude (0-3 km) maritime airmasses that
324 travelled over Bangladesh and Bhutan before entering the TP were also sometimes linked to high O₃ at NMC. However, the
325 major summertime O₃ source regions were located to the north of NMC, including southern Xinjiang province, Northern
326 Tibet and western Qinghai Province (Fig. 8c). High O₃ was mostly associated with low altitude airmasses from the NW and
327 N directions (Fig. 9c1). Summertime PAN was only rarely associated with northerly airmasses, but mostly linked to westerly
328 trajectories that travel along the southern TP border (mostly within 0-3 km, small parts within 3-6 km altitude, Figs. 9d1-2)
329 and southerly trajectories travelling over Bangladesh and Bhutan within 3 km altitude (Fig. 9d1).
330 Thus, O₃ and PAN revealed distinct source regions in both spring and summer, while they also shared some common source
331 regions. This explains why despite highly similar diel variation patterns, the day-to-day variation was often different between
332 the two oxidants. Overall, springtime synoptic conditions resulted in a relatively monotone origin of airmasses at NMC,
333 mostly favoring the subsidence of high altitude airmasses under westerly airflows, which were rich in both O₃ and PAN.
334 With the onset of the South and East Asian Monsoon during summer, circulations drastically changed and resulted in
335 influences of various distinct air mass origins at NMC. These vastly different air mass origins also exhibited completely
336 different O₃ levels, with those originated in the north exhibiting even higher O₃ levels than those observed during springtime
337 and southerly airmasses revealing much lower O₃ levels than during springtime. PAN, however, was more linked to westerly
338 and southerly airmasses during summer.
339 Aside from changes in air mass origins at NMC, seasonal variations in large scale synoptic conditions were also
340 deterministic of STE and the overall spatial distribution of O₃. Since the ERA5 reanalysis data has only considered
341 simplified stratospheric O₃ chemistry and the physical transport of O₃, the O₃ mixing ratio in the ERA5 dataset is a good
342 indicator for the investigation of stratospheric influences. During the spring period, the averaged ERA5 500 hPa O₃ revealed
343 relatively lower mixing ratios in the TP region (especially in southeast TP) and higher mixing ratios outside the TP in the
344 latitude band between 15 and 25°N. As was shown in previous studies, the downward transport of stratospheric O₃ and its
345 distribution is closely linked to the location of the subtropical jet stream (Xu et al., 2018a), which is typically located above
346 the TP during the spring period (Fig. 10c1). Due to large scale circulations, lower stratospheric O₃ is typically high in polar
347 regions, decreasing with latitude and reaching its lowest level in the equatorial belt (Fig. 10c1). Deep stratospheric intrusion
348 and O₃ subsidence often occur along the lower edge of the subtropical jet stream, which is a slope extending from the lower
349 stratosphere (150 hPa) between 38 to 42°N down to the middle or upper troposphere below 28°N. STE processes are
350 especially promoted by fronts, which are accompanied by large scale subsidence of cold air from above (Stohl et al., 2003).
351 STE mostly increased the O₃ levels in Southeast Asia to the west and south of the TP, which in turn could enhance O₃ at

352 NMC through the westerly airmass transport passage (Figs. S6). Direct STE influence was also frequently observed during
353 the spring period (on 5-8, 13, 23, 31 May and 3, 5 and 9 Jun, Figs. S7-13), with NMC frequently located near low pressure
354 troughs behind cold fronts. These STE events were typically associated with high O₃ and low PAN concentrations, except
355 for the 13 May, when stratospheric O₃ was transported to lower latitudes and then back to NMC via southwesterly winds,
356 which also carried along high PAN concentrations, suggesting that NMC experienced aged stratospheric airmasses. During
357 the summer period, with the northward shift of the subtropical jet stream, the high lower stratospheric O₃ concentrations
358 were also confined within higher latitudes. 500 hPa ERA5 O₃ revealed a clearly distinct distribution from that during spring,
359 displaying higher O₃ levels north of NMC (>30 °N) and much lower ones in the tropical region. Thus, under the prevailing
360 southerly winds during the summer season, airmasses with lower stratospheric O₃ contents are transported to NMC. However,
361 during two episodes on 7-9 and 21-25 Jul, northerly cold airmasses in front of 500 hPa high pressure systems over the TP
362 brought stratospheric O₃ down to the norther TP regions and transported them within lower altitudes to NMC, resulting in
363 surface O₃ levels even higher than those during springtime (Figs. S14-15), while PAN did not reveal significant increases.
364 Statistically, O_{3,ERA5} only explained 0.1% of the observed daytime O₃ day-to-day variability during spring ($r=0.033$),
365 however, explained 22% of the summertime O_{3,NMC} variability ($r=0.47$), contributing on average 10% during the entire
366 observation period (Fig. S16), which was overall in accordance with previous results reported in Yin et al. (2017). It is also
367 worth noting that observed O₃ at NMC was typically higher than the 550 hPa ERA5 O₃ mixing ratio, especially during spring
368 and early summer (Fig. 10d). During the entire observation, stratospheric O₃ transport explained 83% of the observed
369 daytime O₃ concentration ($O_{3,ERA5}/O_{3,NMC}$), with a lower contribution during spring (77%) and a higher one during summer
370 (88%). This suggests that despite the small contributions of STE to the day-to-day variability of observed O₃, the overall
371 daytime O₃ concentration was mainly maintained by the long-range transport of stratospheric O₃ (as opposed to direct strike
372 of stratospheric O₃ during deep STE intrusions into the PBL). Additionally, the unexplained O₃ concentration might indicate
373 for photochemical O₃ formation aside from pure physical transport. However, whether it was caused by local photochemical
374 production or the long-range transport of photochemically produced O₃ still requires further investigation.

375

376 **3.4 Impact of local photochemistry**

377 As was already manifested, O₃ has its natural sources and is more affected by STE processes at high altitude locations such
378 as NMC. O₃ is highly reactive and can be easily depleted in regions with high NO_x and VOCs emissions, however has a
379 relatively longer lifetime in pristine background areas and can be directly or indirectly transported (transport of its precursors)
380 over large distances, affecting O₃ levels at remote locations (Xu et al., 2018a). The impact of local photochemistry on the
381 budget of O₃, however, was often under debate in previous studies conducted in background areas of the TP. Under such
382 pristine atmospheric conditions, it was manifested that O₃ production was strongly NO_x-limited, with NO_x concentrations
383 being the key factor determining whether O₃ was net produced or destructed in local photochemistry (Ma et al., 2002).
384 However, the lower detection limit and precision of commercial instruments can hardly meet the needs for NO_x
385 measurements in such clean environments, which made it difficult to determine whether there has been net O₃ formation. At

386 higher altitudes, PAN has a long lifetime and can be transported over long distances. PAN measurements have been
387 previously conducted at Mt. Waliguan (Northeastern TP) in 2006 (Xue et al., 2011) and at NMC station in the springs and
388 summers of 2011 and 2012 (Xu et al., 2018b). At both sites, PAN contributed substantially to reactive nitrogen and acted as
389 a good indicator for regional and long-range transport of polluted air plumes. The photochemical formation of PAN requires
390 the presence of peroxy acetyl radical and NO_2 . The former is only formed in photochemical reactions of its precursor
391 OVOCs, which are predominantly emitted within the boundary layer, while the latter is also mostly emitted near surface,
392 with the exception of lightning processes. Altogether, the formation of PAN in comparison with O_3 is more favored near
393 surface and has no natural sources. Nevertheless, the impact of local PAN formation versus those of transport to observed
394 concentration levels was not discussed before due to the lack of its precursor measurements.

395 To evaluate the contribution of local photochemistry to observed O_3 and PAN, simulations were performed using an MCM-
396 based box model for the period of 1 to 21 May, when VOCs measurements were available. Observed O_3 revealed much
397 larger fluctuations than those obtained from all three simulation scenarios, which respectively used measurement constraints
398 on OVOCs, NO_2 or both of them (Fig. 11a). With constraints on NO_2 , modelling results revealed significant daytime
399 increases, indicating positive local net photochemical formation of O_3 (Fig. 12a). However, when NO_2 was unconstrained,
400 modelled O_3 concentrations were significantly lower and displayed very small variability, with very small positive net O_3
401 production during the morning and mostly negative ones during the day (Fig. 12a). Nevertheless, none of the simulations
402 could reproduce the large variability and steep morning increases within observed O_3 , with OVOCs and NO_2 both
403 constrained by measurements, modelling results could only explain $28 \pm 19\%$ (5-66%) of the observed daytime increases (Fig.
404 11b), while even less could be explained when only OVOCs or NO_2 was constrained ($3 \pm 6\%$ and $21 \pm 14\%$, respectively).
405 Days with relatively stronger local photochemical O_3 formation were not necessary days with high observed O_3 , while in
406 return days with high O_3 were also often associated with weak photochemical net O_3 formation. This indicates that physical
407 transport and mixing processes were determinative of O_3 diel cycle as well as the day-to-day O_3 variability, while local
408 photochemistry further added to the daytime O_3 burden. Additionally, intercomparison among simulations also confirmed
409 the high sensitivity of O_3 formation towards NO_x and the relatively weaker sensitivity to VOCs in such a pristine
410 environment.

411 Simulated PAN levels under NO_2 constraints were, however, significantly higher than observed PAN concentrations,
412 especially when OVOCs and NO_2 were both constrained. However, when NO_2 was unconstrained, PAN concentrations were
413 mostly underestimated by simulations. Thermal decomposition of PAN was very weak under low springtime temperatures
414 and net photochemical PAN formation rates were positive under all simulation scenarios, however, only NO_2 constrained
415 cases revealed strong formation throughout daytime hours (08:00-20:00 LT) while unconstrained NO_2 simulations only
416 displayed a very weak morning time (07:00-9:00 LT) photochemical formation. Only NO_2 -constrained simulations
417 overestimated PAN concentrations by a factor of 1.8 on average, however, could reproduce observed daytime PAN
418 increments by $94 \pm 84\%$. Additionally, days with high simulated PAN photochemical production (4-6 and 13-17 May)
419 corresponded to episodes with elevated observed PAN concentrations, which indicates that photochemical formation of PAN

420 were determinative of its day-to-day variability. Compared to O_3 , PAN was sensitive to concentrations of both OVOCs and
421 NO_2 , since some of the OVOCs are direct precursors of PA radicals, which combine with NO_2 in PAN formation. Still, NO_2
422 was more decisive of the overall O_3 and PAN production, since without its constraint, O_3 net loss and negligible PAN net
423 formation would be yielded.

424 It should also be noted that both observed O_3 and PAN were not necessarily formed within the local boundary layer, since
425 springtime winds in the TP are very strong, especially during daytime. Due to its relatively long lifetime, PAN might have
426 been formed on the transport pathway to NMC, while O_3 might undergo both destruction and production during air mass
427 transport. This might partly explain why PAN formation was overestimated by simulations representing surface conditions.
428 But overall, it could be concluded that O_3 was mainly determined by physical transport, particularly STE processes, while
429 PAN was largely determined by local photochemistry and that along the transport passageway. Fresh STE plumes reaching
430 NMC from the north where PAN concentrations result in depleted surface PAN, while relatively aged STE air masses
431 crossing over polluted regions of Indo-Gigantic Plain led to simultaneous enrichment in surface O_3 and PAN. The high
432 sensitivity of O_3 and PAN formation towards NO_x indicates that increased natural emission of NO_x under global warming,
433 enhanced anthropogenic emissions of NO_x within the TP region due to the development of highways and transportation as
434 well as increased transport input from South Asia might greatly enhance O_3 and PAN formation in background regions,
435 while increased VOCs emissions and regional transport promotes PAN formation more than that of O_3 .

436

437 **4 Conclusions and implications**

438 In this study, continuous measurements of O_3 and PAN as well as its precursors were conducted during spring and summer
439 at a highly pristine high-altitude site in the southern TP (NMC station) to investigate the factors determining their variations.
440 Due to the local topography, surface observations at NMC reflects free tropospheric air conditions during daytime and
441 nocturnal boundary layer conditions during nighttime. Both O_3 and PAN revealed steep increases after sunrise and reached a
442 flat plateau during daytime. While averaged diurnal variations of O_3 and PAN highly resembled each other, their day-to-day
443 variations were often different, suggesting that they might have been influenced by distinct physiochemical processes.

444 Backward trajectory modelling and PSCF analysis revealed distinct source regions connected to high O_3 and PAN. During
445 spring, air masses rich in O_3 were mainly associated with high altitude westerly air masses that either entered the TP from the
446 west of from the south, while PAN was only rich in westerly air masses that transported along the polluted regions in North
447 India and Nepal before entering the TP from the south or in southerly maritime air masses that crossed over polluted South
448 Asian regions before entering the TP. During the summer monsoon season, air masses from the north were associated with
449 the highest O_3 levels, while westerly and southerly air masses revealed lower O_3 levels. Elevated PAN concentrations,
450 however, were still linked to westerly and southerly air masses crossing over polluted South Asian regions. O_3 at NMC was
451 strongly influenced by STE, which brought down high stratospheric O_3 concentrations from the southwest route during
452 spring and from the northwest during summer, explaining 77% and 88% of the observed O_3 level in spring and summer,

453 respectively. PAN concentrations were, however, typically lower in airmasses with strong stratospheric influence, except if
454 they transported over polluted regions south of the TP.

455 Photochemistry resulted in positive net formation of both O₃ and PAN. While only 28±19% of the observed daytime growth
456 in O₃ could be explained by photochemical simulations, the daytime growth of PAN was highly overestimated by the model
457 if OVOCs and NO₂ were both constrained. Photochemistry was not the factor determining the day-to-day variability of O₃,
458 however, explained observed PAN variabilities well. While both O₃ and PAN formation were highly sensitive to NO_x levels,
459 PAN was also quite sensitive to VOCs concentrations. Therefore, future concentrations of O₃ and PAN over the TP may be
460 significantly impacted by increases in the concentrations of NO_x, VOCs, and other precursors, which either originate from
461 the surrounding regions (in particular South Asia) or from anthropogenic and natural sources within the TP. Special attention
462 should be addressed to PAN, which is mostly determined by photochemical processes sensitive to both NO_x and VOCs and
463 can be transported over very long distances.

464

465 **Data availability.** The data used in this study are available on the @Tibet ftp server (<http://at-tibet.quickconnect.cn/>) and
466 can be applied for upon request to the corresponding authors (zhanggen@cma.gov.cn and c.ye@pku.edu.cn)

467

468 **Author contributions.** WX and CY designed the experiment and led the research. WX, GZ, CY, YW, YZ, YB, WL, XX
469 were responsible for the maintenance of trace gas and meteorology measurements in the experiment and WX, YZ and YW
470 processed the data. WX analyzed the data and wrote the paper with help from XZ, XX and GZ.

471

472 **Competing interests.** The authors declare that they have no conflict of interest.

588 **draw based on Map service in ArcGIS World Imagery (<https://doc.arcgis.com/en/data-appliance/6.4/maps/world-imagery.htm>)**

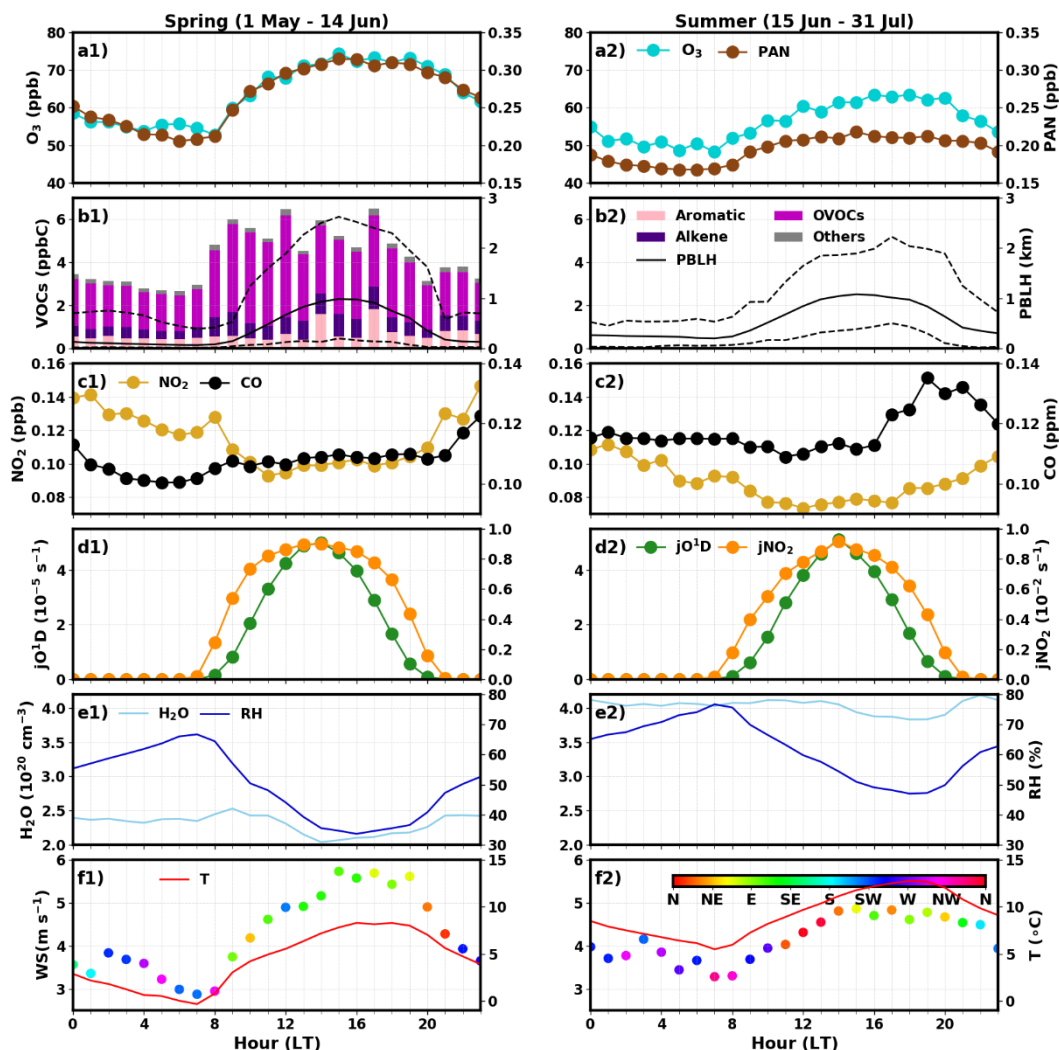

589

590

591 **Figure 2 Timeseries of a) O₃, PAN, b) NO₂, CO, c) jO¹D, jNO₂, d) RH, T, e) wind speed and wind direction during the Nam Co**
592 **campaign from 1 May to 31 Jul.**

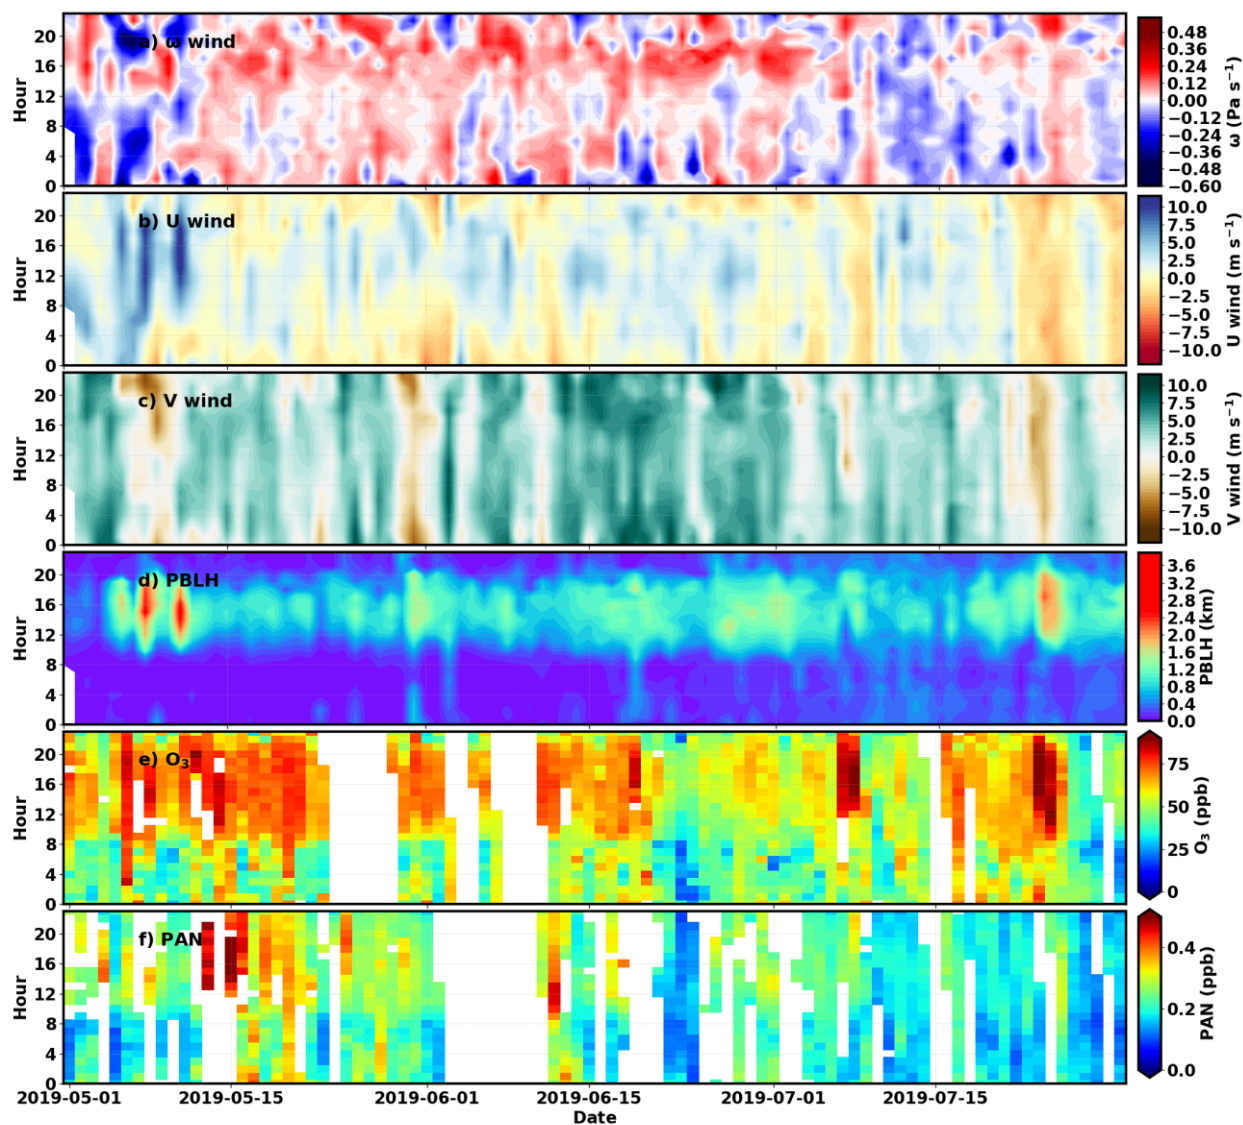

593

594

595 Figure 3. Averaged diurnal variations of a) O₃, PAN, b) VOCs, PBLH (solid line black line: average value, dashed black lines:
 596 minimum and maximum value) c) NO₂, CO, d) jO¹D, jNO₂, e) H₂O, RH and f) temperature, wind speed and wind direction during
 597 the 1) spring and 2) summer period, respectively.

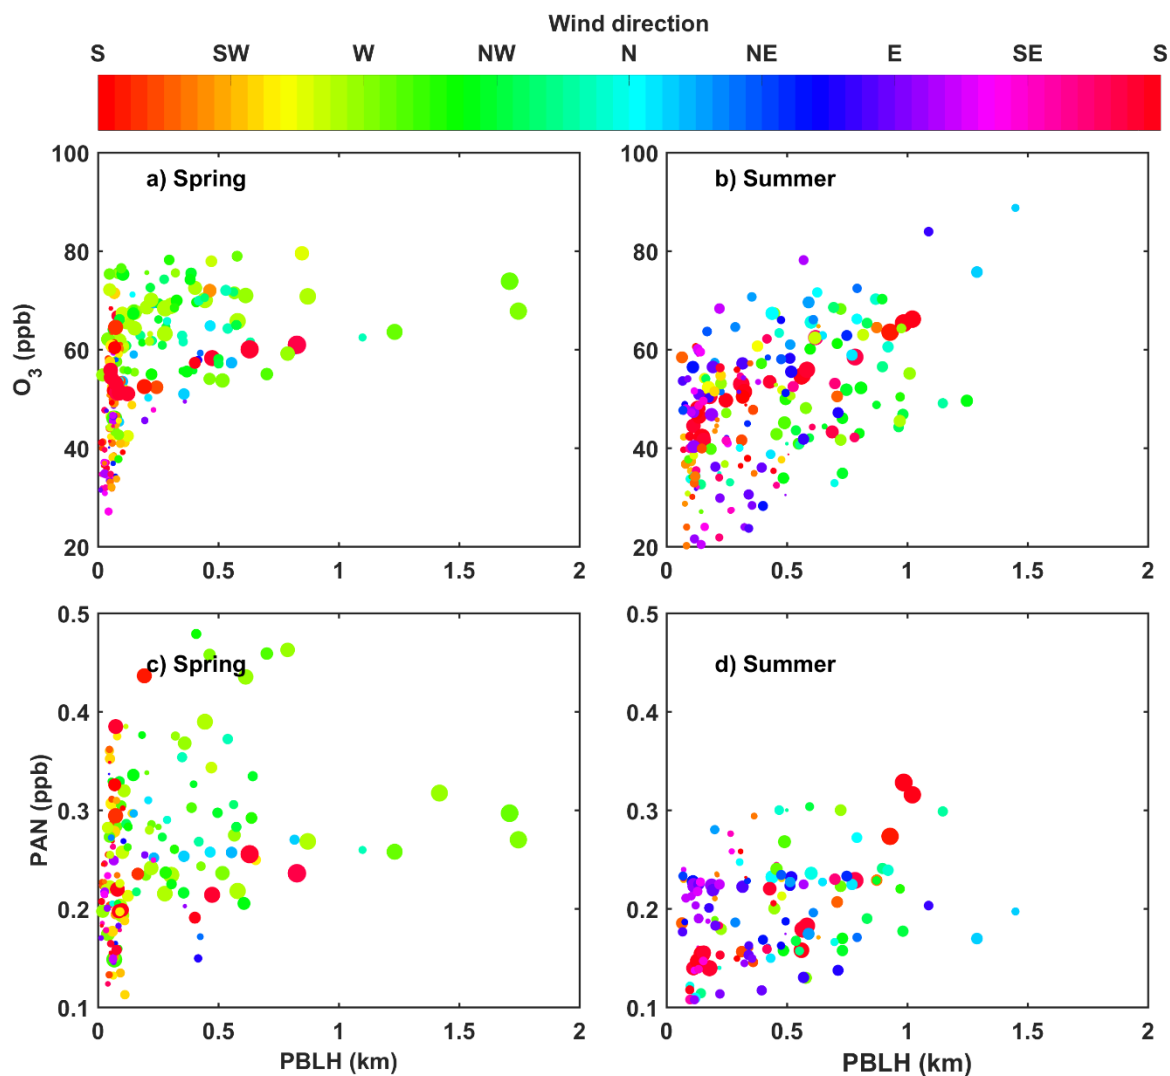

598

599

600 Figure 4. Season-diurnal variations of a) ω wind, b) U wind, c) V wind, d) PBLH, e) surface O_3 and f) PAN between 1 May and 31
601 Jul 2019 at Nam Co.

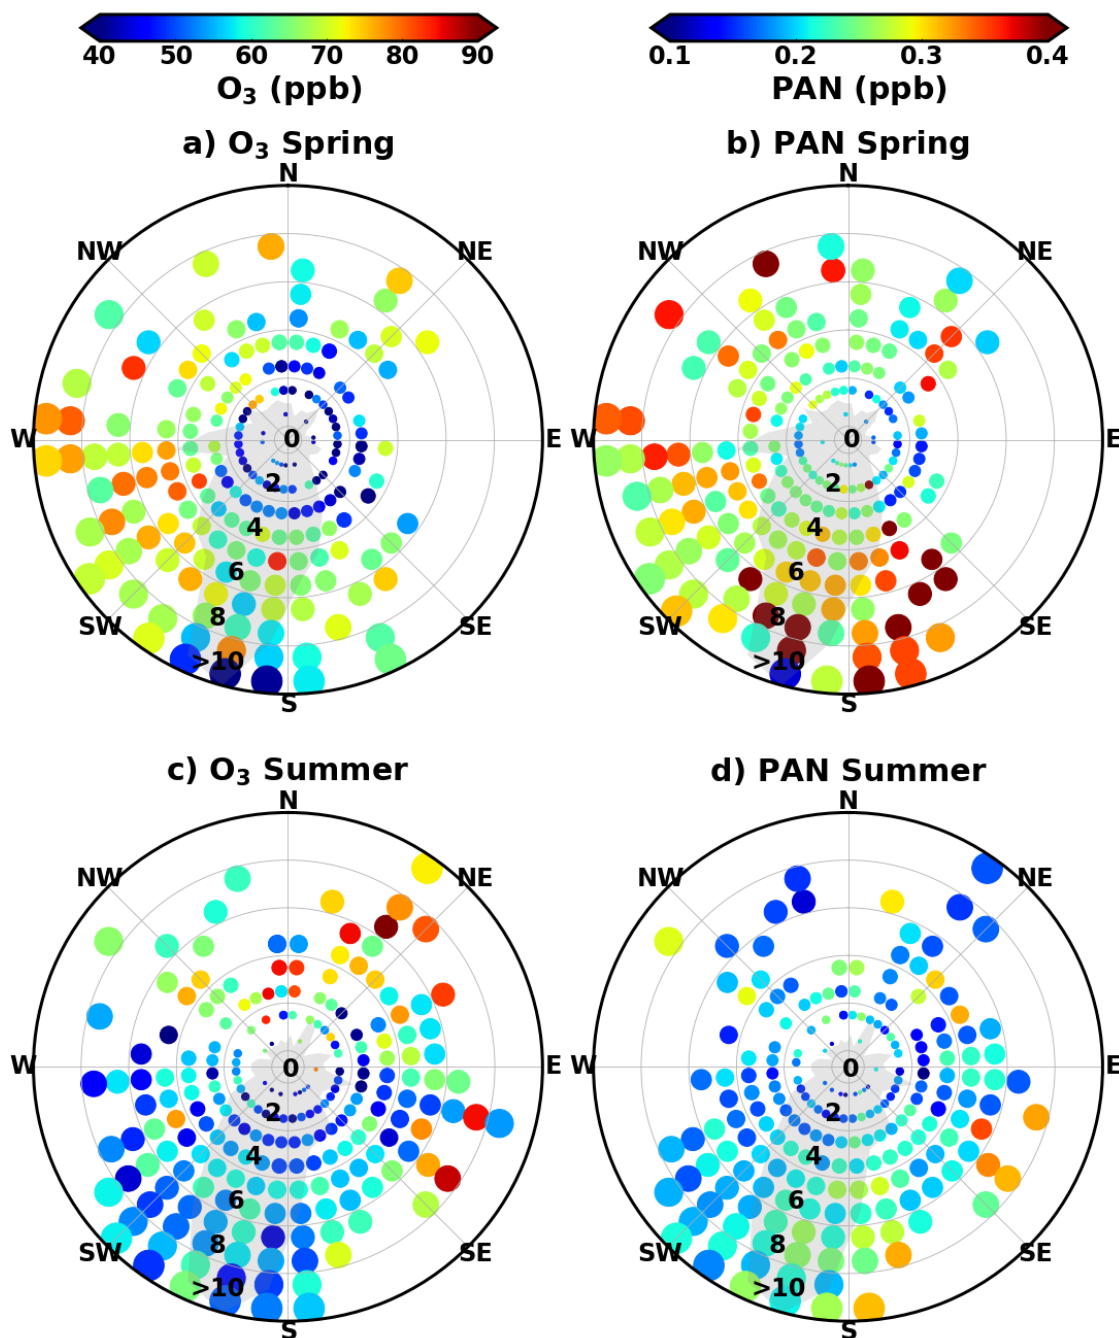

602

603

604 **Figure 5. Variation of prenoon (6:00-12:00) O₃ (a,b) and PAN (c,d) with PBLH (from ERA5 reanalysis data) during spring (a,c)**
605 **and summer (b,d) periods, with wind speeds and directions indicated by sizes and colors of scattered dots (precipitation associated**
606 **data points excluded).**

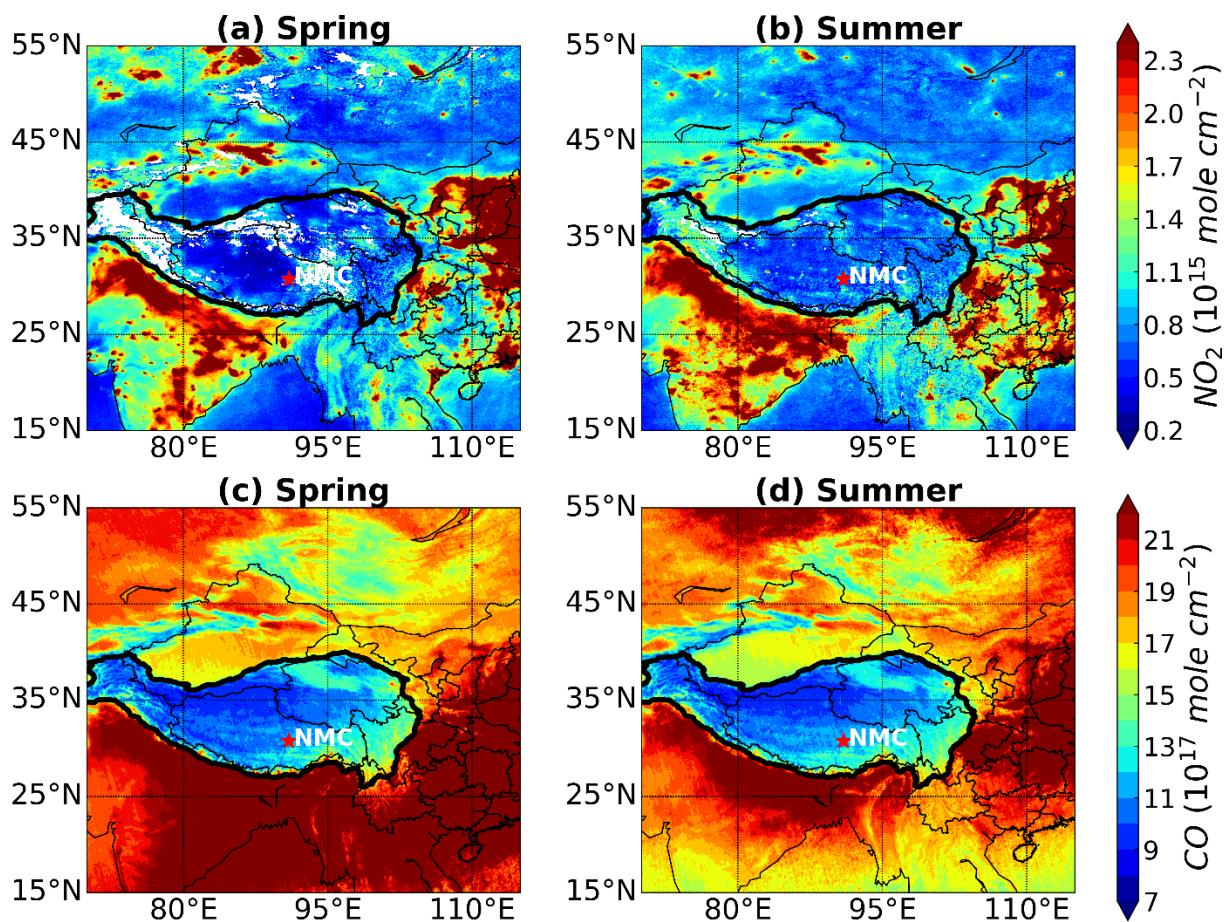

607

608

609 Figure 6. Variation of springtime (a,b) and summertime (c,d) O₃ (a,c) and PAN (b,d) concentrations with 2m wind speeds and 500-
610 550 hPa wind directions from ECMWF ERA5 data. Gray shading represents the relative occurrence frequency of wind directions.

611

612

613 **Figure 7.** TROPOMI NO₂ (a,b) and CO (c,d) column concentration distributions averaged over spring (a,c) and summer (b,d)
614 periods.

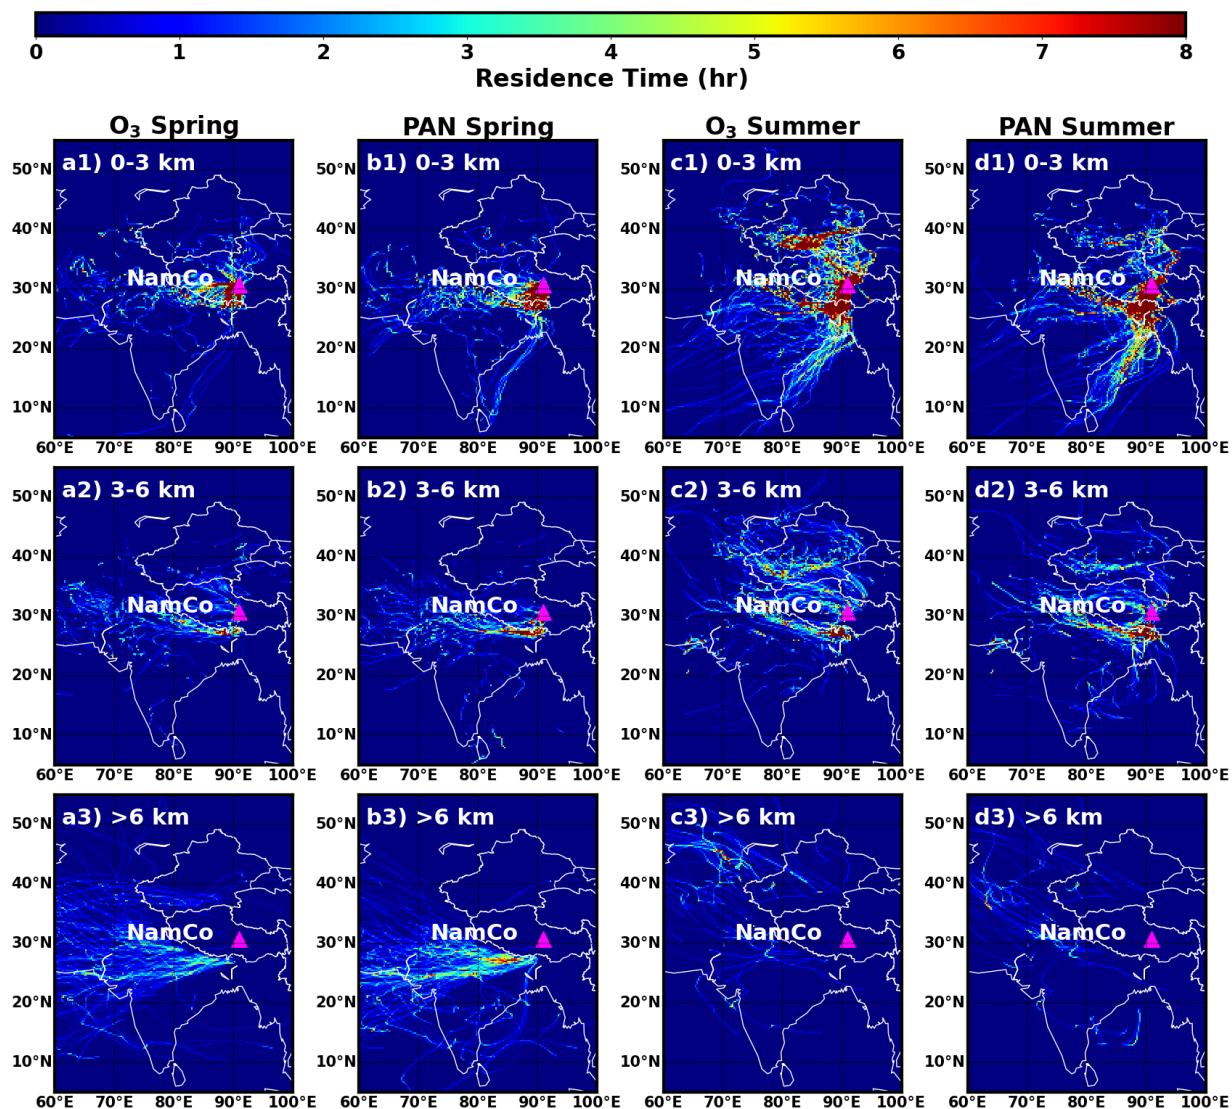

615

616

617 Figure 8. Potential Source Contribution Function (PSCF) of O_3 (a,c) and PAN (b,d) during spring (a,b) and summer (c,d) periods.

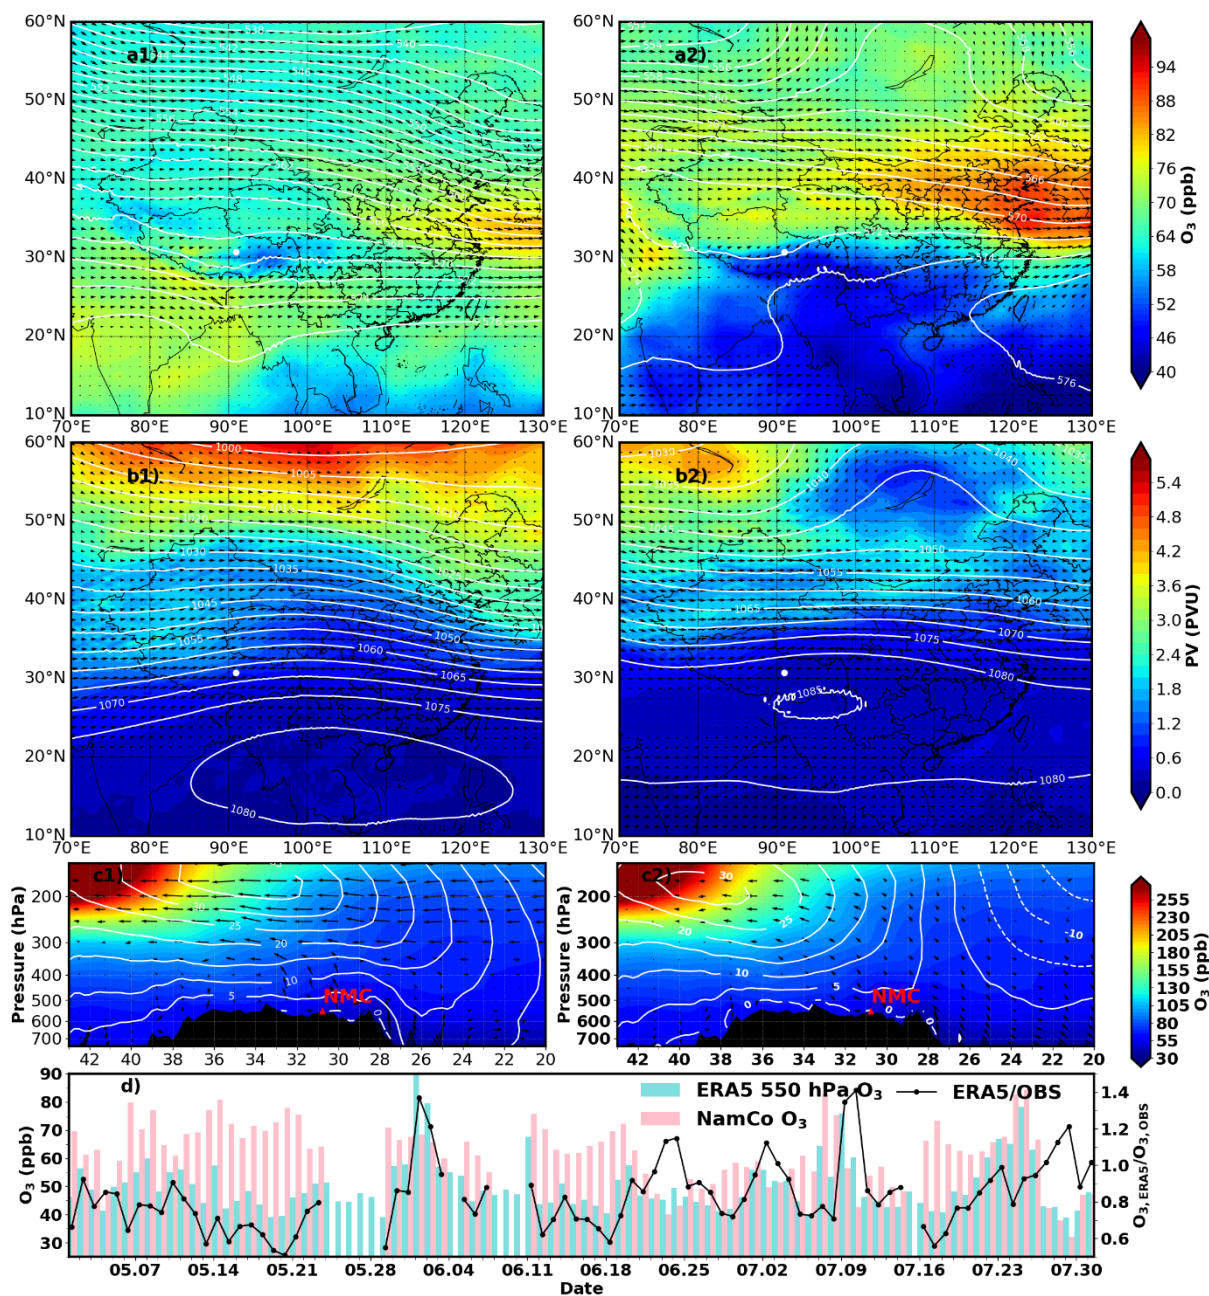

618

619

620 Figure 9. Residence time of trajectories associated with O₃ (a,c) and PAN (b,d) above their respective 67th percentiles during spring
621 (a,b) and summer (c,d) periods within height ranges (above ground level) of 1) 0-3 km, 2) 3-6 km and 3) >6 km.

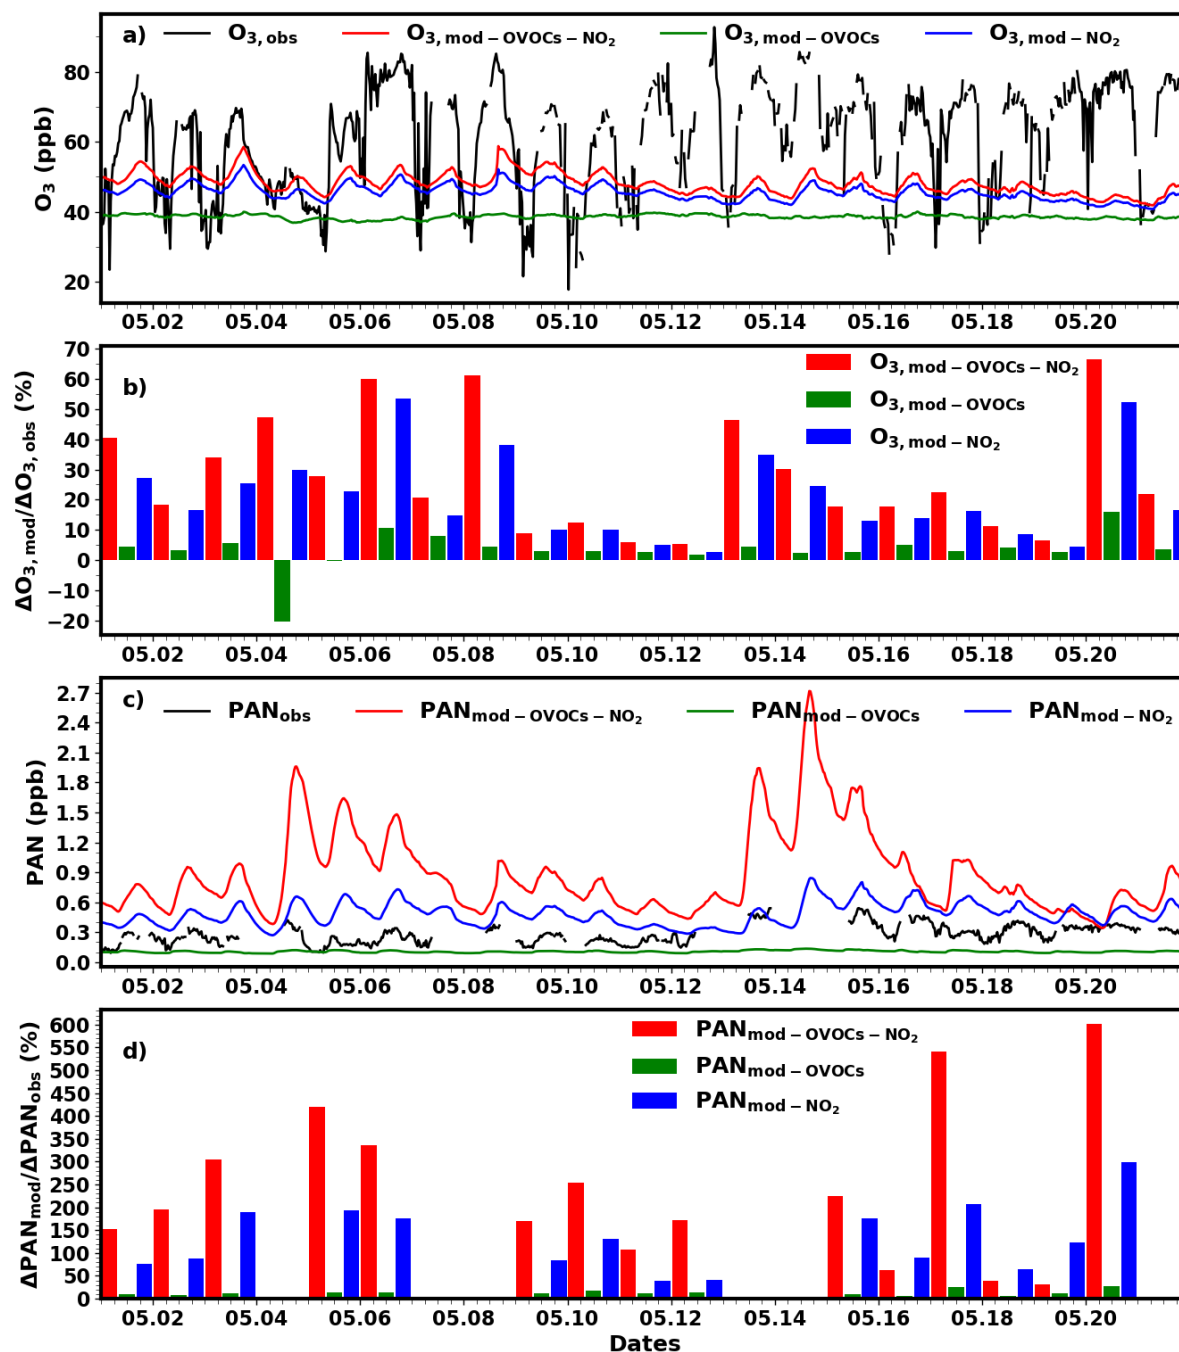

622

623

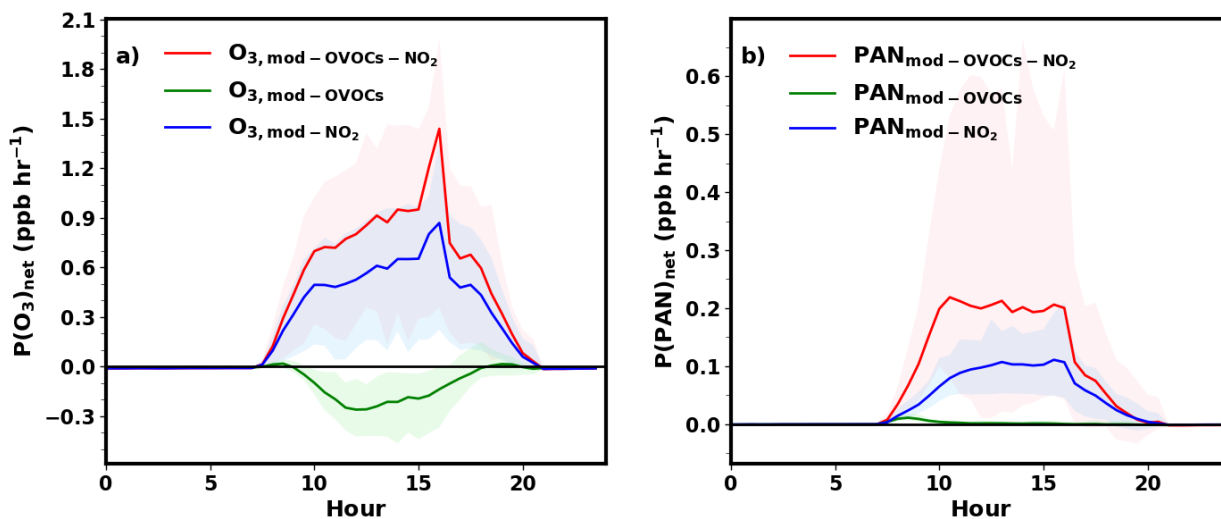

624 Figure 10. Distribution of a) ERA5 500 hPa O₃ mixing ratio, geopotential height (white contour lines) and winds (black arrows), b)
 625 250 hPa potential vorticity, geopotential height and winds, c) cross-section of O₃ mixing ratio, u winds (white contour lines), v
 626 winds and vertical velocity (black arrows) at the longitude of Nam Co station and d) the comparison between daytime ERA5
 627 550 hPa and observed O₃ mixing ratio at Nam Co.

628

629

630 Figure 11. a) Observed (black) and modelled O₃ using constraints on OVOCs (green), NO₂ (blue) and both (red), b) percentage of
 631 observed daytime O₃ concentration increment ($\Delta O_{3, \text{obs}}$) that can be explained by those modelled under different constraints
 632 ($\Delta O_{3, \text{mod}}$), c) observed (black) and modelled PAN under OVOCs (green), NO₂ (blue) and both constraints (red), d) percentage of
 633 observed daytime PAN concentration increment ($\Delta \text{PAN}_{\text{obs}}$) that can be explained by those modelled under different constraints
 634 ($\Delta \text{PAN}_{\text{mod}}$).

635

636 Figure 12. Net production rate of a) O₃ and b) PAN simulated under OVOCs (green), NO₂ (blue) and OVOCs+NO₂ combined
637 measurement constraints. Shaded areas represent calculated ranges of 5th to 95th percentiles.
